## An Economics Approach

Sanjeev Goyal

Arthur C. Pigou Professor of Economics  
Fellow of Christs' College  
University of Cambridge

March 9, 2022

We shall not cease from exploration  
And the end of all our exploring  
Will be to arrive where we started  
And know the place for the first time.

—T.S. Eliot, *Little Gidding, Four Quartets*. 1943.

# Preface

We lead lives that are immersed in networks that range across physical infrastructure to tangible economic ties and encompass the subtle and delicate ties that connect us to our friends and family. The aim of this book is to provide an introduction to the structure of these networks and the principles that govern their formation and their functioning.

Networks are extraordinarily diverse, so the principles we will develop must be general. I view networks through the lens of economics. This means that we will view activity in networks and the formation of networks as arising out of trade-offs we make between the costs and benefits of different course of action. One virtue of this approach is that it suggests a natural point of reference for assessing performance: how well does a network deliver on the goals of the actors who created them. An assessment of the performance will guide us to ways in which different types of interventions can improve matters.

I would like the book to be readable for readers with different backgrounds. With this in mind, every chapter will begin with an introduction to a high level phenomenon that will be illustrated with the help of case studies that will be used to motivate lines of formal enquiry. The core of the chapter will be a theoretical model. The insights from the analysis of the model will be developed through simple examples that will be followed by a statement of general results. Formal proofs will be provided to help readers develop a deeper appreciation of the structure of the argument. Where possible we will return to the original motivating phenomenon and show how the theory helps us understand it better.

## ORGANIZATION OF BOOK

The book starts with a short introduction and consists of four parts.

I . Chapters 1-4: Foundations.

II . Chapters 5-10: Economic Networks.

III . Chapters 11-15: Social Networks.

#### IV . Chapters 16-19: Broader Themes.

Part I contains four chapters. Chapter 1 introduces the main themes of the book through a discussion of a number of real world networks and the definition of basic network concepts. Chapter 2 begins our study of how networks are formed through an introduction to the theory of random graphs. Chapter 3 introduces the basic elements of an economic approach to the formation of networks. Chapter 4 provides an introduction to how networks shape human activity through the study of games played on networks. Taken together chapters 2-4 provide us the theoretical concepts that are used in the rest of the book.

Part II contains six chapters each of which takes up a specific economic sector or a theme. Chapter 5 studies the determinants of the input-output network and how its structure shapes economic activity. Chapter 6 studies infrastructure networks. Chapter 7 studies security of networks that face natural and human threats. Chapter 8 takes up the study of interlinked wars. Chapter 9 studies how network effects give rise to market power. Chapter 10 studies the role of interconnections in propagating shocks in financial networks.

Part III contains five chapters on social networks. Chapter 11 studies how interaction patterns shape the coordination of human activity. Chapter 12 studies problems of communication and learning in social networks. Chapter 13 studies the origins of specialization and unequal information networks. Chapter 14 studies diffusion of ideas and epidemics in networks. Chapter 15 studies questions at the intersection of social and economic networks and impersonal markets

Part IV contains 4 chapters that locate social and economic networks in a broader context in conjunction with cultural beliefs, impersonal exchange and the nature of the state. Chapter 16 takes up the study of networked markets – in which trading restrictions and structures are modelled as networks. Chapter 17 takes up the role of communities in economic development. Chapter 18 takes up the question of trust. Chapter 19 studies the relation between kinship networks, impersonal exchange and the state.

#### POSSIBLE COURSE OUTLINES

Parts of this material have been used to teach networks courses in the UK and in the US system. Here are two ways of organising the material for a 10 week course.

1. Applied course: Chapter 1, chapters 3-4; chapters 5-6, chapters 8-9; chapters 16-19.
2. Theoretically Oriented Course: Chapters 1-4; chapters 5-6; chapters 11-15.

In the US a semester may be around 14 to 17 weeks. Here are two ways of organizing the material for a 15 week course.

1. Applied course: Chapters 1-4; chapters 5-6, chapter 8-10; chapters 11, 15, 17-19.
2. Theoretically oriented course: chapters 1-4; chapters 5-7; chapters 11-19.

# Acknowledgements

I started writing this book in January 2020 when I arrived in New York to visit Columbia University and I am completing the book in February 2022 on a visit to New York University in Abu Dhabi. In between these visits, my office at the Faculty of Economics in Cambridge offered me the perfect place to work during the long months of Covid. It is difficult to convey in words the gratitude I feel for the support of these institutions, offered graciously and unconditionally, in what have been very difficult times.

This is a long book and it reports on a research programme that has been in the making for many years. In this time I have been singularly lucky to have worked with some wonderful people who have shared their ideas and their thoughts with me generously. I would especially like to thank Venkatesh Bala, Francis Bloch, Yann Bramoullé, Syngjoo Choi, Partha Dasgupta, Lorenzo Ductor, Bhaskar Dutta, Marcin Dziubinski, Matthew Elliott, Marcel Fafchamps, Julien Gagnon, Andrea Galeotti, Christian Ghiglino, Ben Golub, Matthew Jackson, Maarten Janssen, Sumit Joshi, Michael Kearns, Marco van der Leij, Dunia Lopez-Pintado, Frederic Moisan, Jose Luis Moraga-Gonzales, Stephanie Rosenkranz, Omer Tamuz, Fernando Vega-Redondo, Adrien Vigier and Leeat Yariv for their collaboration and for their friendship.

I have had the good fortune to interact closely and learn from some outstanding doctoral students and post-doctoral fellows at Erasmus, Essex and Cambridge: Ana Babus, Oliver Baetz, Leonie Baumann, Deigo Cerdiero, Vessela Daskalova, Sihua Ding, Julien Gagnon, Andrea Galeotti, Fulin Guo, Joerg Kalbfuss, Willemijn Kets, Marco van der Leij, Gustavo Nicolas Paez, James Rutt, David Minarsch, Manu Munoz, Anja Prummer, Bryong Reich, Roberto Parra-Seguro, Klaas Staal, Eduard Talamas, Tony To, Adrien Vigier, and Alan Walsh.

More broadly, I have learnt a great deal from a number of friends and colleagues who are far too numerous for me to mention exhaustively. It would be remiss of me however not to thank Daron Acemoglu, Arun Agrawal, Sinan Aral, Larry Blume, Timothy Besley, Vasco Carvalho, Antonio Cabrales, Antonio Calvo-Armengol, Gabriele Demange, Steven Durlauf, David Easley, Drew Fudenberg, Aditya Goenka, Mark Granovetter, William

Janeway, Navin Kartik, Rachel Kranton, Eric Maskin, Jim Mirrlees, Markus Möbius, Dilip Mookherjee, Stephen Morris, Santanu Roy, Debraj Ray, Hamid Sabourian, Larry Samuelson, Arun Sundararajan, Adam Szeidl, Coen Teulings, Duncan Watts, Asher Wolinsky, Myrna Wooders, Muhamet Yıldız, Peyton Young, and Yves Zenou.

Sihua Ding, Francis Bloch, Matthew Elliott, Mark Granovetter, Sam Jindani, Bryong Reich, Evan Sadler, Misha Safronov, and Ricky Vohra read an earlier draft of the book and made comments and suggestions and pointed out several errors: to all of them, I am deeply grateful. I thank James Moody, Mohammad Akbarpour, Michele Barnes, Antonio Cabrales, Ozan Candogan, George Charlson, Krishna Dasaratha, Dave Donaldson, Marcel Fafchamps, Maryam Farboodi, Michel Konig, Dunia Lopez-Pintado, Stephen Nei, Lin Peng, Agathe Pernoud, Ruohan Qin, and Edouard Schaal for sharing insights and materials and for comments on specific chapters of the book.

I would like to thank Ying Gao, from the MIT Economics Department, who worked as Research Assistant on the book, for detailed and very helpful comments on every chapter of the book. Most of all I thank Tony To, my Phd student at Cambridge, who has been a Research Assistant throughout the writing of the book. Tony's contributions show up on almost every page of the book – he has produced most of the pictures and tables in the book, he has offered suggestions and comments on the exposition, and he has proposed questions for a number of the chapters.

The remaining errors in the book are solely my responsibility; corrections from readers would be much appreciated.

Emily Taber at MIT Press helped steer me toward the textbook style the book now has; I started with rather different ideas. It is a pleasure for me to thank her for all her help in bringing the project to fruition. I am also grateful to three anonymous referees who offered encouraging and very helpful comments on an earlier draft of the manuscript.

My wife, Pauline Rutsaert, has supported me with great patience as the weeks rolled into months and the months became years and the book still continued to take up most of my time. Our older son, Dilip, read large parts of the book and set me right on many points of presentation and also offered me the benefit of a student's perspective. Our younger son Sachin entertained the right level of detachment and kept up an unfailing sense of humour during our long months of joint seclusion. My sister, Shama Goyal, and brother-in-law, D. Sen, and their daughters, Sneha and Soumya, enquired about the progress of the book regularly, and, by doing so, kept me going. My parents-in-law, Monique and Paul Rutsaert, have supported me and my family with great generosity as we have moved across the Netherlands, England and France. I thank them all for their support.

This book is a tribute to my father, Prem Chand Jain, who, many years ago, first got

me started on the road to asking questions about how the world works and who always encouraged me to work out my own answers. He sadly passed away before the book was completed. My father was a civil engineer with a taste for solving concrete problems and I like to think that he would have liked the style of the book and found some of the ideas developed here interesting. The book is dedicated to him and to my mother, Lakshmi Jain, for their love and for their support.

# Introduction

## Why networks?

Economics is concerned with the allocation of scarce resources to meet desired ends. For the decisions to be made correctly it is vitally important that the appropriate information is available to the decision makers in a timely manner. Networks are key to an understanding of the fundamental processes concerning production and consumption and information. Firms located in production and supply networks combine labour, knowledge and material inputs to produce goods and services. Production and consumption rests on the movement of goods and services and of people on infrastructure networks like roads, trains, airlines and the internet. The flow of information take place in networks of social interactions. Individuals build friendships and social ties that give them access to information, shape their values, and ultimately determine who they become. Economic exchange rests on trust but, trust, combining elements of beliefs and behaviour, is a feature of personal ties and kinship relations.

Twentieth century economics has made major advances in the study of these fundamental processes. Economists have sophisticated theoretical methods for individual decision making both in small and in large groups. For small groups, the models are based on strategic reasoning and for large groups the models are based on ideas of perfect competition.

A background assumption in the strategic models is that everyone interacts uniformly with everyone else. This is true for instance in models of buyer-seller trading, oligopoly, matching, and auctions. However, due to social, geographic, and economic constraints, there often exist restrictions on who can interact with whom. For instance, traders within a city trade freely with all other traders in the same city but there may be ties between a select few traders that are located in different cities (this may be costs of transport or costs of cultural distance reflected in lower trust). Networks provide us a framework to accommodate restrictions on who interacts with whom.

In the study of large scale interactions, economists use models of competitive interaction and the background assumption is that agents are anonymous. In a production

network or in Twitter the system as a whole is very large – with hundreds of thousands of entities – but individual entities have interaction with only a small subset of the population. The average firm will have a few input suppliers and a few output purchasers; similarly, the average individual will form a few following links to some Twitter account holders. These interactions can hardly be said to be anonymous. Networks provide us a framework that accommodates local and personalized interaction and also allows for a large number of entities. This versatility offers us the possibility to develop methods for the study of a central problem in economics (and in the other social sciences) – the so called *problem of aggregation*, how to develop an understanding of large scale macroscopic phenomenon through micro founded reasoning that applies to small scale settings.

Graphically, we may think of a network as a collection of points joined together by lines. The points are called nodes or vertices, the lines are called links or edges. This graphical and abstract nature of a network is helpful as we can easily adapt the language to describe very different systems. The points may be individuals, firms, and countries, and the lines may refer to friendships, supply relations, physical contiguity or alliances. The points may be physical objects or locations and the lines may refer to tangible connections like cables, trains, roads and airlines routes.

Starting in the early 1990's, economists became aware of these discrepancies between their models and the empirical phenomena of interest and started to develop models that incorporate networks alongside the familiar concepts of purposeful individual actions, strategic reasoning, competition, externalities, and asymmetric information. The initial models grew out of an interest in the study of how social connections shape information diffusion and social learning. This early work pointed to the powerful effects of networks and led to the study of the origins of different types of networks, i.e., to the theory of network formation. These two ideas – that networks affect behaviour and that individuals strive to create networks that are beneficial for themselves – have given rise to a new research programme in economics. The programme has over time taken on progressively broader and more ambitious themes. As a result, networks are now central to our understanding of macroeconomic volatility and cycles, patterns of trade and intermediation, contagion in financial networks, diffusion and epidemics in social systems, resilience of infrastructure and supply chains, wars, economic development, unemployment and inequality, the nature of trust, and a host of other important phenomena.

The aim of this book is to offer an introduction to this body of research.

## Examples of networks

Production of goods or services involves a set of firms that are linked together through buyer seller relations. Similarly, the financial system consists of banks, insurance companies and other institutions connected through borrowing and lending and other relations. In many cases the linkages crisscross national boundaries, and so events such as a flood or an earthquake can have an impact on us as they travel through these connections. To get a first high level impression we present a snapshot of the network of production in the United States in Figure 1. In this network, a node corresponds to a sector of the US economy. Every edge corresponds to an input-supply relation between two sectors. Larger (red) nodes, closer to the center of the network, represent sectors that supply inputs to many other sectors. The highlighted labels refer to (313) Wholesale Trade , (270) Real Estate, (297) Electric Power Generation and Distribution, (145) Management of Companies and Enterprises, and (21) Iron and Steel Mills. The presence of these hub sectors means that most other sectors are ‘close’ to each other – as they are often connected to the hub sectors.

The presence of prominent, large sectors that are hubs and the small average distances between sectors raises a number of questions about the functioning of the economy. Why are some sectors so large relative to the rest of the economy, how do hubs matter for the transmission of shocks, and how should governments target public policy in order to have maximum impact. Indeed, very similar questions arise when we consider the impact of shocks on banks and financial institutions: what is about the production and financial network that allowed a financial shock in the real estate sector of the United States in 2007-2008 to spread to the rest of the world and create a global recession?

We now turn to the infrastructure networks such as trains, roads, airlines, pipelines, shipping, canals, and the internet. Figure 2 presents the routing network of British Airways: this network resembles a hub and spoke, with one highly connected central city that links to all other cities (who are not otherwise linked). The train network in many countries has a similar hub-spoke structure, with major cities serving as hubs. By contrast to the airline and rail networks, the road network in many cities around the world has a grid structure. Figure 3 depicts the original urban plan for Philadelphia that stretched two miles from east to west between two rivers the Delaware and Schuylkill. It comes from Thomas Holme’s 1683 ‘A Portraiture of the City of Philadelphia in the Province of Pennsylvania’. At the centre is a civic square, and this structure is echoed in each quadrant by a spacious park that is planted with trees. The grid plan became central to the division of land during the westward expansion across America. This grid proposal was used as a basis for the

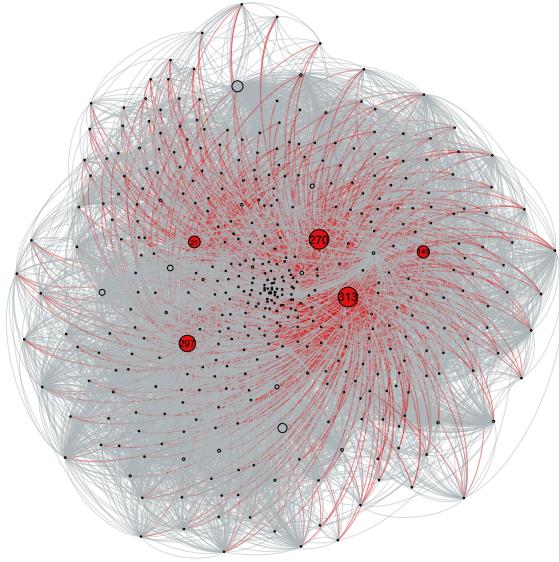

Figure 1: US Production Economy 2002. Source: Bureau of Economic Analysis.

city plan of Philadelphia. It was an inspiration for the design of many cities in America and continues to shape city planning across the world.

Finally, we take up social networks. Prominent examples of social networks include kinship based groups like the family, friendships and colleagues, professional relationships such as co-authorships and online social networks. Figure 4 presents the friendship network in an American High School in 1994. We notice that pupils have similar number of ties. The colour of node represents the race of the pupil: we see that most pupils form friendships with others of the same race. Moreover, we see that within the same colour there a further partition of nodes and this reflects the class year. We see that links form between pupils of the same year and the same race a tendency we will term *homophily*. Pupils share information and ideas, take part in joint activities and develop shared values through friendships. This leads us to explore questions such as, how does the number of friends and location in a school network shape a pupil's performance, what are the effects of relatively segregated groups on pupil and school performance? In order to answer such questions, we need a theory of how social structure affects individual values and behaviour. A challenge in thinking about these questions is that individuals themselves create these friendship networks, thus we need to take great care to separate cause from effect.

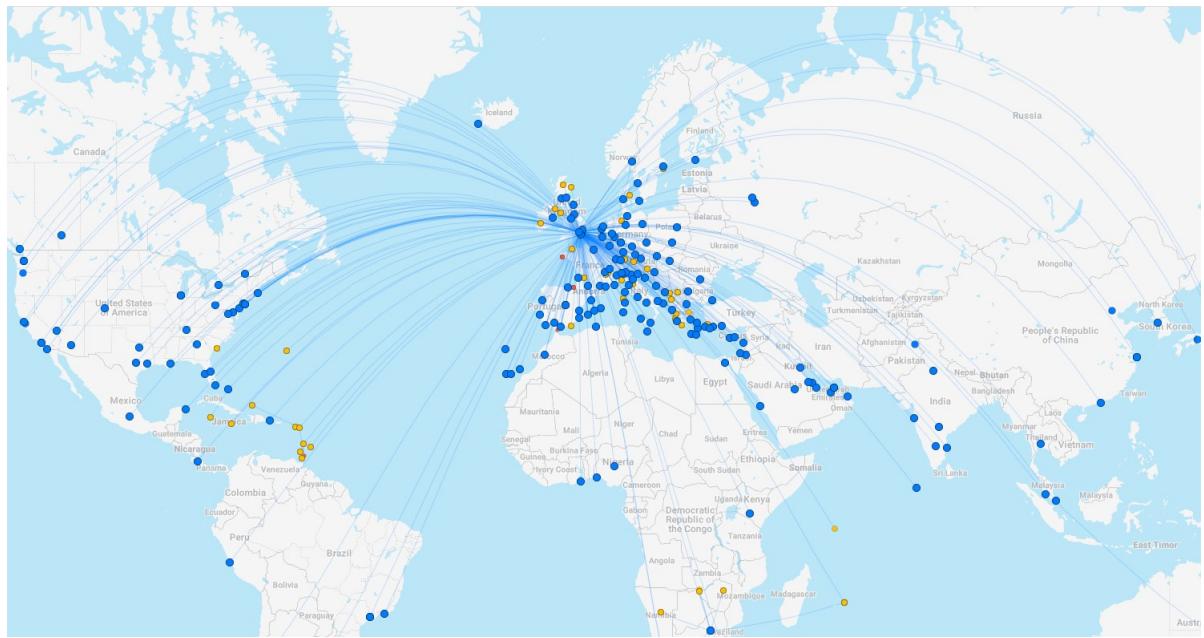

Figure 2: British Airways Network

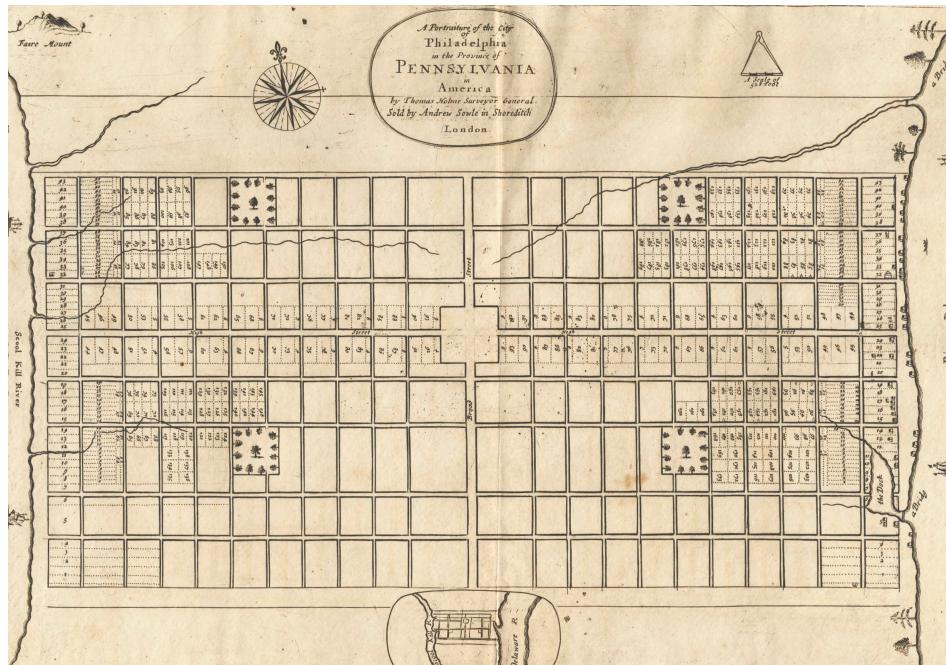

Figure 3: Plan for Philadelphia 1683, from <https://explorephistory.com/displayimage.php>

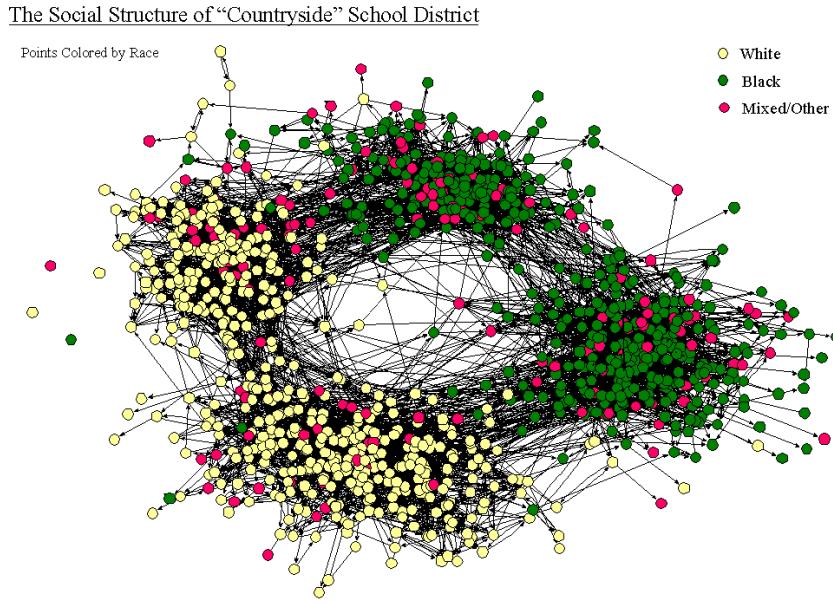

Figure 4: Countryside High School Friendship Network. Courtesy: James Moody

Large scale online social networks like Twitter, Whatsapp, and Facebook are a defining aspect of social life in the early twenty first century. On Twitter a user can send out messages that are known as ‘tweets’. The tweets are seen by other users who ‘follow’ this user. An important feature of Twitter is that ‘followers’ can forward the tweets they receive; this ‘retweet’ is then seen by their followers in turn and the messages can be retweeted further. Thus Twitter creates the possibility for messages to be passed on from one user to another, through the network of links. In the Figure 5, we present the network of users who have over a million followers. The size of the ‘nodes’ scales with the number of links and the tweets.

As Twitter is used by individuals, firms, and governments to share ideas and information, we would like to understand how far does information travel on Twitter and how does it depend on the point at which it is first tweeted, what is the influence of different individuals and how is this influence related to the network of connections? Does the truth prevail or do mutually contradictory views persist over long periods of time in the network? What are optimal nodes to target to maximize influence or to minimize the spread of false information?

We conclude this section with a network that combines elements of a social interaction, professional relations, and information sharing. Scientists collaborate to conduct research, co-authorship is perhaps the most concrete form of this collaboration. The patterns of

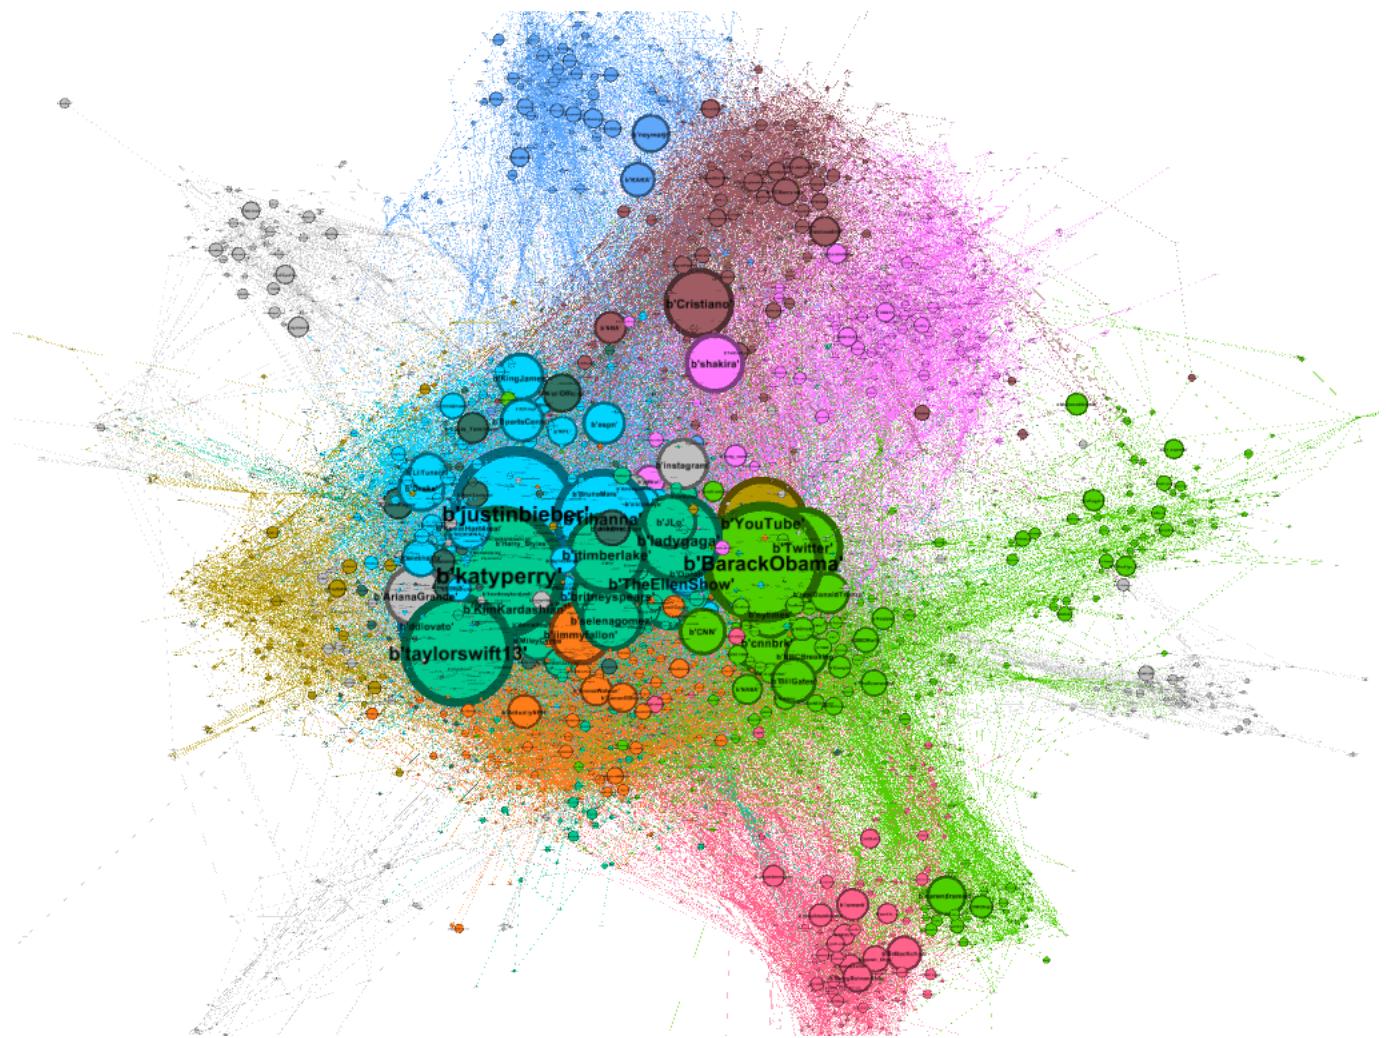

Figure 5: Twitter Millionaire Club, plotted in Gephi by Brian Srebrenik. Based on Data from “Twitter Network Edges” by Luca Hammer

co-authorship can have a profound effect on what questions economists study, how well informed they are and therefore what methods they use to conduct their research. Figure 6 presents the local network of a prominent economist, Daron Acemoglu, for the period 2000-2009. In this network we start with Mr Acemoglu (in blue) and trace his coauthors (who are represented in yellow) and their coauthors (in green). The thickness of an edge reflects the number of papers the two authors have written together. This figure leads us to explore the process that gives rise to such a collaboration network, what are its implications for productivity of individual scholars, and how does it shape the performance of the profession of economics research as a whole?

These examples give us a first impression of the extraordinary variety of tasks that networks perform and their diverse structure. They pose three high level questions: what are the processes of network formation and how do they explain the networks we observe in the world, what are the economic effects of the networks, and how can individuals (firms and governments) use networks to achieve their objectives?

## Properties of Networks

A network consists of points and the lines that connect these points: this parsimony and abstraction allows us to represent a wide variety of important economic systems as networks. The advances in data collection methods and in our computational capacity over the past three decades allows us to collect progressively richer data on networks and the different processes that take place on networks. In this section we draw attention to aspects of networks that play an important role in economics. Formal definitions on network concepts and measurements are presented in chapter 1.

A fundamental building block for much of network theory is the simple idea of connections: how many connections does a node possess? The nodes with which a node has a connection are called its neighbours and the number of neighbours is called the *degree* of the node. In a production network the links refer to input and output relations and will have a directionality. Similarly, on Twitter individuals follow others, a directed relation. In these cases, it will be useful to define *indegree* for incoming links and *outdegree* for out-going links. A recurring theme in this book is that networks contain hubs, i.e., very high degree, and that on the other hand very many nodes have very low degree. The *degree distribution* of a network will be an important object of study. We will be led to study the processes and the circumstances that give rise to unequal degree distributions and we will examine the performance of networks with unequal degree distributions on a number of dimensions.

Another important object of study is how far apart are nodes in a network. It is cus-

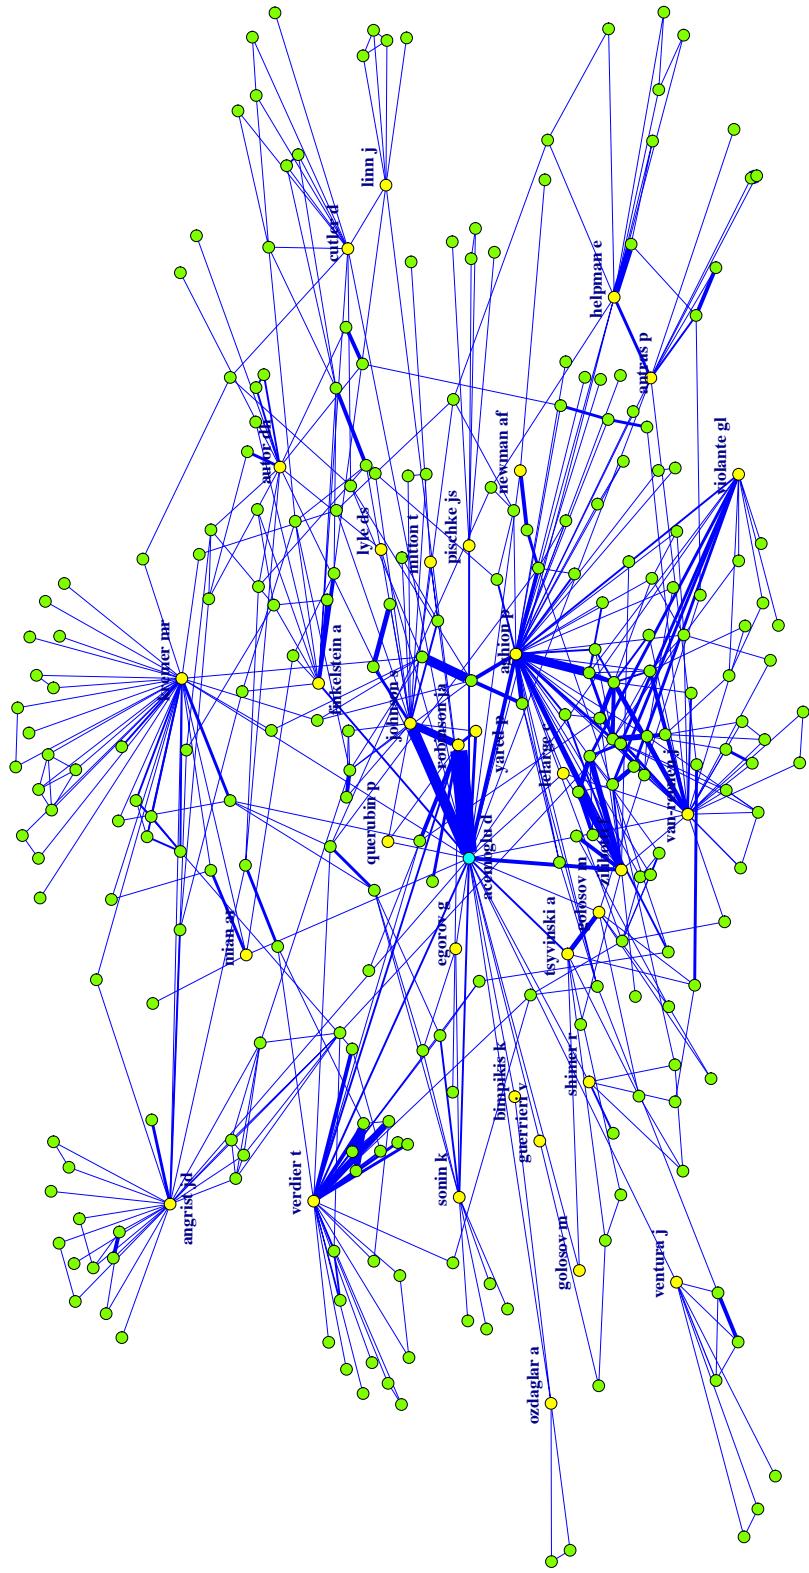

Figure 6: Coauthors of Daron Acemoglu, 2000-2009.

Note: Some economists might appear twice or are missing due to the use of different initials or misspellings in EconLit. The width denotes the strength of a tie. The figure was created by software program *Pajek*.

tomy to define distance between two nodes in a network, the *geodesic* distance, as the minimum number of edges one would have to cross to get from one node to the other. The distance between two linked nodes is 1, while the distance between two nodes that are not linked but have a common neighbour is 2, and so forth. A distinctive feature of many networks of interest is that nodes will on average be very close to one another. We commented on this in our discussions in the previous section. This has given rise to the well known expression – the *small world* in which one can get from any node to any other node with just 6 hops in the network, the so called *six-degrees of separation*.

The role of a node in a network may depend on how *central* it is. Degree is a natural measure of centrality, but there are notions of centrality that play an important role. For instance, centrality may rest on proximity and then a node with a few connections with nodes that have many connections may be very central. This suggests a *recursive* definition of centrality: a node is central if it is connected to nodes that are central. Google's *PageRank* is an example of a measure of centrality that rests on such a recursive definition. We will present a number of notions of centrality.

Another feature of network is the idea of community. The interest in community draws attention the local structure of a network. We will introduce a number of ideas relating to the local structure of a network such as *cliques* and *clustering*. In the example of friendships we saw that pupils have friends from the same year and ethnicity. This draws attention to the notion of *homophily*, an idea that lies somewhere between the local and global. We will present definitions of homophily and use them to study important phenomena such as diversity in social norms and the persistence of different opinions in a society.

## Outline of Book

The book is divided in four parts.

The first part of the book consists of chapters 1-4 and it provides the theoretical foundation for the rest of the book. Chapter 1 introduces the main network concepts and measures that we use throughout the book. The chapter also illustrates the concepts by presenting computations on simple examples and then applies them to measure a range of real world networks. Chapter 2 introduces the theory of random graphs. This helps us to appreciate the basic mechanics of how linking processes shapes the essential properties of networks such as the degree distribution, average distances, and clustering. Chapter 3 introduces the basic elements of the economic theory of network formation. In this theory individuals use links to create networks in order to achieve their different objectives. This discussion draws attention to the central role of *directedness* or *undirectedness* of a link in shaping net-

works. We present the role of *externalities* and of *strategic considerations* in the process of linking. This leads us to draw attention to a fundamental *tension* between strategically stable networks and collectively desirable or efficient networks. Chapter 4 presents a theoretical framework in which individuals interact locally with neighbours who are embedded in broader chains of interaction. This model offers us a simple model where behaviour in small groups can be scaled up to very large populations through a sequence of overlapping neighbourhoods. It illustrates an important high level function of networks: they offer a language that can allow us to talk at one and the same time about the fine grained interactions within a family or a kinship group and how this interaction feeds through links of individuals into engagements that they have with the world at large. The chapter also draws attention to the role of the *content of interaction* – whether individuals actions generate positive or negative spillovers on their neighbours and non-neighbours and whether the actions of different individuals are *strategic complements* or *strategic substitutes*.

The second part of the book consists of chapters 5-10 and it covers economic and infrastructure networks. Chapter 5 introduces the production economy as a network and studies how properties of networks – such as degree distributions and centrality – shape the size and the behaviour of individual sectors and how it determines the resilience of an economy. We also discuss the role of profit making incentives of firms in shaping the structure of networks and their robustness to shocks. Chapter 6 takes up the study of infrastructure networks such as airlines and trains and roads. We present a number of case studies of prominent infrastructure networks and then develop theoretical models that help explain the economic factors that give rise to grid and hub-spoke networks. We also study the implications of these networks for the distribution of goods and mobility of labour and the performance of the system. Chapter 7 studies the robustness of different infrastructure networks to natural and man-made shocks. This chapter draws attention to the circumstances that support the robustness of dense (*grid-like*) networks and sparse (*hub-spoke*) networks, respectively. Chapter 8 studies the effects of network size and the role of intermediaries (such as platforms). It presents a theoretical model that examines the role of pricing protocols in shaping intermediation networks. Chapter 9 takes up the role of networks in financial contagion. We develop the basic economics that give rise to links across financial institutions. We then study the role of networks in propagating shocks to individual institutions. Finally, we examine the role of complexity of connections in giving rise to the possibility of bank runs in financial networks. Chapter 10 takes up the study of wars among inter-connected parties. The chapter draws attention to the versatility of networks: we may think of links as reflecting defence alliances or physical contiguity. The chapter uses theoretical models of conflict on networks to provide a better understanding of the

Great War of Congo, the fall in wars after Second World War, and the growth of empires in history.

The third part of the book consists of chapters 11-15 and it covers social networks. Chapter 11 revisits the subject of personal influence and presents a theoretical model to understand an important feature of social network of communication: the law of the few that says that such networks are characterized by specialization in linking and in information gathering. The chapter also presents an experiment that brings out in sharp relief the dynamics of linking and information purchase and how they feed into extreme levels of specialization in linking and in information purchase. Chapter 12 studies social coordination. Almost all human activity involves coordination: ranging from our use of time, when and how we eat, what to wear, and our use of particular languages and technologies (such as fax machines or telephones). As coordination is so central to our life, it is important for societies to have ‘norms’ or ‘standards’. In this chapter, we explore how the patterns of interaction – who interacts with whom – matter as societies work their way toward norms, how they respond to new circumstances and arrive at new norms, and how they navigate the tension between differing personal tastes and the benefits of coordination on common norms. Chapter 13 takes up the study of how information flows in a network and how that shapes beliefs and opinions and the optimality of long run decisions. The chapter presents theoretical models of Bayesian learning and of bounded rational learning and shows how these models lead to similar predictions on the role of networks. The final part of this chapter presents experimental evidence in support of the main theoretical predictions. Chapter 14 studies the dynamics of diffusion. The first part of the chapter takes up the study of diseases and examines how disease characteristics and network structure determines the size of an epidemic. The second part of the chapter examines diffusion of ideas and modern technology and identifies circumstances under which the seeding of nodes can make a big difference for the extent of diffusion. Chapter 15 studies markets as networks. We take the view that bonds of trust and cooperation lead to personalized relations and geographical distance and national boundaries place restrictions on who can undertake exchange with whom. These restrictions may be formulated in terms of (present or absent) ties within a network. The chapter presents models of networked markets that help us understand the ways in which prices and quantities are determined in such settings.

The fourth part of the book consists of chapters 16-19 and it situates networks in a broader context. In chapter 16 we study the role of social networks in the functioning of modern product, labour and financial markets. In chapter 17 we take up the role of communities in the process of economic development – here the interest is in the relation between how traditional ties of family or kinship interact with the arrival of modern technologies

and with impersonal exchange. In chapter 18 we take up the fundamental notion of trust. Trust is central to most economic exchange, however the level of trust varies greatly across countries and across communities within the same countries. We discuss trust in small scale groups and trust in large groups and we explore the fundamental question of how trust scales up from the small to the larger scale, and how the structure of the social network matters in this process. Chapter 19 goes one step further and introduces the role of state. We lay out a theoretical framework to study the scale and efficiency of economic exchange in a context that combines elements of civic capital, impersonal exchange and state capacity.

## Reading Notes

For an introduction to the use of networks in economics see Goyal [2016b] and Goyal [2017]. The opening lines on the nature of economics paraphrase the definition of the subject offered in 1932 by Lionel Robbins (for a recent imprint of the essay see Robbins [2007]). Hayek [1945] offers an influential statement on the central role of information and knowledge in economic systems. Bramoullé, Galeotti, and Rogers [2016] present a panoramic overview of the literature on the economics of networks.

# **Part I**

## **Foundations**

# Chapter 1: Concepts and Measures

## 1.1 Introduction

The introductory chapter drew attention to the extraordinary diversity of networks and described in very general terms a broad set of properties of networks. This chapter begins our formal study of networks: we introduce definitions of network concepts and use them to compute different properties of some prominent real world networks.

## 1.2 Concepts and terminology

We introduce concepts from graph theory in this section. The discussion is brief and we will cover the key concepts we use; for a more comprehensive treatment of the subject the interested reader is referred to Newman [2018].

We shall think of a network as a collection of nodes and edges. An edge between two nodes signifies a (direct) relation between them. Recalling the examples from the previous chapters, in a production network an edge represents an input-output relation, in an airline networks it is a route between two cities, in a social network it may be a friendship, on Twitter it is a ‘following’ relation and in scientific collaboration network it reflects co-authorship. In this book, we will use the terms edge and link interchangeably.

Let the set of nodes be given by  $N = \{1, 2, 3, \dots, n\}$ , where  $n \geq 2$  in the number of nodes. In the simplest case, a relationship or a link between two nodes  $i$  and  $j$  is represented by a number 0 or 1; so a link is either present or absent. This may be true for a friendship. In other cases, such as a production network, a link may have different weights depending on the input levels. In the discussion here, we will mostly focus on the case where a link takes on a 1-0 value.

A directed link  $g_{ij}$  indicates a directionality from  $i$  to  $j$ : so in Twitter it may mean that “ $i$  follows  $j$ ”, while in a production network it may refer to flow of inputs from sector  $i$  to sector  $j$  (as is clear from the examples, there may be no flows going the other way).

	1	2	3
1	0	1	0
2	1	0	1
3	0	1	0

Table 1.1: Adjacency Matrix

An undirected link has no directionality (or equivalently the values in both directions are equal), so  $g_{ij} = g_{ji}$ . An example could be friendship or a research collaboration or a transport link between two cities. The nodes  $N$  and the links between them  $\{g_{ij}\}$  define a network,  $g$ . The set of all networks on  $n$  nodes is denoted by  $\mathcal{G}_n$ .

A network may be described through an enumeration of all the links in it. So for instance in a network with 3 nodes  $N = \{1, 2, 3\}$  where nodes 1 and 2 are linked and 2 and 3 are linked, we may write the network as  $g = \{g_{12}, g_{23}\}$ . Here  $g_{ij}$  refers to the presence of a link. Sometimes we will find it more convenient to describe the network in matrix form: the 3 node 2 link networks is represented as an adjacency matrix as follows:

A matrix representation allows us to represent directed as well as undirected links. Moreover, and this will be useful in some applications, it also allows us to consider networks in which the links have weights i.e., they may take on positive or negative real numbers, not only the values 0 and 1.

It is important to note that even a small number of nodes give rise to a very large set of networks. To see this, suppose  $n = 100$  and let us consider undirected links. There are approximately 5000 distinct pairs i.e.,  $\binom{100}{2}$ , of nodes. Note that this is also the number of potential undirected links possible in a network with 100 nodes. As every link is either present or absent, there are  $2^{5000}$  possible networks. This is greater than the number of atoms in the (observable) universe! Given a network,  $g$ , let  $N_i(g) = \{j \neq i | g_{ij} = 1\}$  be the set of nodes with whom  $i$  has a link. The set  $N_i(g)$  will be referred to as the set of neighbours of node  $i$  in network  $g$ . We will define the *degree* of node  $i$  in network  $g$ ,  $d_i(g)$ , to be the number of neighbours of  $i$ , i.e.,  $d_i(g) = |N_i(g)|$ .

### 1.2.1 Regular and irregular networks

A network is said to be *regular* if every node has the same number of links. Figure 1.1 presents examples of regular networks. In the empty network the degree is 0, in the circle the degree is 2, while in a complete network it is  $n - 1$  (in this case  $n = 12$  so the degree in the complete network is 11). As we add links in a regular network, all the time maintaining the equal degree property, we trace out a progressively denser network. We see this as we move from figure (a), to (b) to (c) to (d) in Figure 1.1.

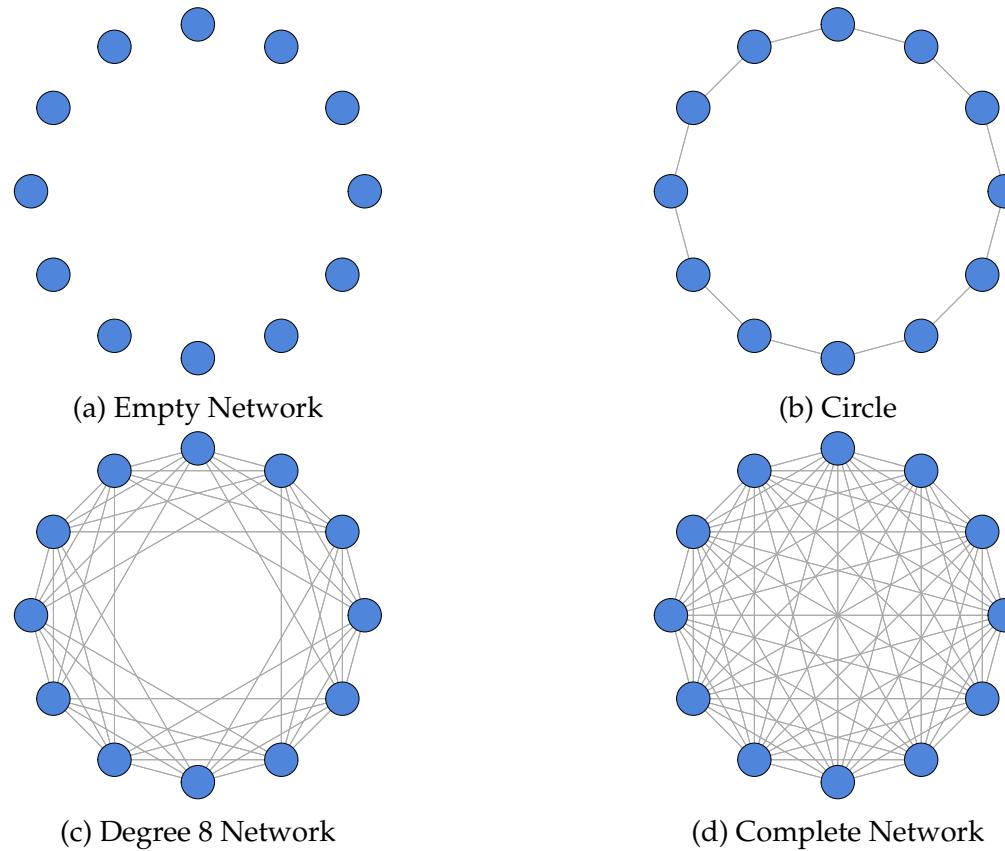

Figure 1.1: Regular Networks

We now turn to *irregular* networks, these are networks in which the degrees of at least one pair of nodes is different. A prominent member of this class of networks is the *core-periphery* network. This network contains two types of nodes – the core and the periphery. Figure 1.2 presents two types of core-periphery networks. In both cases, the nodes in the core are fully connected among themselves (i.e., they constitute a clique). The difference lies in the degree of the periphery nodes. In one case, the periphery node has a single link as in panel (b), while in the other it may be linked to a subset of the members of the core (as in Figure 1.2(c) and (d)). The *star* network in figure 1.2(a) is perhaps the best known special case of the core-periphery network, with a singleton core member. We will sometimes refer to the star as a *hub-spoke network*.

A *line* network has the form of a line, the two nodes with one link each are at the two ends of the line, while the nodes with 2 links are in between. Figure 1.3 presents a line network.

Sometimes, as when we study Twitter or the production network of firms, we are interested in large networks with hundreds of thousands of nodes. When studying such large

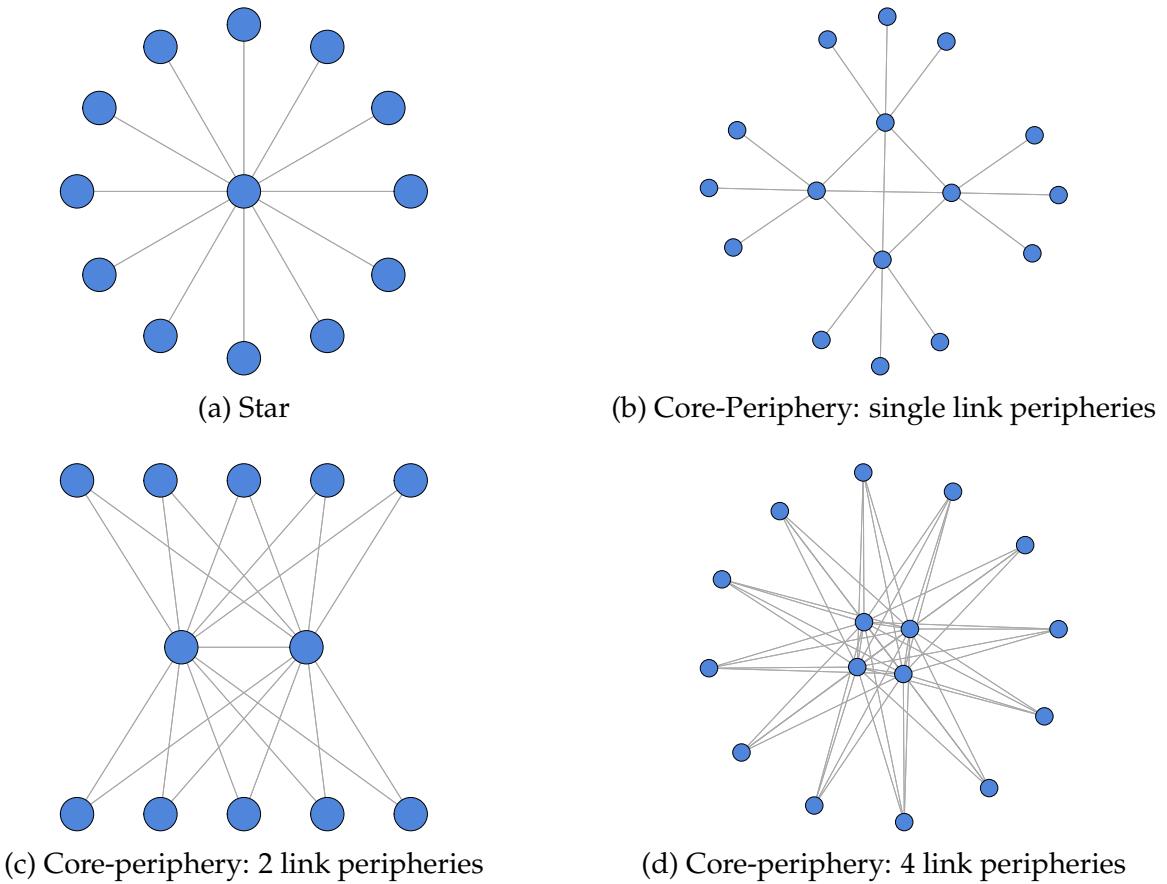

Figure 1.2: Core-Periphery Networks

Figure 1.3: Line network

networks it is more convenient to work with ‘summary’ statistics rather than a complete description – with all nodes and each and every link – of a network.

### 1.2.2 Degree distributions

A natural way to measure links across nodes is to consider the *degree distribution* of a network. Let  $P(d)$  be the frequency or fraction of nodes with degree  $d$ . The degree distribution of a regular network will take on a specially simple form:  $P(k) = 1$  for a single degree and it will be zero for all other degrees. Next consider an irregular network. For the star network the degrees take on values 1 and  $n - 1$ , with  $n - 1$  nodes having degree 1, and 1 node having degree  $n - 1$ . Thus the degree distribution is as follows:  $P(n - 1) = 1/n$ ,  $p(1) = n - 1/n$  and  $P(d) = 0$  for all other degrees  $k \in \{0, \dots, n - 1\}$ . Finally, in a core periphery network given in Figure 1.2(b) the degree distribution is given by  $P(n - 1) = 4/n$ ,  $P(d) = n - 4/n$  and  $P(k) = 0$  for all other degrees  $d \in \{0, \dots, n - 1\}$ .

The *mean* (or average) degree in network  $g$  is the sum of degrees across nodes divided by the number of nodes:

$$\bar{d}(g) = \sum_{i \in N} \frac{d_i(g)}{n} = \sum_k P(d)d \quad (1.1)$$

The mean degree in a regular network is the same as the degree of all nodes, while the mean degree of a star network is  $2 - 2/n$  (which is approximately equal to 2, when the number of nodes grows). It is worth noting that the mean degree of a line network is the same as that of a star (because they have the same number of links,  $n - 1$ , in a network with  $n$  nodes).

The *variance* of the degree distribution is

$$\text{var}(g) = \sum_{d=0}^{n-1} P(d)[\bar{d}(g) - d]^2. \quad (1.2)$$

To develop a feel for degree distributions for large networks we next consider two widely used examples – the Poisson and the Pareto distribution. Under a Poisson distribution, the probability that a random selected node has degree  $d$  is given by

$$\frac{e^{-\lambda} \lambda^d}{d!} \quad (1.3)$$

where  $\lambda$  is the mean number of links. Figure 1.4 presents a network with 25 nodes with a Poisson degree distribution ( $\lambda = 4, 5, 6$ ) and the corresponding degree distribution: an

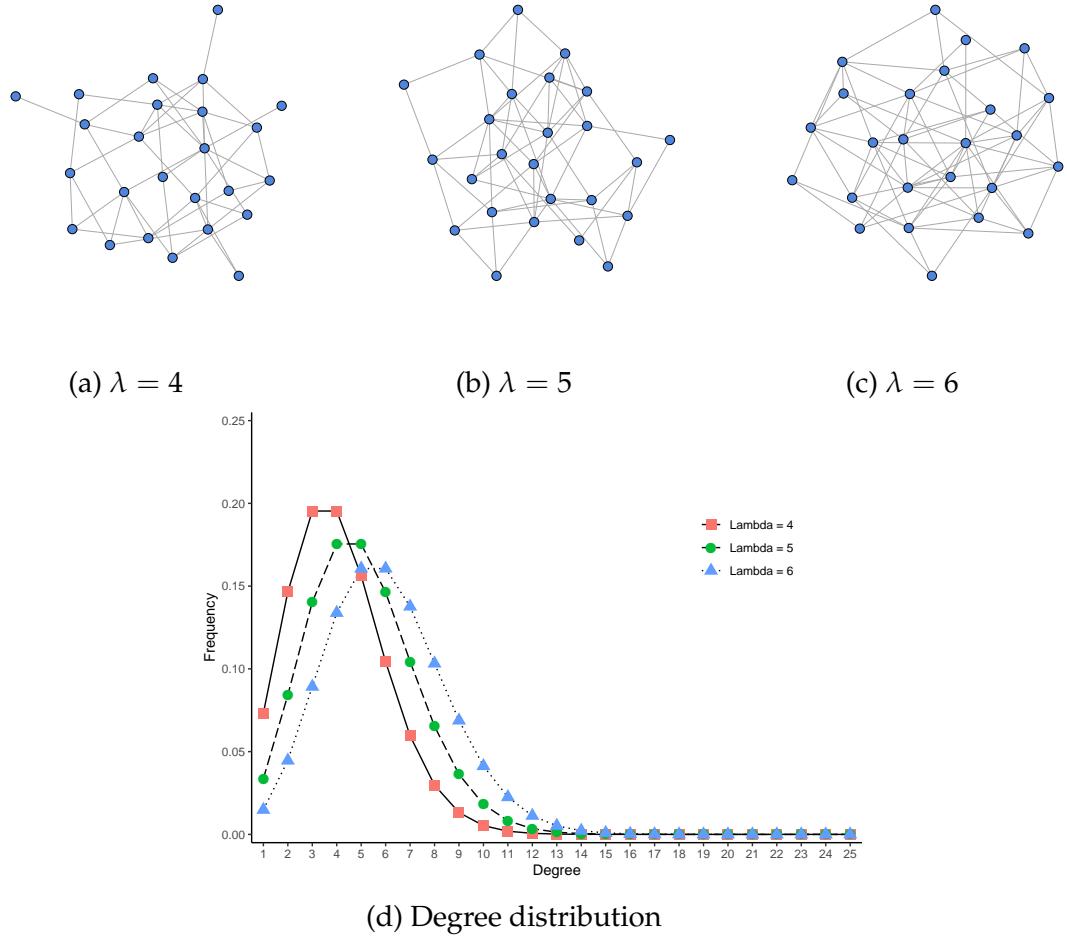

Figure 1.4: Poisson Networks

important feature of the Poisson distribution is that most of the nodes will have degrees close to the mean degree  $\lambda$ . We also note that the variance of this degree distribution is equal to its mean,  $\lambda$ .

Under the Pareto distribution, the probability that a node has degree  $d$  is

$$P(d) = cd^{-\gamma}, \quad (1.4)$$

where  $c$  is a positive constant (that normalizes sum of probabilities to 1) and  $\gamma \in (1, 3)$ . Figure 1.5 presents networks with coefficient values of  $\gamma = 1.5, 2, 2.5$  (the mean degree is 3.76). We see that as we raise the value of  $\gamma$  this leads to a network with a few very highly linked nodes and a large number of poorly linked nodes. The variance of the Pareto distribution is undefined if  $\gamma \in (1, 2)$  and it grows without bound (in the number of nodes) if  $\gamma \in (2, 3)$  (for a derivation of this property, see chapter 2 on random graphs).

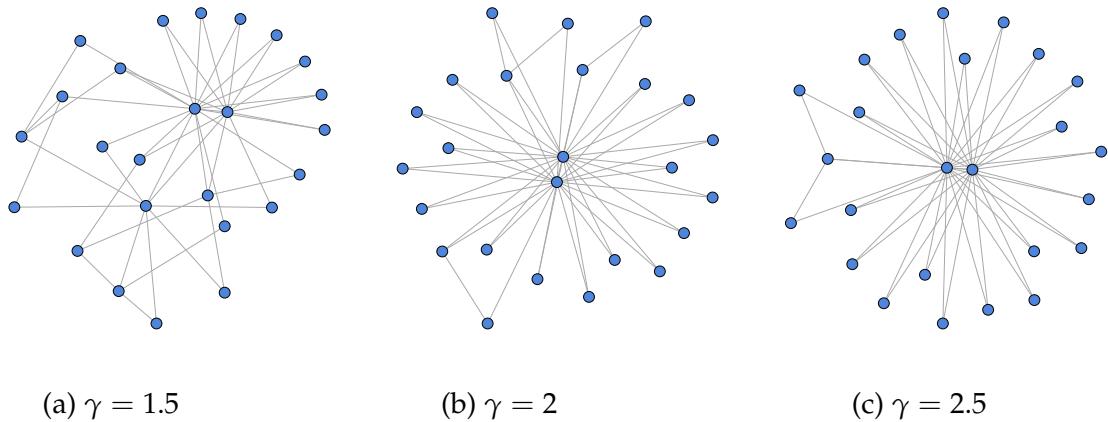

Figure 1.5: Pareto Degree Networks (average degree  $\approx 4$ )

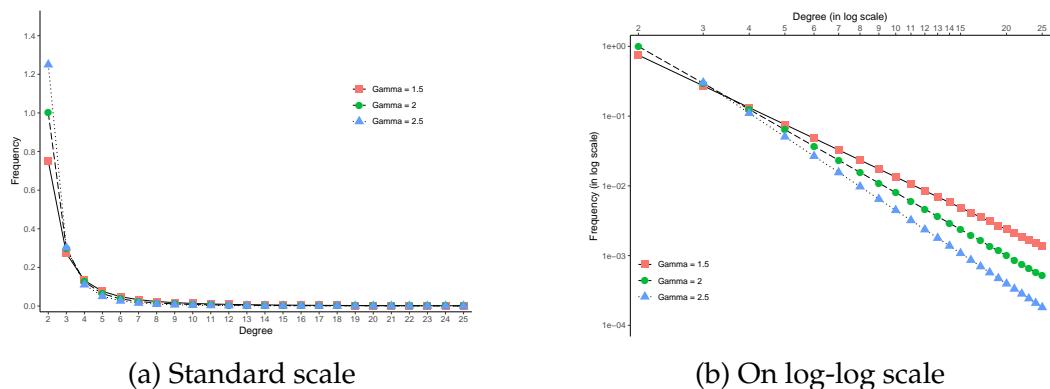

Figure 1.6: Pareto Degree Distributions

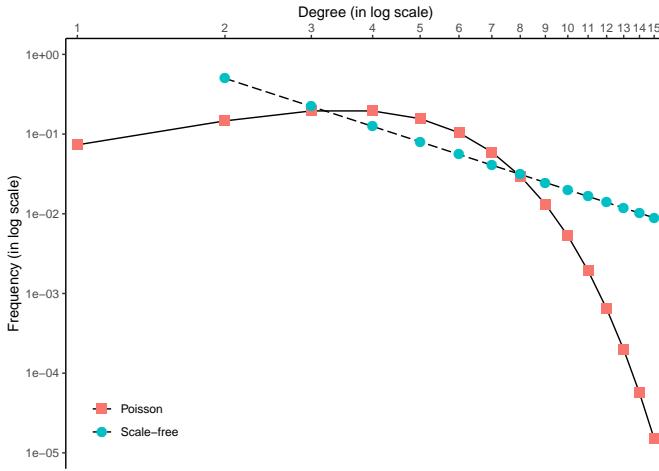

Figure 1.7: Poisson vs Scale Free ( $\lambda = 4$ ,  $\gamma = 1.5$ )

To appreciate the differences between Poisson and Pareto degree distributions it is helpful to plot them on the same scale. Figure 1.7 presents the degree distributions for Poisson and Pareto distributions (where both x-axis and y-axis are on a log scale). We note that there is a larger fraction of less connected but also a significantly larger fraction of more highly connected nodes under the Pareto distribution, as compared to the Poisson degree distribution. We also see that the probability falls at a rate that is independent of the degree, and this suggests a widely used name for such distributions – the *scale-free* distribution. As probability in the Pareto distribution scales with a power coefficient, this degree distribution is sometimes referred to as a power-law degree distribution.

In a small network, it is easy to describe what happens when we add a link to the network. We write the operation of adding or deleting a link as  $g + g_{ij}$  and  $g - g_{ij}$ . In large networks, degree distributions allow us to conduct the same thought experiment as follows. Given a degree distribution  $P$ , let the cumulative distribution function be denoted by  $\mathcal{P} : \{1, 2, \dots, n-1\} \rightarrow [0, 1]$ , where:

$$\mathcal{P}(d) = \sum_{x=0}^d P(x). \quad (1.5)$$

Let  $P$  and  $P'$  be two degree distributions and  $\mathcal{P}$  and  $\mathcal{P}'$  be their corresponding cumulative distribution functions.

The notion of adding links in a large network may be expressed as follows.

**Definition 1.1.**  $P$  first-order stochastic dominates (FOSD)  $P'$  if and only if  $\mathcal{P}(k) \leq \mathcal{P}'(k)$  for every  $k \in \{1, 2, \dots, n-1\}$ .

So the plot of the cumulative degree distribution,  $P(d)$  will lie (weakly) below the cu-

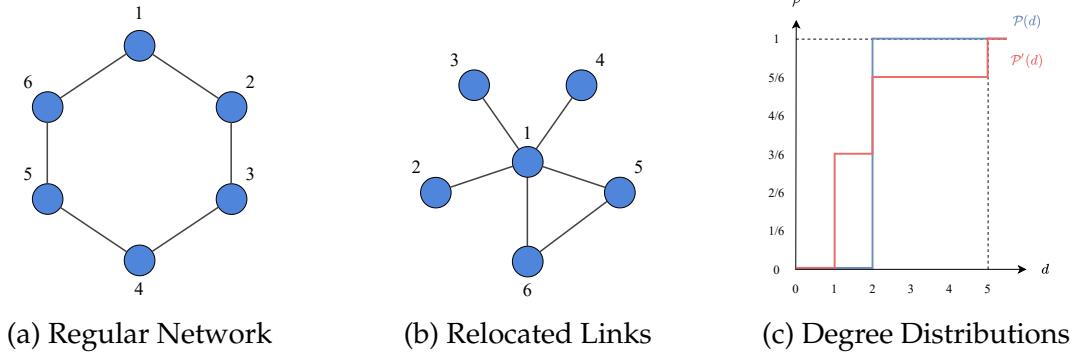

Figure 1.8: Mean Preserving Spread of Degrees

mulative degree distribution  $P'(d)$ , for every  $d$ .

Motivated by the observations on Poisson and Pareto distributions above, we now turn to issue of dispersion of degree distribution. Our interest is in understanding if the degrees or one network are more dispersed as compared to another network. The idea of dispersion is captured by Mean Preserving Spreads and Second Order Stochastic Dominance that we now define formally as follows.

**Definition 1.2.**  $P$  second order stochastically dominates  $P'$  if and only if  $\sum_{k=1}^x \mathcal{P}(k) \leq \sum_{k=1}^x \mathcal{P}'(k)$  for every  $x \in \{1, 2, \dots, n-1\}$ .

**Definition 1.3.**  $P'$  is a mean preserving spread of  $P$  if and only if  $P$  and  $P'$  have the same mean and  $P$  second order stochastic dominates  $P'$ .

A simple example of first order stochastic shift in degree distribution arises when we move from a regular network with degree  $k$  to a regular network with degree  $k+1$ . An example of a second order shift arises when we move from a cycle to a hub-spoke network with one pair of spokes connected. Figure 1.8 illustrates this in the case of a network with 6 nodes.

### 1.2.3 Distances

A *path* exists between two nodes  $i$  and  $j$  if  $g_{ij} = 1$  or if there is a sequence of distinct intermediate nodes  $j_1, j_2, \dots, j_n$ , such that  $g_{ij_1} = g_{j_1 j_2} = \dots = g_{j_n j} = 1$ . A component is a maximal group of nodes with the property that there is a path between every pair of them. A network is *connected* if there exists a path between every pair of nodes.

The *distance* (the *geodesic distance*) between two nodes  $i$  and  $j$ ,  $d(i, j; g)$ , is the length of the shortest path between them. The *diameter* of a connected network is equal to the geodesic

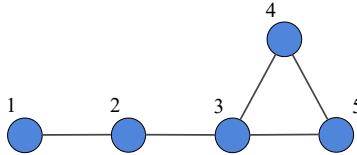

Figure 1.9: Walks, cycles and paths

distance between the pair of nodes that are farthest apart in that network. The *mean distance* between nodes in a connected network  $g$  is then the arithmetic mean of distance across all pairs of nodes.

$$AD(g) = \frac{\sum_{i \in N} \sum_{j \in N \setminus \{i\}} d(i, j; g)}{n(n - 1)} \quad (1.6)$$

Let us examine the distances in two standard networks: the star and the line. The mean distance in a star is  $2 - 2/n$  and the mean distance in a line network is (approximately)  $n/3$ . The difference in average distances between the star and the line grows without bound with the number of nodes. This contrast is worth noting given that both networks have  $n - 1$  links.

In some contexts, it is helpful to consider more general ways of traversing the network. In this context, an elementary notion is a *walk*: a walk is a sequence of nodes in which two nodes have a link between them in the network (they are neighbors). A node or a link may appear more than once in a walk: a walk is the most general sequence of nodes and links possible in a network, subject to the restriction that any two consecutive nodes must have a link in the network. The length of a walk is simply the number of links it crosses, which is one less than the number of nodes involved. A walk with three or more nodes, no duplication of links, and where the initial and the end node are the same is called a *cycle*.

It is helpful to illustrate these ideas with the help of Figure 1.9. A possible walk in this network is 2,3,4,3,2. This walk contains the links  $g_{23}$  and  $g_{34}$  twice and the nodes 2 and 3 also appear twice in this walk. The walk 3,4,5,3 constitutes a cycle, and the walk 2, 3, 4, 5 is a path.

The matrix representation of a network is helpful in figuring out walks of different lengths between nodes of a network. To see this let us recall the simple 3 nodes line network represented in Table 1.1. In this network there is one walk of length 1 between 1 and 2 and no such walks between 1 and 3. We can infer the number of walks of length 2 by writing out the matrix  $\mathbf{G}^2$  as given in Table 1.2:

Table 1.2 reveals that there is 1 walk of length 2 between 1 and 1 and between 3 and 3, and 2 walks of length 2 between 2 and 2. There are no other walks of length 2 in this

	1	2	3
1	1	0	1
2	0	2	0
3	1	0	1

Table 1.2:  $\mathbf{G}^2$ : Walks of Length 2

network.

### 1.2.4 Local structure

A simple example of a local measure is the number of triangles in the neighbourhood of a node. In the context of social networks, this is motivated by the following intuitive idea: if A has two close friends B and C, then sooner or later she will introduce them to each other, thereby making it likely that they will also become friends. The *clustering coefficient* of a node  $i$  (that has two or more links) is defined as:

$$Cl_i(g) = \frac{\sum_{l,k \in N_i, l \neq k} g_{lk}}{d_i(d_i - 1)}. \quad (1.7)$$

The numerator is the number of pairs of neighbours of  $i$  who have a link, while the denominator is the number of all possible pairs among the neighbours.

By way of illustration, let us compute the clustering of nodes in some of the networks in Figures 1.4 and 1.2. The clustering for every node in a circle is 0, as none of the neighbours have a link. Moving on the core-periphery networks, in Figure 1.2(b), clustering for hub is  $1/5$  and for spoke is not defined; Figure 1.2(c) clustering for hub is  $2/11$  and for spoke is 1; Figure 1.2(d), clustering for hub is  $13/35$  and for spoke is 1.

The clustering of a network  $g$  can be expressed in two different ways. One way is to take the average across the clustering of individual nodes. This is simply the “mean” of clustering across all nodes (that have degree two or more) and is given by

$$Cl(g) = \sum_{i \in N} \frac{Cl_i(g)}{n}$$

The clustering in the star is therefore 0 (as none of the triangles involving the links of the centre are present), and clustering in the complete network is equal to 1 (as it contains all possible links and hence all possible triangles). An alternative way to proceed is to weight the nodes by their degree. This leads to the following measure of clustering. Define *weighted or overall clustering* in a network  $g$  as:

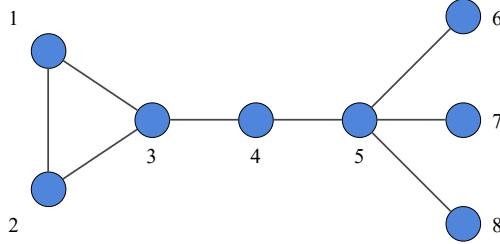

Figure 1.10: Network for centrality computations

$$Cl_w(g) = \frac{\sum_{i:j \neq i; k \neq j; k \neq i} g_{ij}g_{ik}g_{jk}}{g_{ij}g_{ik}}. \quad (1.8)$$

The two measures can differ quite significantly if there is a strong correlation between degrees and clustering coefficient. A question at the end of the chapter examines the relation between these two measures of clustering.

The study of local structure can be generalized beyond three nodes to a larger group of nodes. A *clique* in a network  $g$  is a complete subgraph of  $g$ , i.e., a set of nodes  $I = \{i_1, i_2, \dots, i_k\} \subset N$ , such that for every pair  $i, j \in I$ ,  $g_{ij} = 1$ . In the complete network, the clique consists of all the nodes. In the core-periphery network, the clique consists of the nodes in the core (see Figure 1.2).

### 1.2.5 Centrality

The centrality of a node in a network captures a number of ideas relating to the prominence of a node in a network. Perhaps the simplest notion pertains to the idea of how many links a node has: *degree centrality* measures the relative prominence of a node vis-a-vis other nodes in terms of its degree. The (standardized) degree centrality of a node  $i$  is its degree divided by the maximum possible degree.

$$C_d(i; g) = \frac{d_i(g)}{n - 1} \quad (1.9)$$

We compute degree centrality for nodes in the network presented in Figure 1.10. We see that nodes 6, 7 and 8 have the lowest while node 5 has the highest degree centrality and nodes 1,2,3 and 4 lie in between.

A node may be said to be central if it is “close” to other nodes. The total distance from node  $i$  to all other nodes in the network  $g$  is given by  $\sum_{j \neq i} d(i, j; g)$ . To account for the number of nodes, we normalize the measure by multiplying it with the minimum possible total distance in any network,  $n - 1$ . The *closeness centrality* of node  $i$  in network  $g$  is defined

	Nodes 1 & 2	3	4	5	6,7, & 8
Degree	0.29	0.43	0.29	0.57	0.14
Closeness	0.37	0.50	0.58	0.58	0.39
Betweenness	0.00	0.48	0.57	0.71	0.00
Eigenvector	0.40	0.52	0.40	0.40	0.17

Table 1.3: Centrality measures

as:

$$C_c(i; g) = \frac{n - 1}{\sum_{j \neq i} d(i, j; g)} \quad (1.10)$$

Table 1.3 presents closeness centrality of nodes in the network in Figure 1.10. In line with intuition, we see that nodes 1 and 2 have the lowest, nodes 4 and 5 the highest, and nodes 3 and 6,7,8 have intermediate levels of closeness centrality.

In some contexts a node's status may arise from its location between other nodes due to intermediation and brokerage. With this idea in mind let us define *betweenness* for a node  $i$  with respect a pair of other nodes  $j$  and  $k$

$$b_i^{jk}(g) = \frac{\# \text{ shortest paths between } j \text{ and } k \text{ on which } i \text{ lies}}{\# \text{ shortest paths between } j \text{ and } k} \quad (1.11)$$

Aggregating this across all possible other pairs yields us the *betweenness centrality* of a node:

$$C_b(i, g) = \frac{2}{(n - 1)(n - 2)} \sum_{j, k \neq i} b_i^{jk}(g). \quad (1.12)$$

where the denominator is  $\binom{n-1}{2}$ . This measure lies between 0 and 1.

We compute betweenness centrality for nodes in the network presented in Figure 1.10 and they are presented in Table 1.3. We see that nodes 1,2 and 6, 7 and 8 do not lie on the shortest paths for any other pair of nodes and therefore have 0 betweenness centrality. Nodes 3, 4 and 5 do lie on some shortest paths; node 7 has the highest centrality measure as it lies on the shortest paths of nodes 6,7 and 8, in addition to connecting 6, 7 and 8 with the rest of the population.

A natural idea is that a person's standing in a society depends on the standing of his

associates. This leads us to consider prestige or influence recursively. In this spirit, Katz [1953] proposed that a node's *prestige* is given by

$$P_i^K(g) = \sum_{j \neq i} g_{ij} \frac{P_j^k(g)}{d_j(g)} \quad (1.13)$$

Let us set  $\hat{g}_{ij} = g_{ij}/d_j$ , i.e., we normalize the weight of a link with the degree of the corresponding neighbour. We can then write *Katz's first prestige measure* in matrix form as:

$$[I - \hat{G}]P^K(g) = 0, \quad (1.14)$$

where  $P^K$  is the  $n \times 1$  vector,  $I$  is the identity matrix and  $\hat{G}$  is the degree-adjusted adjacency matrix of the network.

In words, calculating prestige requires us to find the unit eigenvector of the adjacency matrix  $\hat{G}$ . Katz prestige values are presented in Table 1.3. We note that the weighting of a neighbour's prestige by his degree is important: we see that nodes 6, 7 and 8 have the lowest measure in spite of them being connected to the most prestigious node 5: this is because 5 has degree 4. Moreover, node 5 has higher prestige as compared to node 4 because node 5 is linked to 6, 7 and 8 who are each only linked to 5 (thus have low degree).

We may also define a recursive notion of prestige that does not normalize for degrees of neighbours: this yields us the *eigenvector centrality* of a node. The eigenvector centrality of a node is proportional to the sum of the eigenvector centrality of its neighbours, i.e.,

$$\lambda C^e_i(g) = \sum_j g_{ij} C^e_j(g). \quad (1.15)$$

where  $\lambda$  is a proportionality factor. In matrix notation we write this as

$$\lambda C^e(g) = G C^e(g). \quad (1.16)$$

$C^e(g)$  is an eigenvector of  $G$  and  $\lambda$  is an eigenvalue of the matrix. In general, there are many different eigenvalues for which a non-zero eigenvector solution exists. However, since the entries in the adjacency matrix are non-negative, there is a unique largest eigenvalue which is real and positive (this is a consequence of the Perron–Frobenius theorem, Seneta [2006]). The eigenvector is only defined up to a common factor. To define an absolute score one can normalise the eigenvector for instance by requiring that it be unit valued. Table 1.3 presents computations for eigenvector centrality for nodes in Figure 1.10. The contrast with Katz prestige measures, especially with regard to node 5, brings out the

role of the normalization by degree.

Katz [1953] introduced a second measure of centrality in which prestige of a node is a weighted sum of the walks that emanate from it, and a walk of length  $k$  is worth  $a^k$ , for some parameter  $0 < a < 1$ . Katz [1953]'s *second prestige measure* is given by

$$P^{K2}(g; a) = [I - aG]^{-1}aG\mathbf{1} \quad (1.17)$$

where  $I$  is the identity matrix,  $\mathbf{1}$  is the  $n$  (column) vector of 1's, and  $a$  is sufficiently small. Table 1.3 presents the computations for the second Katz prestige measure. We see that nodes 3 and 5 have highest prestige, while nodes 6, 7, and 8 have lowest prestige. Node 4 has intermediate prestige.

We can generalize Katz's second prestige measure to obtain the *Bonacich measure of centrality*.

$$CB(g; a, b) = [I - bG]^{-1}aG\mathbf{1} \quad (1.18)$$

where  $a > 0$  and  $b > 0$  are scalars, and  $b$  is sufficiently small. Bonacich centrality values are presented in Table 1.3. Observe that the parameter  $b$  now provides us the weights for walk length, and, in line with intuition, we see that as  $b$  declines from  $1/3$  to  $1/5$ , the longer walks become less weighted and the centrality measure gets closer to the corresponding degree centrality measure.

## 1.2.6 Homophily

Finally, we take up a network measure that lies somewhere between the local and the global: homophily. Homophily is the tendency of nodes to form links with nodes who are similar to them (Lazarsfeld and Merton [1954]). For example, individuals with similar interest in some sports would like to link with each other. In a high school, pupils with the same gender or race may be more likely to form links with one another.

For simplicity, let us define the notion of homophily with reference to gender. Denote the fraction of men in the population by  $w_m$  and the share of women by  $w_f$ , where  $w_f = 1 - w_m$ . Let  $H_m$  denote the mean share of male links among links of men.

*Relative homophily* reflects a straightforward idea: we say that a group of men display relative homophily if the fraction of links men have with other men is larger than the fraction of males in the population; a similar notion of relative homophily applies to women. Let us define relative homophily of group  $i$  as  $RH_i = H_i - w_i$ , for  $i = m, f$ .

*Inbreeding homophily* goes a step further and measures the proportion of links within the

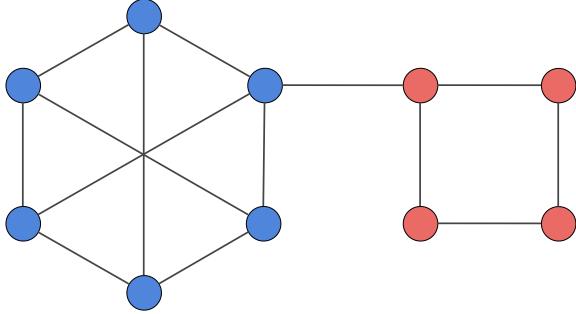

Figure 1.11: Homophily in a Network

same group (such as gender) in relation to the fraction of population that belongs to this group and then normalizes the difference by the maximum bias that a group could possess (this measure was introduced by Coleman [1958]). Inbreeding homophily for group  $s$  is defined as follows:

$$IH_s = \frac{H_s - w_s}{1 - w_s}, \text{ for } s = \{f, m\}. \quad (1.19)$$

A positive  $IH_s$  indicates homophily while a negative  $IH_s$  indicates heterophily. The definitions of relative and inbreeding homophily can be extended in a natural way to cover multiple groups in a population.

To illustrate the definitions of relative and inbreeding homophily we present an example of a network with 10 nodes in Figure 1.11.

In this network, there are 6 men (indicated in blue) and 4 women (indicated in red). The homophily statistics for this network are given in Table 1.4.

$H_{blue}$	$H_{red}$	$w_{blue}$	$w_{red}$	$RH_{blue}$	$RH_{red}$	$IH_{blue}$	$IH_{red}$
0.9	0.8	0.6	0.4	0.3	0.4	0.75	0.67

Table 1.4: Gender Homophily

In the next section, we use these network concepts to measure a range of real world networks.

## 1.3 Measuring Networks

### 1.3.1 United States Production Network

In this network, a node is a sector and the  $(i, j)$  link represents the flow of inputs from  $i$  to  $j$ . An edge is present if the associated input transaction is above 1% of a sector's total input purchases. The data is taken from the U.S. Bureau of Economic Analysis (BEA) Commodity-by-Commodity Direct Requirements Detailed Tables. The data classifies the US economy into 417 sectors. The resulting network accounts for about 80% of the total value of intermediate input trade in the US economy in that year.

The first thing to note is that the network is very sparse: there are only 5217 (non-zero) links, thus the network density is 0.03. The mean degree, 11, is very small, relative to the total number of sectors in the network. There is significant heterogeneity across sectors in their role as input suppliers. To develop a feel for this let us define  $w_{ij} \in [0, 1]$ , as the weighted input from sector  $j$  to sector  $i$  i.e., this is the input coming from sector  $j$  as a share of total input coming into sector  $i$ . With this in hand, define the weighted out-degree of a sector  $j$  as

$$d_{out}^j = \sum_{i=1}^n w_{ij} \quad (1.20)$$

This measure ranges from 0 (if a sector does not supply inputs to any other sector) to  $n$  (if a single sector is the sole input supplier of every sector). The mean weighted out-degree in the US production network is 0.5. An average input-supplying technology is ‘cutting tools manufacturing’ – with a weighted out-degree of 0.45, that supplies to 7 other sectors. By contrast, take iron and steel mills: it has weighted out-degree of 5.5, and supplies to 100 other sectors!

Figure 1.12 reports the empirical degree distribution associated with the 2002 input output data. The x-axis is the weighted out-degree for each sector, presented on a log scale. The y-axis (also in log scale) gives the probability that a sector selected at random from the population has an out-degree larger than or equal to  $x$ . The weighted out-degree measure is skewed: in particular, the right tail of this distribution is well approximated by a Pareto degree distribution with coefficient  $\gamma = 1.44$  (as shown in Figure 1.12).

The presence of hubs means that many sectors are ‘close’ to each other – as they are all connected to the hub sectors. Indeed the diameter of the network is approximately 10 and the mean or average distance is only 4! This mean distance is very small, bearing in mind that there are 417 sectors in the economy, and the mean degree is only 11.

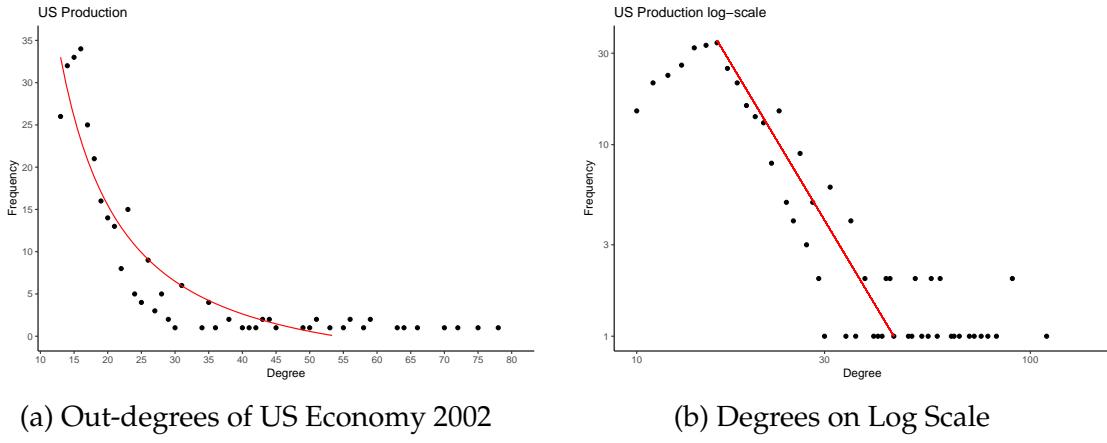

Figure 1.12: The US Economy 2002: A Power Law Degree Distribution

The scale free degree distribution, the presence of hubs, the small average distances between sectors (and possibly also firms) raise a number of questions about the functioning of the economy. Why are some sectors so large relative to the rest of the economy, how do hubs matter for the transmission of shocks, and how should governments target public policy in order to have maximum impact. Indeed, very similar questions arise when we consider the impact of shocks on banks and financial institutions. For instance, what is about the production and financial network that allowed a financial shock in the real estate sector of the United States to spread to the rest of the world and create a global recession?

In later chapters we will examine the determinants of scale free networks (chapter 2), impact of shocks on production networks (chapter 5) and financial contagion (chapter 9). We will also examine the choices of traders and firms located in such networks (chapters 15), and their incentives to create networks (chapters 2,3 and 8). This study will also help us understand the forces that make systems robust on some dimensions but fragile on others.

### 1.3.2 Airline Networks

We discuss the routing of two airlines – British Airways and Southwest Airlines. The data in this section is taken from the web site: <https://www.flightsfrom.com/top-100-airlines>

British Airlines is the flagship airline of the United Kingdom. It commenced operations in 1974. As of February 2020, the airline serves 183 cities (that correspond to the nodes in the network). There are roughly 400 routes operated, but practically all the flights are routed through one of three airports in London – Heathrow, London City and Gatwick. Figure 1.13 illustrates the network. For all practical purposes, this is a hub-spoke network, with a significant fraction of passengers using indirect flights that are routed via London.

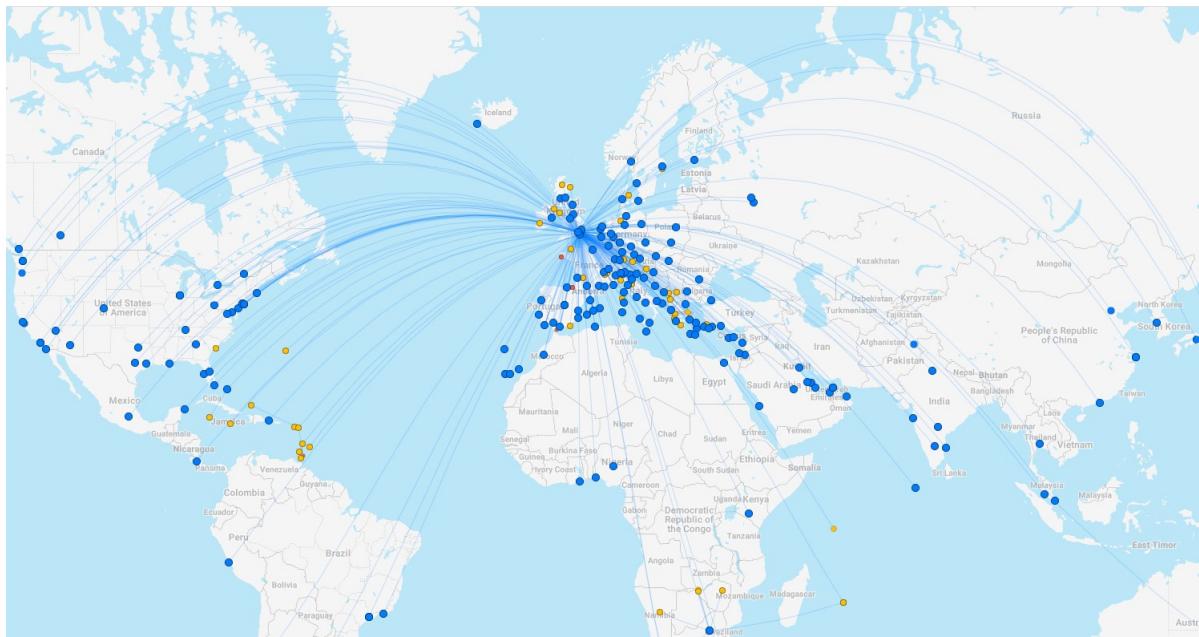

Figure 1.13: British Airways Network

The mean distance in the network is close to 2. Singapore Airlines, Emirates, and Lufthansa and several other major airlines operate a similar hub-spoke network.

Southwest Airlines commenced operations in 1971. It serves 103 cities. As of February 2020, the airline operated flights on 2980 city pairs. Figure 1.14 presents an image of the Southwest Airline network. While it is by no means a complete network, the density of the network – the ratio of operated routes to all possible routes – is 0.56. So, more than half of all possible city pairs are served with a point-to-point flight. To appreciate the extraordinarily high density of the Southwest network, note that in a hub-spoke network with 103 nodes the density would be 0.02. The distances in this network are correspondingly low, while there is significant clustering. Well known low cost airlines like Ryanair and Easyjet similarly operate a very dense network (in fact, Ryanair allows passengers to purchase only point-to-point tickets.)

In later chapters we will examine how transport networks shape economic activity and what are the economic forces that drive these structures toward a grid or hub-spoke structures and how that in turn shapes the location of economic activity (especially chapter 6 on infrastructure). Given the central role of infrastructure networks in modern economies we will also study the robustness of different networks to human attacks as well as natural disasters (see chapter 7).

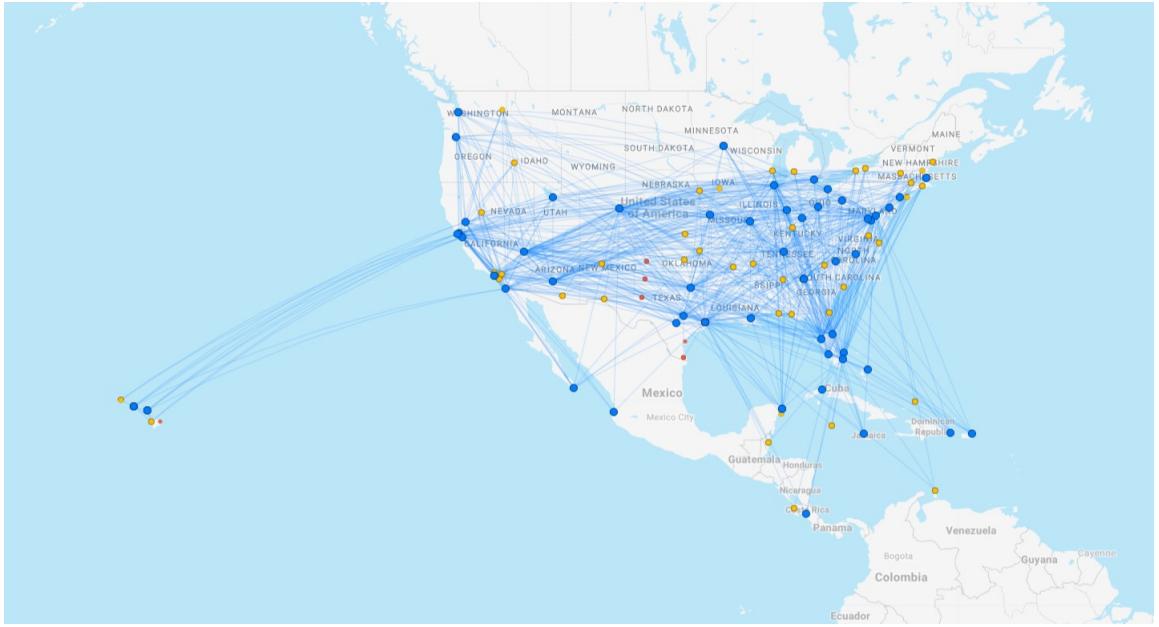

Figure 1.14: Southwest Airways Routing Network

### 1.3.3 Friendship Networks

We study the friendship network at a High School in the United States (in the year 1994). Our data is taken from Moody [2001] and forms part of the first wave component of the United States National Longitudinal Study of Adolescent Health (often referred to as Add Health). The nodes in this network are the 673 students from a school that we will refer to as the ‘Countryside High School’. A directed link from node A to node B is a nomination by A that B is their friend. Students were asked to nominate up to 10 friends (5 of each gender). The mean degree was 5; the network is therefore relatively sparse. The diameter of the network was 9 (if we consider every nomination as an undirected link). The clustering coefficient was 0.165. Figure 1.15 presents the friendship network.

The friendship network shows that pupil characteristics such as gender, race, and age, are important in shaping the network. We note that links are concentrated within racial groups. And even within a racial group, there appear to be strong ties within smaller sub-groups. These sub-groups represent the year of the students.

Turning to a closer examination of friendships, Table 1.5 presents the data on the role of race. There are five racial groups: white, black (African-American), Hispanic, Asian and Others. The whites and blacks constitute the two dominant groups – respectively 49% and 39%; the other groups are relatively small in this school. Observe that 88% of the friendship nominations by whites are to other whites, while 81% of friendship nominations by blacks

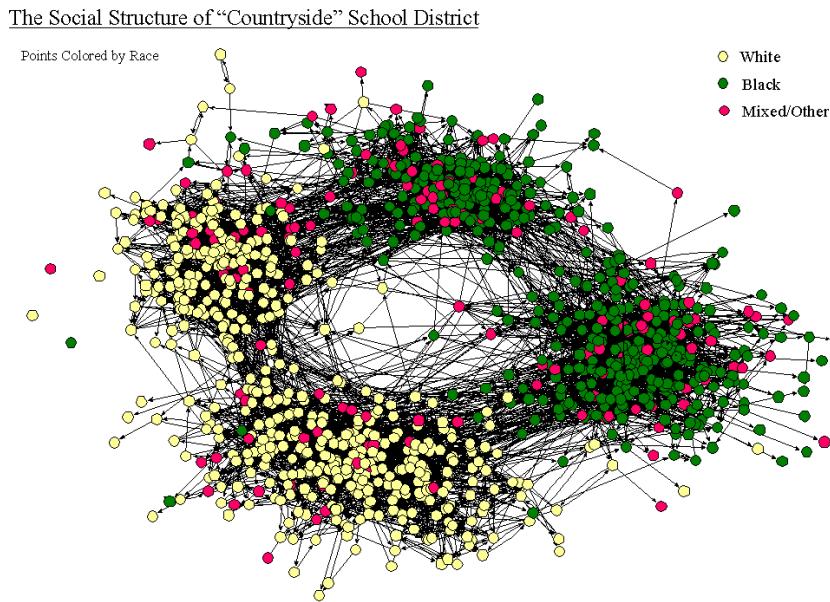

Figure 1.15: Countryside High School Friendship Network. Courtesy: James Moody

are to other blacks. It is clear that both blacks and white pupils exhibit relative homophily. Inbreeding homophily is high for both whites and black pupils – 0.76 and 0.68, respectively.

Table 1.6 presents evidence on the role of year: as one would expect, most of the friends of a student would be his/her classmates. Finally, Table 1.7 provides evidence for the role of gender: in this school, gender appears to play a relatively minor role in shaping friendships. A student’s friends of the same gender are roughly in line with the fraction of own gender pupils in the school (the gender balance in friendships looks like it reflects the requirement in the survey that students nominate up to 5 friends of each gender).

Race	Number	Fraction	Nominated	Nominated/Fraction
White	333	0.49	0.88	1.79
Black	263	0.39	0.81	2.09
Hispanic	33	0.05	0.02	.48
Asian	3	0.00	0.00	0.00
Others	47	0.07	0.09	1.28

Table 1.5: Racial Homophily in Friendships

Grade	Number	Fraction	Nominated	Nominated/Fraction
9	239	0.35	0.66	1.87
10	167	0.25	0.52	2.12
11	140	0.21	0.65	3.17
12	135	0.20	0.69	3.51

Table 1.6: Year Homophily in Friendships

Gender	Number	Fraction	Nominated	Nominated/Fraction
Male	336	0.49	0.54	1.11
Female	346	0.51	0.58	1.14

Table 1.7: Gender Homophily in Friendships

Pupils share information and ideas, take part in joint activities and develop shared values through friendships. This leads us to ask: How does the number of friends and location in a school network shape a pupil's performance, what are the effects of relatively segregated groups on pupil and school performance? In order to answer such questions, we need a theory of how social structure affects individual values and behaviour. A challenge in thinking about these questions is that individuals themselves create these friendship networks, thus we need to take great care to separate cause from effect. In later chapters we will examine how the network of relations among individuals arises (see chapters 2 and 3) and how it shapes the spread of norms and of information and the formation of opinions (see chapters 4, 11, 12, 13, 18 and 19). In these studies, we will pay special attention to the role of homophily.

### 1.3.4 Chains of Affection: Romantic and Sexual Relations

We describe the network of romantic and sexual relationships in an American High School, 'Jefferson High School' over the period 1993-1995. Our data is taken from Bearman, Moody, and Stovel [2004] and forms part of the first wave component of the United States National Longitudinal Study of Adolescent Health (often referred to as Add Health). This high school has roughly 1,000 students and it is located in a mid-sized midwestern town. The town is over an hour's drive from the nearest large city. In all, 90% of the students on the school roster participated in the in-school survey, and over the course of the interview period, 83% of all students in the school completed in-home interviews.

Jefferson is a close-knit, insular, predominantly working-class community, which offers few activities for young people. The relative isolation of the community helps us build a relatively complete picture of all relationships in the high school.

Jefferson High is similar to other American schools across many dimensions such as grades, prevalence of smoking, religious affiliation, and alcohol consumption. More than half of all students report having had sexual intercourse, a rate comparable to the national average and only slightly higher than observed for schools similar with respect to race and size.

The data is drawn from the first round of a longitudinal survey that is commonly referred to as the Add Health Survey. Adolescents were asked if they were in or had been involved in a special romantic relationship at some point during the past 18 months (in the years 1993-1994). Adolescents in such relationships were asked to describe their three most recent relationships (including any current relationships). In addition, adolescents were asked to identify up to three individuals with whom they had a non-romantic sexual relationship in the past 18 months. A non-romantic sexual relationship was defined as a relationship involving sexual intercourse that the respondent did not identify as special and in which the partners did not kiss, hold hands, or say that they liked each other. A little less than one quarter of all Jefferson students reported no romantic or non-romantic sexual relationship.

Figure 1.16 presents the network of romantic and sexual relations among adolescents attending high school in Jefferson. The Figure maps the actual network structure that connects the 573 students involved in a romantic or sexual relationship with another student at Jefferson High. In this network, a node is a student, romantic or sexual relations are edges between the nodes.

The figure reveals a number of interesting facts. Recall from chapter 1, that a component is a subgraph of a network in which all nodes are reachable through paths from other nodes in the subgraph. A component is the natural object for the study of diffusion of diseases if infection can spread only via close contact. We note that dyads – two individuals whose only partnership is with each other – is relatively common (it occurs 63 times). Thus 126 students are involved in isolated dyadic relations. In addition a large number of other individuals have a single relationship but their partners have multiple partners. Triads composed of one male and two females occur 12 times, and triads composed of one female and two males occur 9 times. In all, 189 students at Jefferson (this is roughly 35% of the romantically active students) are involved in components containing three or fewer students.

Another striking feature of the network is the existence of a giant component involving 288 students, i.e., 52% of the romantically involved students at Jefferson. This giant component contains many individuals with multiple partners, it has short branches and a large diameter: the two most distant individuals are 37 steps apart. Interestingly, though

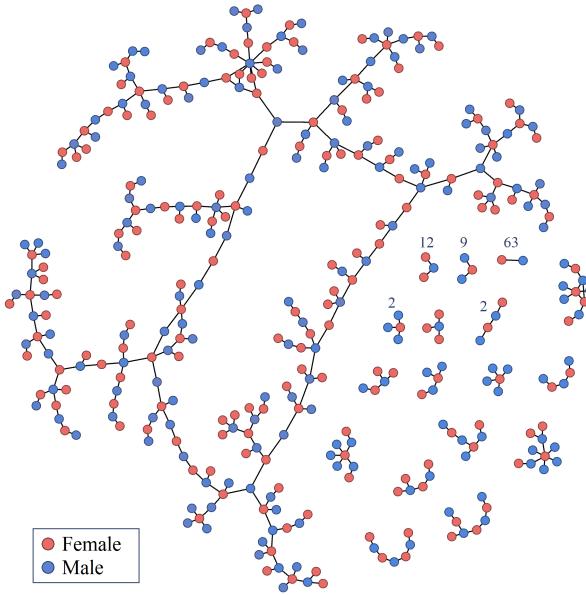

Figure 1.16: Romantic and Sexual Relations Network at ‘Jefferson School’ 1993-1994

perhaps not surprisingly, it contains no short cycles.

The romantic relations network has some striking properties — a large component size, the long paths, gender heterophily in links, and the absence of small cycles. In later chapters we will draw attention to the wide range of individual motives that shape linking behaviour and determine the architecture of social networks (chapters 2 and 3), and how the structure of the network shapes behaviour (chapter 4), and the spread of diseases (chapter 14).

### 1.3.5 Caste Networks in Rural India

We describe the social network in a village in the Indian state of Karnataka (in the year 2006). This data is taken from the large scale study conducted by Abhijit Banerjee, Arun Chandrashekhar, Esther Duflo and Matthew Jackson. The nodes in this network are 413 households. A link reflects a variety of social interactions, ranging across labour exchange, advice, monetary transfers, and exchange of daily necessities (such as cooking fuel). There were 1756 ties between these households. The mean degree was 8.50; hence the network is very sparse.

Let us examine the local features of the network next. There was significant overlap in neighbours: the clustering coefficient of the network was 0.40! This is very high, if we bear in mind that only 2.5% of the potential links were realized, suggesting that if links were

formed at random then clustering would be roughly 0.025. This suggests that there is a powerful driving force that shapes the social relations in this village.

To understand the drivers of link formation, we turn to the role of individual characteristics. In the Indian setting, caste is an important social category. It is therefore useful as a first step to categorize the village in terms of general groups based on legally defined categories of castes and tribes: Other Backward Caste, Scheduled Caste, Scheduled Tribe and General. Figure 1.17 presents the network of social relations in the village. We see that there is significant concentration of social relations within castes and tribes.

Table 1.8 presents the evidence on sub-caste based relations. There are four sub-caste categories covered: Other Backward Castes (OBC), Scheduled Caste (SC), Scheduled Tribe (ST) and General Castes (G). The Other Backward Caste and Scheduled Caste constitute 69% and 26% of the population.

We examine the distribution of links within and across links through the lens of caste based homophily. As an example, consider Scheduled Caste: they constitute 26% of the population, but 80% of their links within their own caste, yielding an inbreeding homophily ratio 0.73 for a definition of inbreeding homophily refer to the previous section). Similarly, we have a case of Scheduled Tribes: they constitute only 2% of the population of the village, but 31% of their social relations are with other Scheduled Tribe members, yielding an inbreeding homophily ratio of 0.30.

	Fraction	Nomination	Nom/Fraction
OBC	69	89	1.2
SC	26	80	3
ST	2	31	13
G	2	15	7

Table 1.8: Caste Homophily and Social Relations.

Favour exchange is an important element in these social relations. The strong imprint of caste in shaping the patterns of favour suggests that kinship based networks are important. These networks sustain cooperation and trust within the caste. But the sparsity of links across the castes raises the possibility that many possibly beneficial exchanges are not taking place. In later chapters, we will examine the role of network structure in shaping the magnitude and the patterns of cooperation. In that study we will also take up the question of how trust and cooperation at the level of a community scales up and how it related to generalized trust – the possibility of cooperation at a society level – and how such commu-

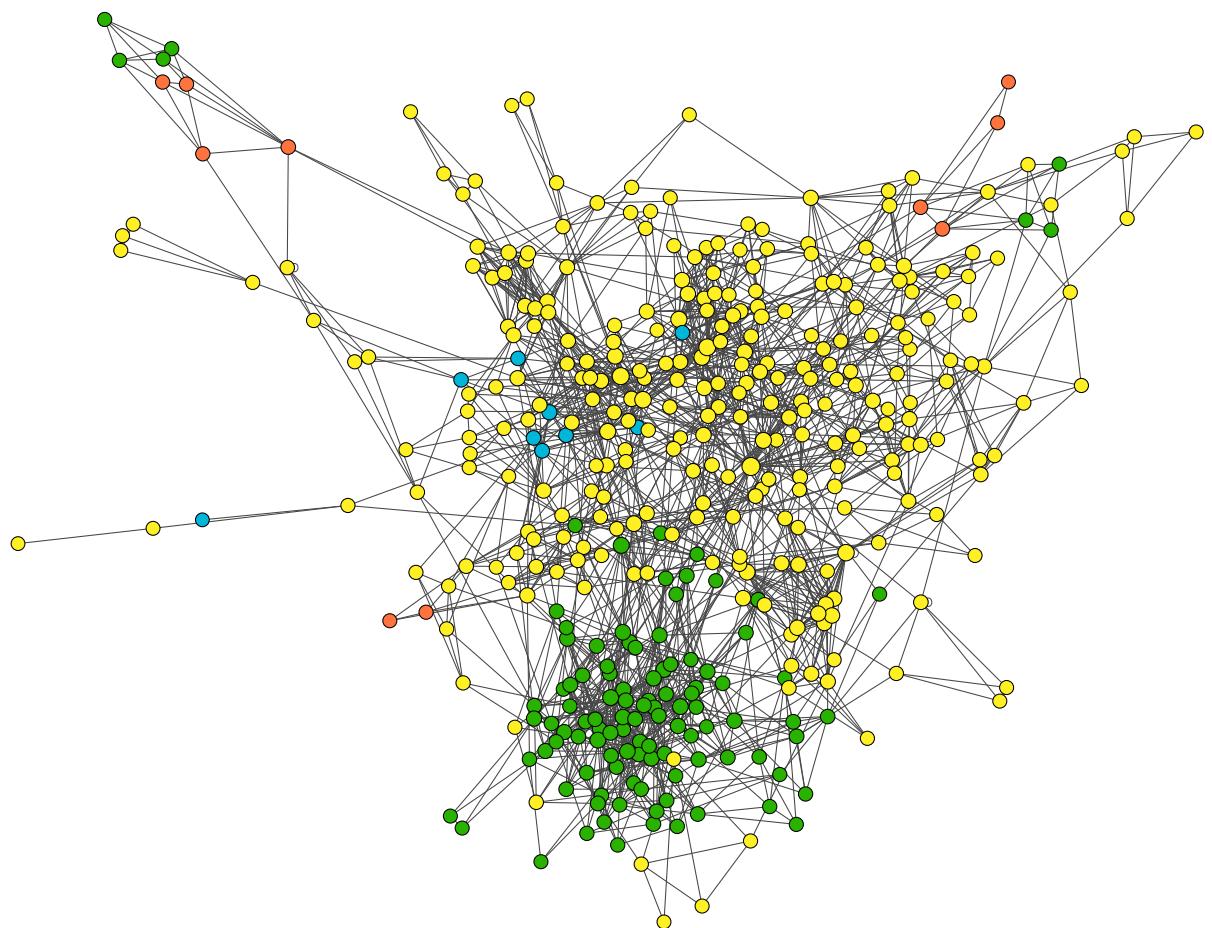

Figure 1.17: Networks in an Indian Village: 'Other Backward Castes' is in Yellow, 'Scheduled Caste' is in Green, 'Scheduled Tribe' is in Red, General is in Blue.

nities interact with other institutions like the market and the state to sustain high economic performance. These issues are examined in chapters 12, 17, 18 and 19.

### 1.3.6 Twitter

Twitter is an online information network that was established in July 2006. Twitter allows users to keep up to date with messages from other users, a relation which is referred to as ‘following’. If A is following B then tweets received by A from B can be passed on to their followers. In other words, a tweet may be ‘retweeted’. This creates the possibility of users spreading information of their choice beyond the neighborhood of the original tweeter, along the paths of the Twitter social network.

In a 2018 study conducted by the Pew Research Centre, Twitter had 321 million users (see Wojcik and Hughes [2019]). The median in-degree was 25, while the median out-degree was 89: the median out-degree is therefore much greater than the median in-degree (recall that in-degree of a node refers to the number of ‘followers’, while out-degree refers to the number of people he/she is ‘following’). This gives us a first sense for the imbalance in Twitter suggesting that in-degree distribution is very unequal as compared to the out-degrees distribution.

There are also very large differences in level of activity and they correlate strongly with the network structure. The top 10% of tweeters on average made 138 tweets, and these users were responsible for 80% of all tweets. In this set of highly active tweeters, the median in-degree was 387, while the median out-degree was 456. Users like Donald Trump, Barack Obama and Katy Perry had over 25 million followers. These statistics are in sharp contrast to the behaviour of the bottom 90% of tweeters. This last category made 2 tweets per month, their median in-degree was 19 and their median out-degree was 74.

As Twitter is used by individuals, firms, and governments to share ideas and information, we would like to understand how far does information travel on Twitter and how does it depend on the point at which it is first tweeted, what is the influence of different individuals and how is this influence related to the network of connections? Does the truth prevail or do mutually contradictory views persist over long periods of time in the network? What are optimal nodes to target to maximize influence or to minimize the spread of false information?

In later chapters, we will examine how such sparse and unequal networks emerge (chapters 2, 3, 11), what are their implications for the amount of information acquired (chapters 11), how they shape the spread of information (chapter 13), and how the structure of such a network can be used for more effective diffusion of ideas (chapter 15).

### 1.3.7 World Wide Web

The World Wide Web is network in which the basic units being connected are pieces of information and links join pieces of information that are related to each other in some fashion. Our discussion draws on Broder, Kumar, Maghoul, Raghavan, Rajagopalan, Stata, Tomkins, and Wienerca [2000], Kleinberg [1998] and Easley and Kleinberg [2010].

The World Wide Web was designed by Tim Berners-Lee during the period 1989-1991. At a basic level, the Web is an application developed for people to share information with each other over the Internet. There are two central elements to the Web. One, it provides a way to make documents – in the form of Web pages – easily available to anyone on the Internet. Two, it provides a way for others to easily access the Web pages, using a browser that could connect to the public spaces on computers across the Internet.

Web pages use ‘hypertext’. In writing a Web page, the web page designer can annotate any portion of the document with a virtual link to another Web page: this allows a reader to move directly from one page to another. The set of web pages thereby becomes a graph, and in fact a directed graph.

We now discuss two features of the network structure of the Web. The first feature pertains to the connectivity of the network. We shall say that a directed graph is *strongly connected* if there is a path from every node to every other node. When a directed graph is not strongly connected, it’s important to be able to identify which nodes are “reachable” from which others using directed paths. The key is to find the right notion of a “component” for directed graphs, and in fact one can do this with a definition that strictly mirrors the formal definition of a component in an undirected graph. We shall say that a strongly connected component (SCC) in a directed graph is a subset of the nodes such that one, every node in the subset has a path to every other, and two, the subset is not part of some larger set with the property that every node can reach every other.

With this background in network theory, we turn to the description of the network structure of the Web. Our description is based on a study of the Web in 1999 by Broder, Kumar, Maghoul, Raghavan, Rajagopalan, Stata, Tomkins, and Wienerca [2000], when the Web had been growing for about a decade. For their raw data, they used the index of pages and links from one of the largest commercial search engines at the time, AltaVista.

First we note that it is not possible for us to present a “map” of the Web given the scale and complexity of the network being analyzed. So we will take a more abstract high level perspective: we will divide the Web into a few large pieces, and then show how these pieces fit together. Figure 1.18 presents a plot of the network at this high level of abstraction.

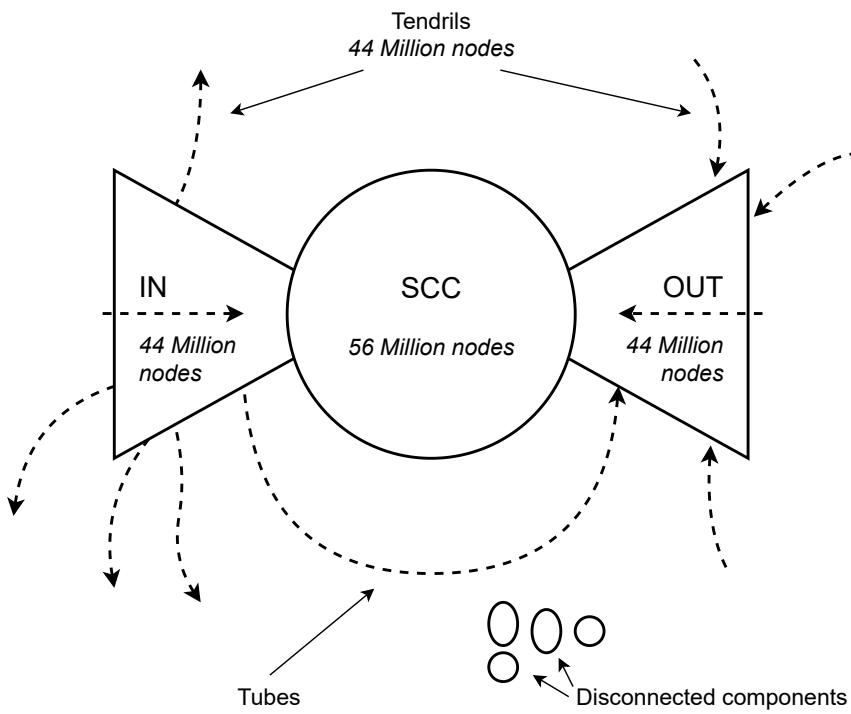

Figure 1.18: Architecture of the World Wide Web: based on Broder, Kumar, Maghoul, Raghavan, Rajagopalan, Stata, Tomkins, and Wienerca [2000]

The first observation is that the Web contains a giant strongly connected component. Let us discuss the constituents of this SCC. It consists of a number of major search engines and other “starting page” sites that have links leading to directory-type pages from which one can, in turn, reach the home pages of major educational institutions, large companies, and governmental agencies. From here one can reach most of the pages within each of these large sites. Further, many of the pages within these sites link back to the search engines and starting pages themselves. Thus, all these pages can mutually reach one another, and hence all belong to the same strongly connected component.

The second step is to position all the remaining SCCs in relation to the giant one. We consider groups of nodes in terms of ‘reachability’ from the SCC. There is a set of ‘IN’ nodes that can reach the giant SCC but cannot be reached from it. And there is a set of ‘OUT’ nodes that can be reached from the giant SCC but cannot reach it.

When we put the SCC and IN and OUT together, there is the visual effect of IN and OUT as large lobes hanging off the central SCC: these are the considerations that lie behind the ‘bow-tie picture’ of the Web in Figure 1.18.

There are nodes that do not lie in SCC or in IN or OUT. These nodes can be further classified as follows. There are the “tendrils” of the bow-tie that consist of (a) the nodes

reachable from IN that cannot reach the giant SCC, and (b) the nodes that can reach OUT but cannot be reached from the giant SCC. It is possible for a tendril node to satisfy both (a) and (b), in which case it forms part of a “tube” that travels from IN to OUT without touching the giant SCC. Finally, there are nodes that are disconnected: these are nodes that do not have a path to the giant SCC even if we ignore the directionality of the edges.

Thus we see that Web contains a central “core” containing many of its most prominent pages, with many other nodes that lie ‘upstream’, ‘downstream’, or “off to one side” relative to this core. It is important to keep in mind that the high level snap shot reveals an order that persists in spite of the extraordinarily dynamic nature of the Web. Every day people create pages and links and so, at the micro-level, the constituent pieces of the bow-tie are constantly shifting their boundaries, with nodes entering (and leaving) the giant SCC over time. But the aggregate or high level picture has remained essentially unchanged.

The fundamental function of the Web is that it allows information to be shared. A first thought would be that a Web page’s information is more shared in proportion to how many links point to it: i.e., its in-degree. Early studies suggest that the in-degrees are extremely unequal and that they follow a scale free distribution. Over the years a number of studies have been done with regard to the degree distribution: they suggest that both the high level bow-tie structure as well as the great inequality in connections are robust features of the World Wide Web.

Our description raises the question of how powerful or influential a Web page is relative to other Web pages. To understand questions like this, we need to dig deeper into the details of the Web’s network structure and to develop a theory of how information travels through a network. Our discussion on centrality measures in the previous section reveals that the power or influence of a node can be understood recursively in terms of the influence of the Web pages that point to it. In particular, traditional concepts from matrix algebra such as eigenvector centrality are closely related to the notion of Page Rank (PR), an algorithm used by Google Search to rank web pages in their search engine results. According to Google, ‘PageRank works by counting the number and quality of links to a page to determine a rough estimate of how important the web site is’.

These striking features of Web motivate a closer examination of the processes that lead to the bow-tie structure, the great inequality in links, and invite further study of the implications of such structures for information sharing and opinion formation. These questions are explored in chapters 2 and 3 (on the formation of networks) and in chapters 11 and 13 (that take up the generation and the flow of information in networks).

### 1.3.8 Scientific Collaboration: the case of co-authorship

Scientists collaborate to conduct research. Co-authorship is perhaps the most concrete form of this collaboration. This can have a profound effect on what questions that scientists study, how well informed they are and therefore what methods they use to conduct their research and most of all on how fast they make progress. These considerations motivate the study of coauthor networks. Our discussion draws on Goyal, Leij, and Moraga-González [2006a], Ductor, Fafchamps, Goyal, and Van der Leij [2014], and Ductor, Goyal, and Prummer [2021].

We discuss the network of co-authorships among economists over the ten year period, 2000-2009. The data is taken from ECONLIT, a publicly available data set. In this period, over 151, 000 authors published papers. The mean or average number of coauthors, 1.95, was very small, given the period of time – 10 years – and the number of potential coauthors. This is tiny compared to the total number of authors: our first observation is that this network was very sparse. The most connected 100 authors in this period had an average degree of 25: thus this is a very unequal network.

We turn to the local structure: the clustering coefficient was large: 0.17. To get a sense of why this is a very large figure, note that if coauthors were to be formed at random then the clustering ratio would correspond to the average number of co-authors divided by the total number of authors and this number is close to zero!

Next consider the macro level properties of the network, an interesting feature is that it is relatively well integrated. The largest component contained over 67,000 nodes (this is over 44% of all authors) with a mean distance of only 9.80. At first brush, this average distance should come as a surprise: if individual authors have 2 coauthors on average then an author will have 2 authors who are neighbours of neighbours and so forth. Thus the number of nodes reached only grows by a factor of 2 at every step. How can we reconcile the size of the largest component with its small average distance?

The key to understanding the puzzle is to recall the great difference in average or mean distance in a line and a star network. They have roughly the same average degree but very different mean distances. Indeed, in the economic coauthor network, there exist some very highly connected authors (as noted above). To see in the simplest way, suppose we were to delete 5% of authors at random: this has practically no impact on mean distance in the largest component. But the deletion of the 5% most connected authors completely fragments it. Thus the most connected authors span the research profession and hold it together. The figure of the local network of Mr Acemoglu in the previous chapter the local network of Jean Tirole from the 1990-1999 period presented in Figure 1.19 illustrate this

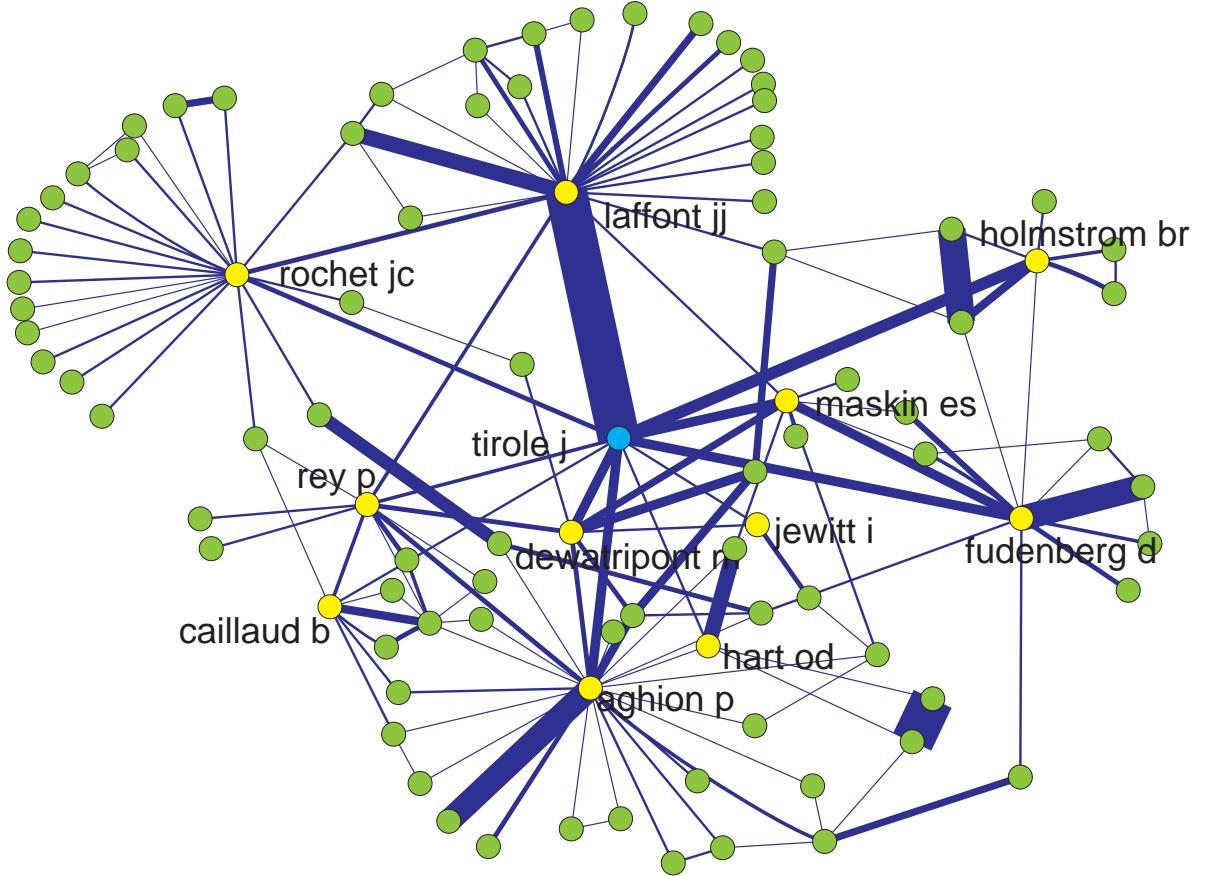

Figure 1.19: Local coauthor network of Jean Tirole, 1990-1999.

Note: The figure shows all authors within distance 2 of J. Tirole as well as the links between them. The width denotes the strength of a tie. Some economists might appear twice or are missing due to the use of different initials or misspellings in EconLit. The figure was created by software program *Pajek*.

point.

We may wonder if authors of different ethnicity or gender have very different modes of collaboration. Ductor, Goyal, and Prummer [2021] study the role of gender. They find that the economics coauthor network exhibits homophily along the lines of gender: on average, a male economist (a woman economist) coauthors more often with men (women) than their fraction in the population of economists. On average, 81% of men's collaborations are with other men; the fraction of men in the economists population 72%. Similarly, for women, on average 33% of their collaborations are with other women, while the ratio of women in the population is 27%. Perhaps more surprisingly, men and women differ in their degree and clustering: women have roughly 23% lower degree and a 6% higher clustering as compared to men. Figure 1.20 presents the networks of the 2019 Nobel Laureates in Economics – Abhijit Banerjee, Esther Duflo, and Michael Kremer – to illustrate this point (this corresponds to co-authorships over the years 2000-2009). Banerjee had a degree of 22

and clustering coefficient 0.09, Duflo had a degree 19 and clustering coefficient 0.14 and Kremer has degree 34 and clustering coefficient 0.04.

In later chapters we will enquire into how such unequal networks of collaboration and exchange emerge (chapters 2 and 3), what are their implications for individual productivity (chapter 4), and for the creation of norms and standards (chapter 18). We will pay special attention to the relation between networks and inequality.

## 1.4 Reading Notes

There are a number of excellent textbooks on networks. As networks are studied across many disciplines the books are written with different questions in mind. For books written from an economics perspective see Goyal [2007b], and Jackson [2008], and Vega-Redondo [2008]. Bramoullé, Galeotti, and Rogers [2016] provide a panoramic overview of the economics research on networks. For general introductions to the study of networks see Newman [2018] and Easley and Kleinberg [2010]. Networks have been studied in sociology for a very long time, see Burt [1994], Granovetter [1994], Smelser and Swedberg and Wasserman and Faust [1994]. For a mathematical treatment of graph theory see Bollobás [1998b] and Harary [1969]. For a perspective from physics see Barabási [2016] and Watts [1999], and for a computer science perspective see .

The material on network concepts in the chapter draws on Goyal [2007b], Jackson [2008], and the research papers by Katz [1953], Coleman [1958], Bonacich [1987], and Freeman [1979].

The study of personal influence starts with the classical work of Katz and Lazarsfeld [1966] and Lazarsfeld, Berelson, and Gaudet [1948]. For a engaging popular introduction to the subject of personal influence in social networks see Gladwell [2006]. The data on Twitter is drawn from Wojcik and Hughes [2019]. The picture on the Twitter's Millionaire Club is taken from <https://towardsdatascience.com/>.

There is a sizable literature on the structure and the functioning of the World Wide Web and large social media like Twitter. Our description of the Web drew heavily on the seminal empirical study of Broder, Kumar, Maghoul, Raghavan, Rajagopalan, Stata, Tomkins, and Wienerca [2000]. Their study has since been replicated on other, larger, snapshots of the Web that include an early index of Google's search engine (Bharat, Chang, Henzinger, and Ruhl [2001]) and large research collections of Web pages Donato, Laura, Leonardi, and Millozzi [2007].

The study of input-output methods in economics can be traced back to the work of Wassily Leontief in the 1940s; for an overview of this work see Leontief [1941]. The recent

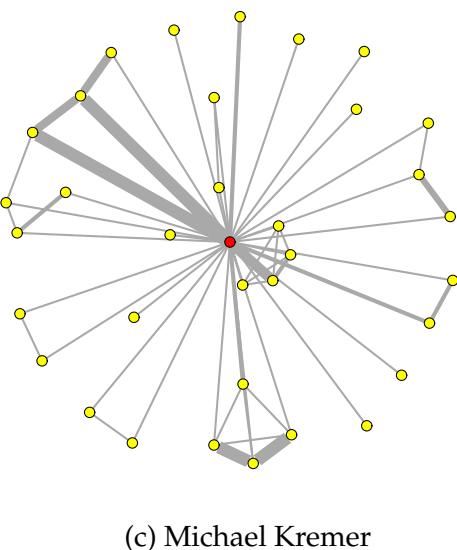

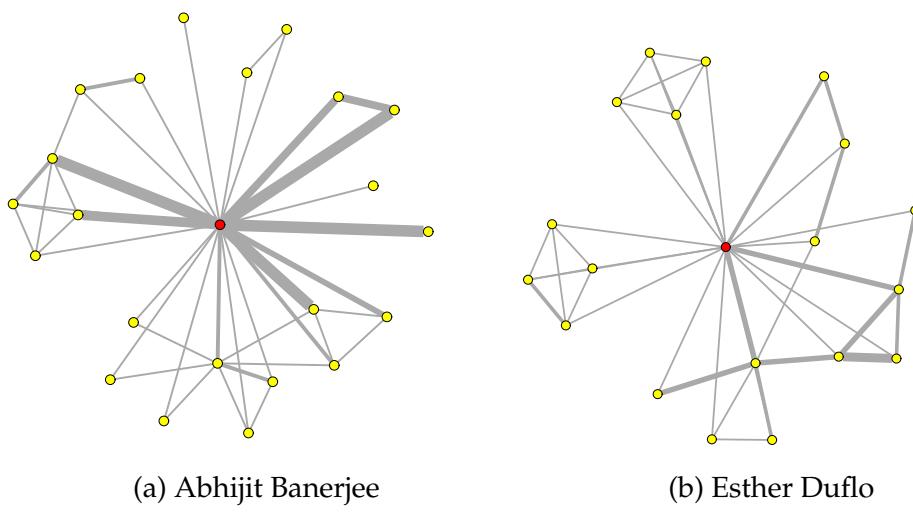

Figure 1.20: Gender and Networks, 2000-2009

revival of input-output networks is due to Long and Plosser [1983], and Acemoglu, Carvalho, Ozdaglar, and Tahbaz-Salehi [2012b]. The material on the US Production Network is taken from Carvalho [2014]. For an overview of the research on production networks see Carvalho and Tahbaz-Salehi [2019].

The study of the sociological aspects of the process of science and its production was pioneered by Robert Merton; for a collection of his essays on this subject see Merton [1973]. Scientific collaboration is a central element in the process of the production and the dissemination of knowledge. The material on co-authorship in economics is taken from Goyal, Moraga, and van der Leij [2006b] and follow up research by the authors. The findings on gender and collaboration are taken from recent work by Ductor, Goyal, and Prummer [2021].

The study of friendships as a social process may be traced to Lazarsfeld and Merton [1954] and Coleman [1958]. Our discussion on American high school friendships draws on Moody [2001]; the data reported here was kindly provided by James Moody.

Robert Fogel pioneered the quantitative study of the role of transport networks in economic growth, see Fogel [1964]. Transport networks and infrastructure are now widely studied in economics; for recent surveys see Donaldson [2015] and Redding and Rossi-Hansberg [2017]. For an early study of economic reasons for hub-spokes in airline networks see Hendricks, Piccione, and Tan [1995]. The data on airline networks is taken from <https://www.flightsfrom.com/top-100-airlines>. A well known early example of the urban grid has come down to us from the ancient city of Mohenjodaro in the Indus Valley Civilization. Our discussion on the urban grid draws on the studies of the urban plan of the city of Philadelphia in America. The map, "A Portraiture of the City of Philadelphia" by Thomas Holme, is taken from <https://explorephistory.com/>.

The study of caste has a long history, notable modern sociological works on caste include Beteille [1965], Beteille [1969], Srinivas [1987] and Mayer [1960]. The data on the caste networks in the Indian Villages of Karnataka is taken from research conducted by Abhijit Banerjee, Arun Chandrashekhar, Esther Duflo, and Matthew Jackson, and may be accessed from <https://economics.mit.edu/faculty/eduflo/social>.

The role of networks in economics analysis may be traced to papers written in the mid 1990s. The examples we present in the first section illustrate settings in which human activity takes place at the intersection of the local and the global. For a discussion of the methodological issues raised by such interactions and the introduction of graph theory in the toolkit of economists see Goyal [2016a] and Goyal [2017].

I am grateful to Ruohan Qin, Mikhail Safranov, Dilip Goyal, Bryony Reich, Ying Gao for helpful comments on earlier drafts of this chapter.

## 1.5 Questions

1. Prove the following facts about graphs:
  - (a) A connected tree with  $n$  nodes has exactly  $n - 1$  links.
  - (b) A leaf in a network is a node which has exactly one link. Show that in a tree there are at least two leaves.
  - (c) In a connected tree network there is a unique path between every pair of nodes.
2. Compute the mean degree and the variance in degrees of the networks presented in Figure 1.2.
3. Compute the average distance in the networks presented in Figures 1.1 and 1.2.
4. This question studies degree centralization of a network. Let  $i^*$  be the node with the highest degree – or equivalently degree centrality – in network  $g$ ,  $C_d(i^*; g)$ . The *degree centralization* of the network  $g$  is defined relative to the maximum attainable centralization:
 
$$C_d(g) = \frac{\sum_{i=1}^{i=n} [C_d(i^*; g) - C_d(i; g)]}{\max_{g \in \mathcal{G}} \left[ \sum_{i=1}^{i=n} [C_d(i^*; g) - C_d(i; g)] \right]} \quad (1.21)$$

(a) Show that the maximum possible centrality of a network is  $(n - 2)(n - 1)/(n - 1)$ . Substituting this in the denominator, the degree centralization of a network  $g$  is given by:

$$C_d(g) = \frac{\sum_{i=1}^{i=n} [C_d(i^*; g) - C_d(i; g)]}{(n - 2)} \quad (1.22)$$

(b) What is the degree centralization of a star and a regular network?
5. We define closeness centrality of a network as follows: Let  $i^*$  be the node that attains the highest closeness centrality across all nodes and let  $C_c(i^*; g)$  be this centrality. The centralization of a network is defined in terms of the difference between this maximum and the centralities of all nodes and we normalize the measure to make sure it lies between 0 and 1.
 

(a) Show that this leads us to define the *closeness centrality* of a network  $g$  as

$$C_c(g) = \frac{\sum_{i=1}^{i=n} [C_c(i^*; g) - C_c(i; g)]}{[(n - 2)(n - 1)] / (2n - 3)} \quad (1.23)$$

- (b) Show that the maximum closeness centrality value of 1 is attained by a star, while a cycle attains the minimum value of 0.
6. Consider a three node network in which there exist two links  $g_{12} = g_{23} = 1$ .
- (a) Leo Katz (1953) (A New Status Index Derived from Sociometric Analysis) defined prestige of node  $i$  in network  $g$

$$P_i^K(g) = \sum_{j \neq i} g_{ij} \frac{P_j^k(g)}{d_j(g)} \quad (1.24)$$

Let us set  $\hat{g}_{ij} = g_{ij}/d_j$  for every link, we can then write Katz's first prestige measure in matrix form as:

$$[I - \hat{g}]P^K(g) = 0, \quad (1.25)$$

where  $P^K$  is the  $n \times 1$  vector and  $I$  is the identity matrix. Calculate this prestige measure for the three nodes in our network and compare it to degree centrality.

- (b) Compute the closeness centrality of nodes 1, 2 and 3 in our network.
7. Define an independent set of nodes as a collection of nodes which have no links among them. Define a maximal independent set as a independent set that is not a strict subset of any independent set.
- (a) identify the maximal independent sets in a star network  
 (b) identify the maximal independent sets in a cycle network.
8. A node  $i$  is said to be critical for two nodes  $j$  and  $k$  in a network  $g$  if it lies on all paths between  $j$  and  $k$  in that network.
- (a) What are the critical nodes in a star network and a cycle network.  
 (b) Compute the betweenness centrality of nodes in the star and a cycle network.
9. Compute the degree centrality, closeness centrality, betweenness centrality, Katz First Prestige, eigenvector centrality, and Bonacich centrality for nodes in the network given in Figure 1.21.
10. Concerning Facebook: Try and learn about the structure of the Facebook network of friendships. Discuss similarities and differences between the Facebook and the Twitter network.

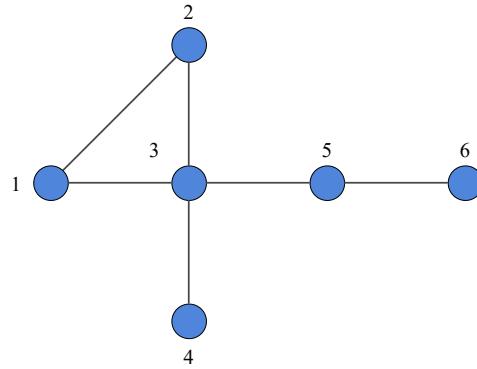

Figure 1.21: Network for centrality computations

11. The clustering coefficient for a node is given by  $Cl_i(g)$ . One way to define the clustering coefficient of a network  $g$  is as the “average” across nodes.

$$Cl_u(g) = \frac{1}{n} \sum_{i=1}^n Cl_i(g). \quad (1.26)$$

Alternatively, we can directly look at the fraction of potential triads which are actually present in the network. Define weighted or overall clustering in a network  $g$  as:

$$Cl_w(g) = \frac{\sum_{i:j \neq i; k \neq j; k \neq i} g_{ij}g_{ik}g_{jk}}{g_{ij}g_{ik}}. \quad (1.27)$$

Compare the average and weighted clustering coefficient in a network when clustering is increasing and decreasing in degree, respectively.

# Chapter 2: Random Origins

## 2.1 Introduction

The introductory chapter introduced a number of network measures and used them to understand prominent real world networks. In this chapter we will begin our journey of understanding how networks form. We will start with the building blocks of networks, the nodes and the linking protocols that connect them, and we will see how varying these protocols gives rise to different degree distributions, connectivity levels, distances and clustering.

We will start with a presentation of a basic model: there are  $n$  nodes and there is a (identical and independent) probability  $p$  that a link forms between any pair of nodes. In the literature this is known as the *Erdos-Renyi model* of random graphs. Observe that for a fixed  $n$  and  $p$ , as links are random, a wide range of networks, ranging from the empty all the way to the complete, can arise with positive probability. An important insight of the research with this model is that as we raise  $n$  and adjust  $p$  in such a manner so as to keep  $np$  unchanged, the structure of the resulting networks acquires a very definite pattern: the degrees in the resulting network exhibit the Poisson distribution. There is a threshold value of  $np$ : above this threshold the resulting network is connected and below the threshold it is not connected. This threshold draws attention to a general theme in network formation: small changes in underlying conditions can lead to dramatic changes in the structure of networks. We then discuss properties of this network such as average distances and clustering. We introduce homophily in this model by defining groups and specifying different probability of linking within and across groups. This richer model is known as the *stochastic block model*.

This model of random graphs is simple and the properties are intuitive. However, as we saw in chapter 1, the degree distribution of empirical networks is often highly skewed and is better approximated by a power law (and therefore is quite unlike the Poisson distribution). This leads us to consider models of growing networks in which nodes arrive over time and a new node links with existing nodes in proportion to the number of its links,

giving rise to a rich-get-richer property. In the literature this is known as the *preferential attachment model*. We derive the degree distributions generated by preferential attachment and develop conditions under which they exhibit a power law.

The Erdos-Renyi random graph model and the preferential attachment model give rise to specific degree distributions. From a theoretical point as well as for empirical purposes it would be helpful to have a random graph model that accommodates general degree distributions. This is the motivation behind the construction of the *configuration model*. We present this model and discuss associated network properties.

As we noted in chapter 1, a distinctive feature of social networks is that they exhibit short path lengths *and* significant clustering: our friends are also often friends of each other. The economics coauthor network discussed in the previous chapter is one such example, but there are many other examples. The Poisson graphs and the networks based on the preferential attachment process generate small distances but they exhibit negligible clustering. We next turn to networks that are able to accommodate both these properties. The approach is to start with an initial network of  $n$  nodes arranged around a cycle, which are connected to their nearest two neighbors to either side. So there are  $2n$  links in all. The diameter is  $n/2$  while the clustering coefficient is  $1/2$ . The key idea is a ‘rewiring’ of links: with a very small probability  $p$ , a link is reoriented away from a neighbour to someone picked at random from the rest of the network. As we move across links, due to the small  $p$ , only a very small fraction of the links are actually rewired. Thus the clustering remains virtually unchanged. However, the few links that are reordered do reduce average distance greatly, as a link to someone across the cycle significantly lowers the length of a very large number of paths. Thus the rewiring generates a sparse network with small diameter and also high clustering. In the literature this is known as the *small-worlds model*.

The preferential attachment model delivers skewed degree distributions but fails to account for clustering, while the small world model provides an account for clustering but exhibits relatively uniform degrees. The chapter concludes with a model of a growing network in which a new node comes creates new links through two routes – random linking with older existing nodes and linking with contacts of these nodes. The possibility of linking based on connections of others gives rise to both a power law degree distribution and to significant clustering. In the literature this is known as the *network based linking model*.

## 2.2 Erdos-Renyi Graphs

This section introduces the Erdos-Renyi model of random graphs and studies some of its main properties. There are  $n$  nodes and there is an equal probability,  $p \in [0, 1]$ , for a

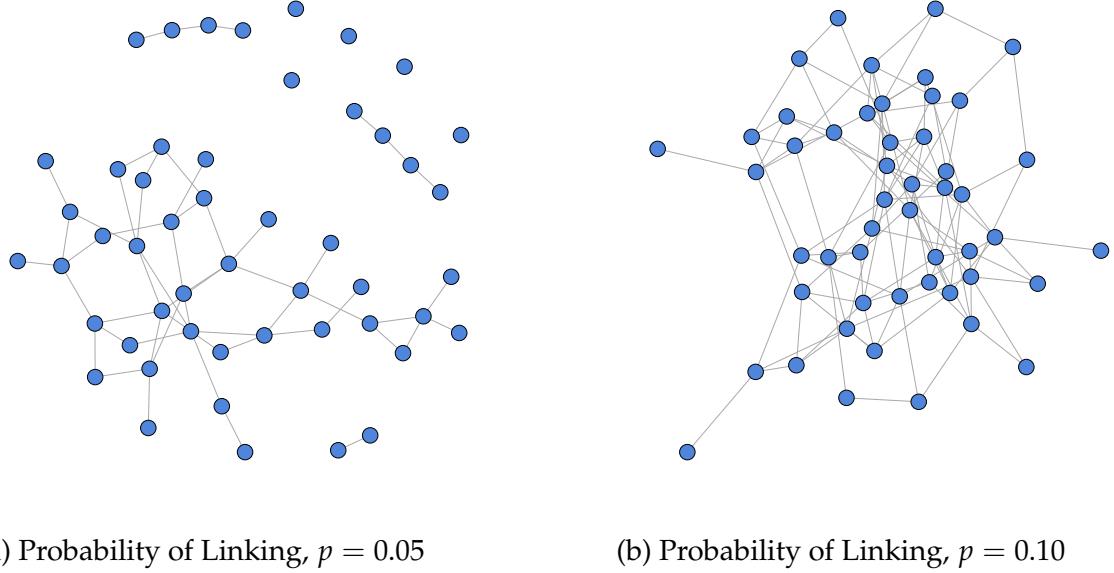

Figure 2.1: Random Graphs with 50 Nodes

link between any two nodes. What is the structure of the network: for instance, what is the distribution of connections, are most nodes in the network connected? What is the distance between the nodes? It will turn out that answers to these questions can be formulated in terms of the relation between the two parameters  $p$  and  $n$ . The model and the principal results in this section originate in the work of Solomonoff and Rapoport [1951], Erdős and Rényi [1959], Erdos and Rényi [1960] and Erdős and Rényi [1961]. Our presentation in this section draws on Bollobás [2004], Bollobás [1998a], Jackson [2008] and Newman [2018].

To get a first impression of this model let us consider a few examples of Erdos-Renyi graphs. Figure 2.1 plots graphs with 50 nodes with the probability of linking being given by  $p = 0.05$  and  $p = 0.10$ , respectively. In the graph on the left there are multiple components and the largest group of connected nodes – the so called giant component – is relatively small. By contrast, the graph on the right is connected – i.e., it contains only one component. This brings out the point that raising the probability of linking from 0.05 to 0.10 can have powerful effects on the connectivity of the graph.

Let us next consider the thought experiment in which the probability of linking is kept constant, but the number of nodes is raised. Fix  $p = 0.05$ . As the number of nodes increases from 25 to 50 to 100, the expected degree ( $np$ ), grows (roughly) from 1.25 to 2.5 to 5. This leads to a progressively more integrated network and also suggests that as we increase the nodes of nodes  $n$ , a smaller value of  $p$  would suffice to ensure the connectivity of the network. Figure 2.2 plots the three random graphs corresponding to this exercise. The

figure shows how, for a fixed probability of links,  $p$ , raising the number of nodes raises the average number of connections of every node and therefore enhances the connectivity of the network as a whole.

Turning to the higher level – macroscopic – properties of the network, consider the probability that a network has  $k$  links: recall that the probability of a single link is  $p$  and all links are ‘independent’: so the probability of a specific set of  $k$  links is  $p^k(1-p)^{\frac{n(n-1)}{2}-k}$ . There are in all  $n(n-1)/2$  links possible, so the probability of  $k$  links in a network with  $n$  nodes may be written as:

$$\frac{(n(n-1)/2)!}{(n(n-1)/2-k)!k!} p^k (1-p)^{\frac{n(n-1)}{2}-k} \quad (2.1)$$

Fix a node  $i$ , there are  $n-1$  other nodes; so, the probability that a node  $i$  has degree  $k$  is

$$P(k) = \frac{(n-1)!}{(n-1-k)!k!} p^k (1-p)^{n-1-k} \quad (2.2)$$

For fixed  $n$  and  $p$  any network – ranging from the empty to the complete network – has a positive probability of being realized. Perhaps the key insight of the Erdos-Renyi approach is that the structure of the network can be very sharply identified when we consider a large number of nodes.

**Degree Distribution:** Suppose that the number of nodes gets very large and the average degree remains finite. The simplest way to do this is to suppose that  $np$  is a fixed number. Suppose  $pn = \lambda$ . Then it is possible to write the probability that a node has  $k$  links as follows:

$$\begin{aligned} \lim_{n \rightarrow \infty} P(k) &= \lim_{n \rightarrow \infty} \frac{n!}{(n-k)!k!} \left(\frac{\lambda}{n}\right)^k \left(1 - \frac{\lambda}{n}\right)^{n-k-1} \\ &= \lim_{n \rightarrow \infty} \frac{n!}{(n-k)!k!} \left(\frac{\lambda}{n}\right)^k \left(1 - \frac{\lambda}{n}\right)^n \left(1 - \frac{\lambda}{n}\right)^{-k-1} \\ &= \lim_{n \rightarrow \infty} \frac{n}{n} \frac{n-1}{n} \dots \frac{n-k+1}{n} \left(\frac{\lambda^k}{k!}\right) \left(1 - \frac{\lambda}{n}\right)^n \left(1 - \frac{\lambda}{n}\right)^{-k-1} \\ &= \frac{e^{-\lambda} \lambda^k}{k!} \end{aligned}$$

Here we are using  $n$  and  $k$  instead of  $n-1$  and  $k-1$ ; for large  $n$  the difference is immaterial. This formula corresponds to the well known Poisson distribution. A property of the Poisson degree distribution that is worth noting is that the probability of degrees drops off sharply as we move away from the mean. Figure 2.3 illustrates the Poisson degree distribution for  $n = 50$  and probability of linking given by  $p = 0.05$  and  $p = 0.10$ .

**Connectivity:** We next discuss the relationship between the number of nodes  $n$ , the probability of linking  $p$ , and the connectedness of the network. It is worth keeping the examples

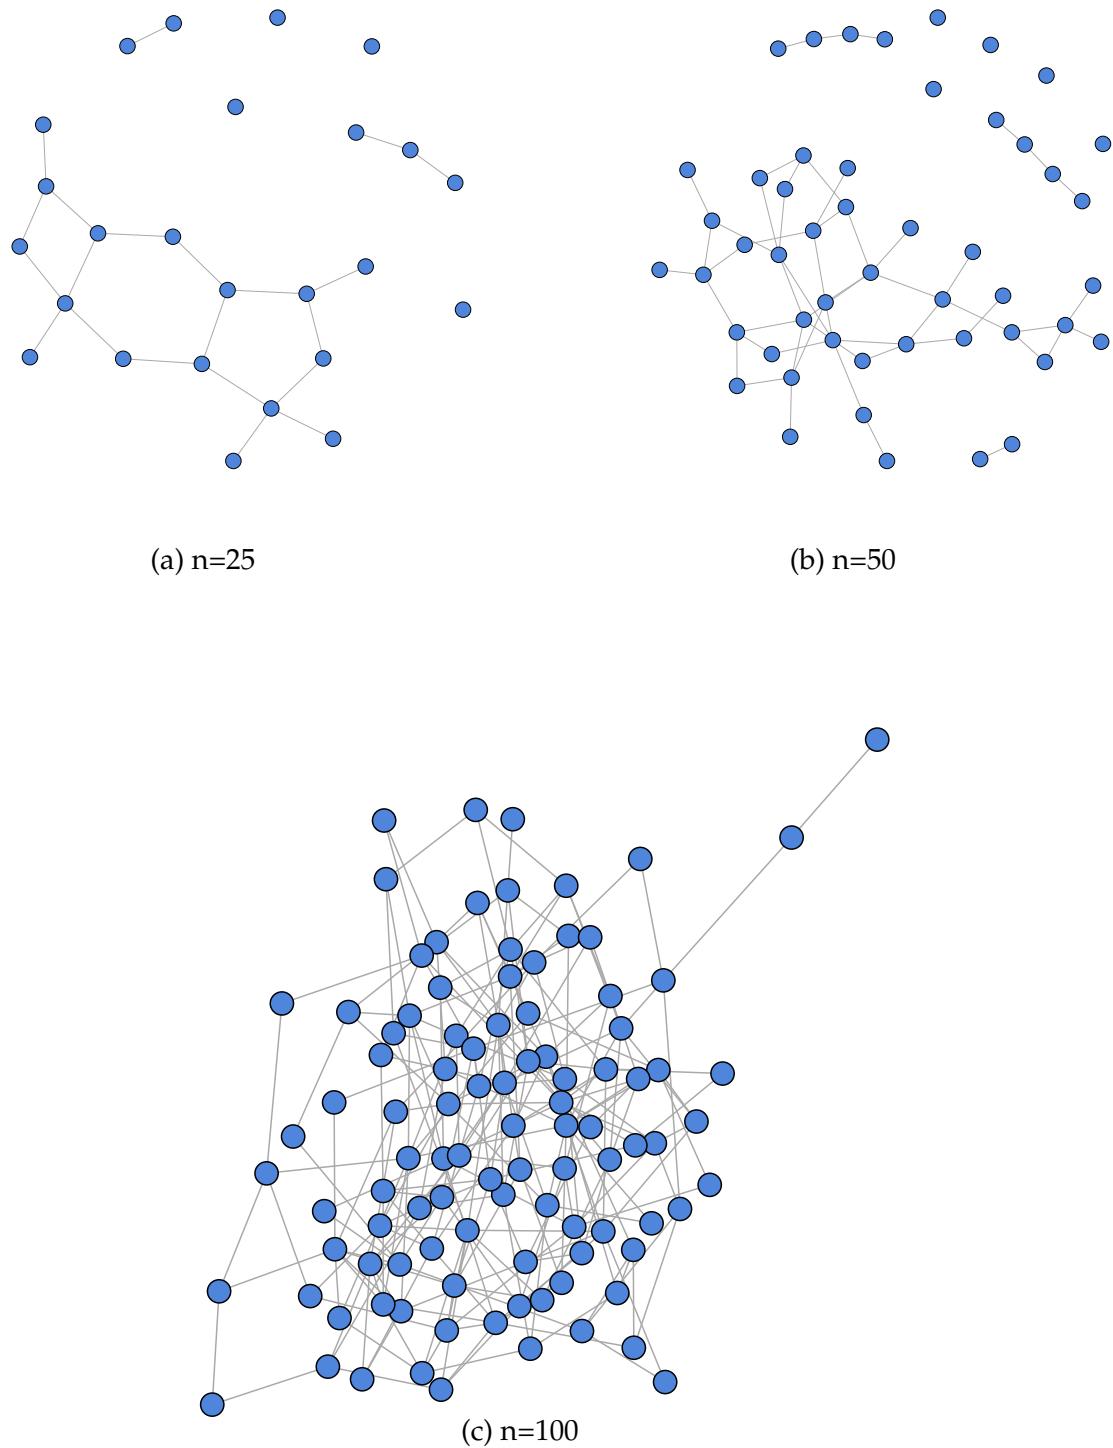

Figure 2.2: Random Graphs with  $p = 0.05$ .

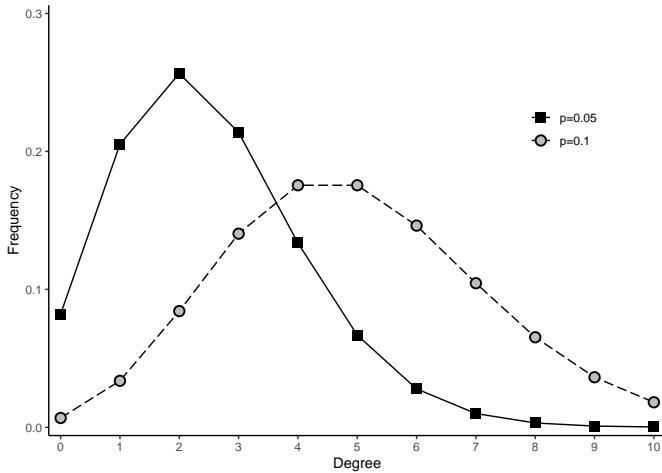

Figure 2.3: Degree Distribution with 50 nodes

above in mind as we move forward. A key building block in the analysis is the concept of *threshold function*. As we vary  $p$  and  $n$  we would like to ask if connectedness holds. The examples illustrated in Figure 2.2 suggest that as we increase  $n$  connectedness would be possible for lower  $p$ . With this idea in mind let us define the probability of linking as a function of the number of nodes,  $p(n)$ . Our aim is to understand if there is some property of  $p(n)$ 's that generates connected and disconnected networks, respectively. Let  $A(N)$  be the set of networks that exhibit a property – e.g., particular nodes have some number of links or connectedness of the graph as a whole. A threshold function for this property,  $A(N)$ , is a function  $t(n)$  such that

$$\Pr[A(N)|p(n)] \rightarrow 1 \text{ if } \frac{p(n)}{t(n)} \rightarrow \infty$$

$$\Pr[A(N)|p(n)] \rightarrow 0 \text{ if } \frac{p(n)}{t(n)} \rightarrow 0$$

If such a function exists then we shall say that there occurs a phase transition at the threshold: the qualitative properties of the networks generated undergo a marked transformation when we move from slightly below to slightly above the threshold. In principle, the threshold will differ as we examine different properties of graphs.

To develop a feel for threshold functions, let us take up the property that node 1 has at least one link. In this case  $A(N) = \{g|d_1(g) \geq 1\}$ . In the Poisson graph with  $n$  nodes, the probability that node 1 has zero links is  $(1-p)^{n-1}$ . Thus the probability that  $A(N)$  holds is  $1 - (1-p)^{n-1}$ . How does this probability vary as we move across  $p(n)$ : for what functions

is this probability equal to 1 and equal to 0, respectively? Let us consider the function

$$t(n) = \frac{r}{n-1}. \quad (2.3)$$

Recalling a standard definition of the exponential function (for some number  $x$ ,  $\lim_{n \rightarrow \infty} (1 + x/n)^n = e^x$ ), it follows that

$$\lim_n (1 - t(n))^{n-1} = \lim_n \left(1 - \frac{r}{n-1}\right)^{n-1} = e^{-r}. \quad (2.4)$$

Thus if  $p(n)$  is proportional to  $1/(n-1)$  then the probability that node 1 has one or more links lies between 0 and 1. We will build on this observation to show that  $t(n) = 1/n$  is a threshold function. Consider  $p(n)/t(n) \rightarrow \infty$ : this means that  $p(n) \geq r/(n-1)$ , for any  $r$  and large enough  $n$ . From equation (2.4), it then follows that  $\lim_n (1 - p(n))^{n-1} \leq e^{-r}$ , for every  $r$ , implying that  $\lim_n (1 - p(n))^{n-1} = 0$ . Similarly, we can verify that for  $p(n) < 1/(n-1)$ , the  $\lim_n (1 - p(n))^{n-1} = 1$ . In other words,  $t(n) = 1/(n-1)$  is a threshold function for the property that node 1 has one or more links.

We now develop the threshold function for connectedness. For a network to be connected it must contain no isolated nodes. In a Poisson degree distribution, the probability a node has degree 0 is approximately  $e^{-(n-1)p}$ . In case one node is isolated the fraction of isolated nodes is  $1/n$ . Equating the two yields us:  $e^{-(n-1)p} = 1/n$ . Taking logs on both sides, we obtain:

$$-(n-1)p = \log\left(\frac{1}{n}\right) \quad (2.5)$$

When  $(n-1)p > \log n$ , the fraction of degree zero nodes becomes small, while for  $(n-1)p < \log n$ , the fraction of degree zero nodes becomes large. The function  $(\log n)/n$  is thus a threshold. The probability of linking  $p$  must decline roughly in line with this threshold as  $n$  grows. For any function  $p$  of  $n$  that remains above the threshold the network will contain no isolated nodes, and for any function  $p$  of  $n$  that lies below this threshold, the network will contain many isolated nodes.

For connectedness to obtain, not only must isolated notes not exist, but there must also be no distinct components. As we scale up the number of nodes, a component with any fixed number of nodes becomes like a single node. Thus the above argument on isolated nodes can be extended to cover finite sized components. Finally, consider the possibility of multiple components that grow with the network. As the network scales up, two components each with an unbounded number of nodes cannot be sustained, as the sheer number of outgoing links in each component makes the probability of the 2 components being un-

connected negligible. So the probability of no links across the component will go to 0. This discussion is summarized in a celebrated result that we can now state.

**Proposition 2.1.** *Consider the Poisson random graph model. The function  $(\log n)/n$  represents a threshold for the connectedness of the network: for  $p$  that lies above this threshold the network is connected, and for  $p$  below this threshold the network is disconnected with probability 1.*

As the reasoning underlying this result is the basis of a number of key results in the theory of random graphs, we now provide a proof.

*Proof.* There are two steps in the proof. In the first step we will consider the existence of isolated nodes: clearly, for a network to be connected it must contain no isolated nodes. We will show that the postulated threshold suffices to rule out isolated nodes. The second step will take up components of size 2 until  $n/2$  and we will show that for probability  $p(n)$  respecting the threshold, the expected number of such components goes to zero for large  $n$ .

Step 1: In a network with  $n$  nodes and with a probability  $p(n)$  of a link, the probability that a node forms no links is given by  $(1 - p(n))^{n-1}$ . As  $p(n)$  becomes progressively small and goes to 0 in large  $n$ , this probability of zero links is approximately equal to  $(1 - p(n))^n$ . Moreover, as  $p(n)/n \rightarrow 0$ , we can approximate the probability by  $e^{-np(n)}$ . In developing the threshold result, we will work with the function  $p(n) = \frac{\log(n) - f(n)}{n}$ , where  $f(n) \rightarrow \infty$  and  $f(n) < \log n$ . With this functional specification, the probability of zero links is given by  $e^{f(n)}/n$ . The expected number of isolated nodes is simply  $e^{f(n)}$ . This grows without bound in  $n$ . We build on this observation to establish that the required property of the postulated function  $\log(n)/n$ .

Let  $X^n$  denote the (random) number of isolated nodes. Let  $\mu^n = E[X^n]$ . We show that the variance of  $X^n$ ,  $E[(X^n)^2] - E[X^n]^2$  is at most twice as large as  $\mu^n$ . Observe that the expected number of isolated ordered pairs,  $E[X^n(X^n - 1)]$ , is given by  $n(n - 1)(1 - p)^{2n-3}$ : this corresponds to the absence of links from each of the pair to all others and the link between the pair themselves. We may write  $E[X^n(X^n - 1)] = E[(X^n)^2] - E[(X^n)]$ . With this in hand,

$$\begin{aligned}
E[(X^n)^2] - E[X^n]^2 &= n(n-1)(1-p)^{2n-3} + E[X^n] - E[X^n]^2 \\
&= n(n-1)(1-p)^{2n-3} + E[X^n] - n^2(1-p)^{2n-2} \\
&\leq E[X^n] + pn^2(1-p)^{2n-3} \\
&= E[X^n](1 + pn(1-p)^{n-2}) \\
&\leq E[X^n] \left(1 + (\log(n) - f(n))e^{-\log(n)+f(n)}(1-p)^{-2}\right) \\
&\leq E[X^n].
\end{aligned}$$

We use this upper bound along with Chebyshev's inequality. Recall that Chebyshev's inequality says: for a random variable  $X$ , with mean  $\mu$  and standard deviation  $\sigma$ ,  $Pr[|X - \mu| > r\sigma] < \frac{1}{r^2}$ , for every  $r$ . In particular, from the above derivation of upper bound on the variance of  $X^n$ , relative to  $\mu$ , it follows that

$$Pr[X^n < \mu - r\sqrt{2\mu}] < \frac{1}{r^2} \quad (2.6)$$

for all  $r > 0$ . As  $\mu \rightarrow \infty$ , this implies that the probability  $X^n$  will be arbitrarily large converges to 1, as  $n$  grows. In other words, most networks will lie close to networks with unbounded number of isolated nodes. To complete the proof of step 1, with regard to the threshold for isolated nodes, we need to show that if  $p(n)/t(n) \rightarrow \infty$  then the probability of isolated nodes goes to 0, as  $n$  grows. Take a function  $p(n) = (\log(n) + f(n))/n$ , where  $f(n) \rightarrow \infty$ , but  $f(n)/n \rightarrow 0$ . We now construct a variant of the argument above to show that the expected number of isolated nodes grows as  $e^{-f(n)}$ , with  $n$ . This expectation tends to 0 with  $n$ . This can only happen if the probability of at least one isolated node tends to 0 in  $n$ . This completes step one of the proof.

Step 2: The second step of the proof shows that the expected number of components of size 2 to  $n/2$  converges to zero close to the postulated threshold function. Let us say that  $X_k$  is the number of components of size  $k$ . Let  $p(n) = (\log(n) + f(n))/n$ , where as before  $f(n) \rightarrow \infty$  and  $f(n)/n \rightarrow 0$ .

$$\begin{aligned}
E \left[ \sum_{k=2}^{n/2} X_k \right] &\leq \sum_{k=2}^{n/2} \binom{n}{k} (1-p)^{k(n-k)} \\
&= \sum_{k=2}^{n^{3/4}} \binom{n}{k} (1-p)^{k(n-k)} + \sum_{n^{3/4}}^{n/2} \binom{n}{k} (1-p)^{k(n-k)} \\
&\leq \sum_{k=2}^{n^{3/4}} \left( \frac{en}{k} \right)^k e^{-knp} e^{k^2 p} + \sum_{n^{3/4}}^{n/2} \left( \frac{en}{k} \right)^k e^{-knp} e^{k^2 p} \\
&\leq \sum_{k=2}^{n^{3/4}} e^{k(1-f(n))} k^{-k} e^{2k^2 \log(n)/n} + \sum_{n^{3/4}}^{n/2} \left( \frac{en}{k} \right)^k e^{-knp/2} \\
&\leq 3e^{-f(n)} + n^{-\frac{n^{3/4}}{5}}.
\end{aligned}$$

The first inequality holds because we abstract from the probability of links within the components. The second inequality holds because of Sterling's inequality ( $\binom{n}{k} \leq (en/k)^k$ ). The third inequality holds because, for  $k \in [n^{3/4}, n/2]$ ,  $k^2 p \leq knp/2$  (and therefore  $e^{-knp} e^{k^2 p} \leq e^{-knp/2}$ ), and because  $e^{k^2 p} = e^{k^2 \frac{\log(n)+f(n)}{n}} \leq e^{k^2 \frac{\log(n)+\log(n)}{n}}$ .  $\square$

■

**Distances and Diameter:** In many contexts of interest – spread of information or disease is one example – we are interested in how far nodes are from each other. One way to get a sense of distances in a network is to measure the diameter of the graph. Recall, from chapter 1, that the diameter of a (connected) graph is the largest (geodesic) distance across all pairs of nodes.

Our interest is in large networks and we consider the case where  $pn$  is a constant, so that  $p$  declines with  $n$ . To develop a sense for diameters in such a graph, it is then helpful to imagine a sparse network in which most nodes have similar degrees. With these remarks in place, we study diameter in a tree network in which every node has exactly  $d$  degree or degree 1. Furthermore, to make the computation simpler, suppose that there is a root node that is exactly distance  $\ell$  from all the leaves. Start from this root node  $i$ . Each of its neighbours has  $d$  links. This suggests that there are  $d + d(d - 1)$  nodes within distance 2 of node  $i$ . Extrapolating, we see that there will be

$$d + d(d - 1) + d(d - 1)^2 + \dots + d(d - 1)^{k-1} \quad (2.7)$$

nodes within distance  $k$  of root node  $i$ . Simplifying,

$$d \left[ \frac{(d-1)^k - 1}{d-1-1} \right] = \frac{d}{d-2} ((d-1)^k - 1) \quad (2.8)$$

So it follows that if we want to cover  $n-1$  nodes, it would suffice to have an  $\ell$  neighbourhood, where  $\ell$  solves the equation:

$$\frac{d}{d-2} ((d-1)^\ell - 1) \geq n-1 \quad (2.9)$$

To get an approximate diameter in a tree network, we can solve for  $(d-1)^\ell = n-1$ . Taking logs on both sides, it follows that  $\ell$  is of order  $\log(n-1)/\log(d-1)$ . The diameter is at most  $2\ell$ . The key point to note is that the diameter grows very slowly as  $n$  grows. To see this consider a few examples. Suppose the degree of every node is 11. The diameter for a network with 1000 nodes is 6, for a network with 100,000 nodes it is 10.

**Homophily:** In chapter 1 we discussed social networks of friendships in an American High School and favour exchange among households in Indian villages. We noted there that a distinctive feature of these networks was homophily: the tendency of individuals to form links with others of their own ‘type’. Depending on the context, the type would correspond to gender, year, race, or caste. In the Erdos-Renyi model, the probability of linking is the same between every pair of individuals. We now extend the basic model to illustrate how it can accommodate homophily. A simple way to think of homophily in the Erdos-Renyi model is to suppose that there are many groups – and that the probability of a link between two individuals within a group is different from the probability of a link between two individuals in different groups. Let there be  $M$  groups and suppose that the probability of linking within group  $i$  is given by  $p_{ii} \in [0, 1]$ , while the probability of a link between two individuals belonging to groups  $i$  and  $j$  is given by  $p_{ij} \in [0, 1]$ . These different probabilities define a random graph and we can study the properties of the resulting random graphs. This is referred to as the *stochastic block model*.

A special case is one where  $p_{ii} = p_s$ , while  $p_{ij} = p_d$ , where  $p_s > p_d$ . Figure 2.4 illustrates network formation in a society with 50 individuals that is constituted of two equal size groups, Blue and Red. In the top panel, on the left we have a uniform Erdos-Renyi graph, with average degree 4. On the right we have a graph in which the probability within the group is .15, while the probability of linking across groups is 0.03. The two graphs have a similar average degree but the differential probabilities of linking create strong homophily effects. In the bottom panel, on the left we have a uniform Erdos-Renyi graph with average

degree 8. On the right we have a graph in which the probability within the group is .30, while the probability of linking across groups is 0.01. The average degree in the two networks is the same, and again we see that the density of links is significantly higher within each group as compared to pairs of individuals across groups.

The Erdos-Renyi random graph model is probably the most widely studied model of networks. The reason for its popularity is that it is easy to present and it provides us insights into the most fundamental questions concerning networks: the determinants of the degree distribution, the connectivity, and the diameter of the graph. A major attraction of the model is that the methods of analysis are transparent and prove useful when we go beyond the basic model and study variations. The block random model provides one illustration of this flexibility. At many points in this book – when we study diffusion and epidemics, games on networks, and network interventions – we will return to this model.

While the model is theoretically very attractive, from an empirical point of view it has some serious weaknesses. One problem is that for large graphs, the network will display *negligible* clustering – observe that since link probability is independent across pairs of nodes, the clustering will be of the order of probability of linking and this probability gets close to zero in large graphs (it is of order  $\lambda/n$ ). To get a sense of the numbers let us reexamine economics coauthor networks. Table 1 (based on Goyal, Leij, and Moraga-González [2006a]) presents some aspects of the economics coauthor network through the period 1970-2010. We see that, in the 2000-2010 decade, average degree is around 2: if links were formed at random the clustering would be equal to the probability of a link and that would be tiny (smaller than 0.001). However, the clustering coefficient in the empirical network is 0.17. This is a general feature of social networks: they exhibit very large clustering relative to what would arise in the Erdos-Renyi network with a similar mean degree.

The random graph also differs from real world networks in one other critical dimension – the degree distribution. Table 1 gives us a first sense of this discrepancy: the average degree at 2 is very small, but the variance around 6.75 is much larger. In a Poisson random graph, the variance would be around 2. Thus the variance is greatly in excess of what a Poisson graph would generate. Let us examine the degree distribution in a little more detail. Figure 2.5 plots the empirical degree distribution alongside the Poisson plot (for a comparable average degree). We see that the empirical degree distribution has many more low degree and high degree nodes, as compared to the corresponding Poisson network. These differences between the Poisson graph and empirical networks motivate the study of alternative models of networks. We first turn to models that can address the issue of skewed distributions.

## 2.3 Preferential Attachment

The empirical study of skewed distributions originates with the Italian sociologist and economist, Vilfredo Pareto. Pareto found that across a range of countries the distribution of income and wealth is very unequal. Skewed distributions have also been documented in a number of other contexts – such as the size of cities, the size of firms, the number of coauthors (see discussion above), and the citations of scientific papers. These skewed distributions are sometimes described as exhibiting a power law or being scale-free. The wide occurrence of these distributions encourages us to think of a general mechanism that may be at work.

The theoretical study of the mechanisms underlying skewed distributions may be traced back to an early paper by Simon [1955]. This rich-get-richer story is central to the study of processes leading to power laws. The existence of power law degrees in networks was first noted in the context of citation networks by de Solla Price [1965]. Motivated by this empirical finding de Solla Price proposed a theoretical model that was built on the rich-get-richer mechanism identified by Simon [1955]. In subsequent work, this mechanism has been termed *preferential attachment* by Barabási and Albert [1999]. We will first present the directed link model from de Solla Price [1976] and then we will present the undirected link model from Barabási and Albert [1999]. The exposition in this section draws on Easley and Kleinberg [2010], Newman [2010], and Jackson [2008].

In the early 2000's a number of researchers drew attention to the following fact about the distribution of hyper-links on the World Wide Web: the fraction of web pages that have  $k$  links is approximately proportional to  $k^{-2}$  (see e.g., Broder et al. [2000]). As the fraction varies in proportion to  $k^{-2}$ , the degree distribution was said to contain a *power-law*. More generally, the fraction of nodes with degree  $k$ , is given by  $P(k) = a/k^c$ , for some positive constants  $a$  and  $c$ . If we take logs on both sides, we get the following equation:

$$\log P(k) = \log a - c \log k. \quad (2.10)$$

Expressed this way, we see that the (log of) probability is a linear function of the (log of) degree. Thus the rate of fall in probability is independent of the degree, giving rise to the terminology 'scale-free distribution'. Given any empirical degree distribution, it is then possible to ask what is the value of  $a$  and  $c$  that offers the best fit. The interest is mainly in the value of  $c$  – sometime referred to as the Pareto coefficient or the power law coefficient – as  $a$  is mostly used for purposes of normalization.

Figure 2.6 presents the degree distribution plots in the production network of four

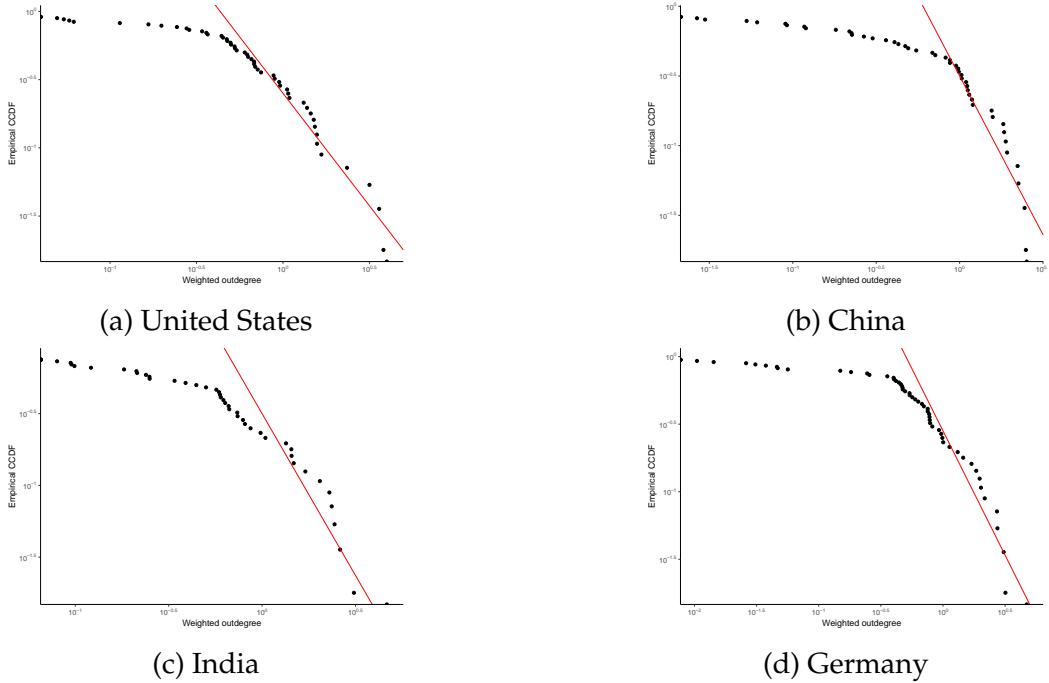

Figure 2.6: Production Networks Degree Distribution (2014): data from World Input-Output Database ([www.wiod.org](http://www.wiod.org))

economies – United States, China, India, and Germany (the Pareto coefficients of the fitted curves are 1.65, 2.28, 2.25 and 1.84, respectively). These plots draw attention to the magnitude of the power law coefficients: they often lie in the range  $2 \leq c \leq 3$ , with occasional values slightly outside this interval. A second general point to bear in mind is that the empirical distribution does not generally follow the power law over its entire range. For example, in Figure 2.6, the power law distribution provides a good fit for the higher degrees, but not for the lower degrees. In this book, in line with common practice, we will say that a degree distribution follows a power law if the empirical degrees match the function for high degrees above some cut-off.

**de Solla Price [1976]’s model of directed linking:** Suppose that links are directed. By way of motivation, think of the process of linking on the World Wide Web: pages are created at regular intervals and numbered 1,2,3.... When page  $j$  is created, it creates a link to an existing web page. With probability  $p$  the link is created at random with one of the existing nodes and with probability  $1 - p$  the page  $j$  picks a node  $i$  at random but then forms a link with the page that  $i$  is linked to. The linking based on copying gives rise to a ‘rich-get-richer’ dynamic: in this case, the probability of linking with a page  $\ell$  is directly proportional to the number of incoming links of  $\ell$ . So, we can rephrase the copying

part of the linking process as follows: with probability  $1 - p$ , page  $j$  chooses a page  $\ell$  with probability that is proportional to  $\ell$ 's current incoming links. This is the essence of the preferential attachment: currently highly connected nodes are likely to receive more new links.

If we run this process for many pages, the fraction of pages with  $k$  incoming links will be distributed approximately according to a power law  $1/k^c$ , where the value of the exponent  $c$  depends in an intuitively plausible way on the choice of  $p$ . As  $p$  becomes smaller, most of the linking is driven by the copying element, and this means that the rich-get richer element gets correspondingly stronger. The result establishes that lower  $p$  leads to a smaller value of  $c$  and that means that pages with very high degrees becomes more likely. We now present the details of this process and explicitly compute the value of the coefficient  $c$  as a function of  $p$ .

Let  $d_i(t)$  be the links of node  $i$  at time  $t$ . The new link to page  $i$  can therefore arise in two ways: one, the new page picks page  $i$  at random, and two, the new page picks a page  $j$  and then links with  $i$  because  $j$  is linked to  $i$ . Observe that it is the second route that creates the rich-gets-richer pressure, as the probability of  $j$  being linked to  $i$  is greater the more links  $i$  has. These two routes to an additional link for  $i$  are captured in the following formula:

$$\frac{p}{t} + (1 - p) \frac{d_i(t)}{t}$$

In principle, there is uncertainty in the growth of links of nodes, as the links are probabilistic, but we can get a good understanding of the process by considering a simpler deterministic analogue. To write out and solve the deterministic process we need to specify the starting point and the rate of change over time. Let us say that at the start every node has in-degree 0. With regard to the rate of change, we write it as equal to the expected change in incoming links.

$$\frac{d}{dt} d_i(t) = \frac{p}{t} + (1 - p) \frac{d_i(t)}{t}$$

Dividing both sides by  $p + (1 - p)d_i$  we get

$$\frac{1}{p + (1 - p)d_i} \frac{d}{dt} d_i = \frac{1}{t}$$

Integrating both sides and rearranging terms we arrive at

$$\log(p + (1 - p)d_i) = (1 - p)\log t + c$$

where  $c$  is some constant. Taking exponents on both sides and setting  $A = e^c$ , we get

$$p + (1 - p)d_i = At^q$$

The degree of node  $i$  at time  $t$  is then given by

$$d_i(t) = \frac{1}{1-p}(At^{1-p} - p).$$

Noting that  $d_i(i) = 0$ , we can obtain  $A = p/i^{1-p}$ . This allows us to rewrite  $d_i(t)$  as

$$d_i(t) = \frac{1}{1-p} \left[ p \left( \left( \frac{t}{i} \right)^{1-p} - 1 \right) \right]$$

Equipped with this formula we proceed and compute the fraction of nodes/pages that have degree more than  $k$ , at time  $t$ . Given a  $k$ , using the above formula it is possible to compute the point of entry of a node which has degree  $k$  at time  $t$ . Define this  $i$  as  $i_t(k)$ .

$$\frac{i_t(k)}{t} = \left[ \frac{1-p}{p}k + \frac{1}{p} \right]^{-1/(1-p)}$$

Given the deterministic process of linking, the nodes with degree greater than  $k$  at time  $t$  are the nodes which were born before  $i_t(k)$ . This means the fraction of nodes with degree greater than  $k$  is

$$\left[ \frac{1-p}{p}k + \frac{1}{p} \right]^{-1/(1-p)}.$$

The (negative) of the derivative of this expression with respect to  $k$  gives us the frequency of degrees with in-degree  $k$ :

$$P(k) = \frac{1}{p} \left[ \frac{1-p}{p}k + \frac{1}{p} \right]^{-(1+1/(1-p))}$$

Our discussion may be summarized as follows:

**Proposition 2.2.** *In the preferential attachment model of linking, with a large number of nodes, the fraction of pages with in-degree  $k$  is proportional to  $k^{-(1+1/(1-p))}$ . This yields a power-law distribution with exponent  $1 + 1/(1 - p)$ .*

If  $p$  is close to 1, linking is mostly random, reinforcement is minimal, and the coefficient takes on very large values. This means that large in-degrees are very unlikely. On the other hand, if  $p$  is very small, the reinforcement aspect of linking is strong: the coefficient is close

to (but larger than) 2. Figures 2.7a to 2.7c illustrate networks with 50 nodes corresponding to three values of the exponent – 2.25, 2.5 and 3. Figure 2.7d plots the degree distributions of these networks. Observe also that as the coefficient increases from 2.25, to 2.5, to 3, the probability of higher degrees falls and this is reflected in the red curve being located above the blue curve which in turn is located above the green curve.

**Barabási and Albert [1999]’s model of undirected linking:** Let us now take up the undirected linking version of the preferential attachment model. Suppose that nodes are born at times  $i \in \{0, 1, \dots, t, \dots\}$  and form  $m$  links with distinct existing nodes when they enter. To keep matters simple assume that there are enough nodes at the start and with the same number of links. A new node forms links with an existing node with a probability that is proportional to its links (relative to the total links). Let  $d_i(t)$  be the links of node  $i$  at time  $t$ . Then the probability of a new link for node  $i$  at time  $t$  is given by

$$m \frac{d_i(t)}{\sum_j d_j(t)} \quad (2.11)$$

Since there are  $m$  links created by every  $i$ , it follows that at time  $t$  there are  $mt$  links in all and  $2mt$  degrees. So the probability may be written as:

$$\frac{d_i(t)}{2t}. \quad (2.12)$$

In principle, this is a stochastic process but, following the approach in physics, for tractability we will look at a mean field continuous time deterministic approximation in which the rate of change of degree is equated to this probability of change in degree. With this in mind, we write rate of change of degree as:

$$\frac{d}{dt} d_i(t) = \frac{d_i(t)}{2t}. \quad (2.13)$$

The differential equation with initial condition  $d_i(i) = m$  has the solution

$$d_i(t) = m \left( \frac{t}{i} \right)^{\frac{1}{2}}. \quad (2.14)$$

We can use the solution to explicitly derive the long run degree distribution. Given a  $d$ , we can compute the point of entry of a node which has degree  $d$  at time  $t$ , using the above formula. Define this  $i$  as  $i_t(d)$ .

$$\frac{i_t(d)}{t} = \left( \frac{m}{d} \right)^2 \quad (2.15)$$

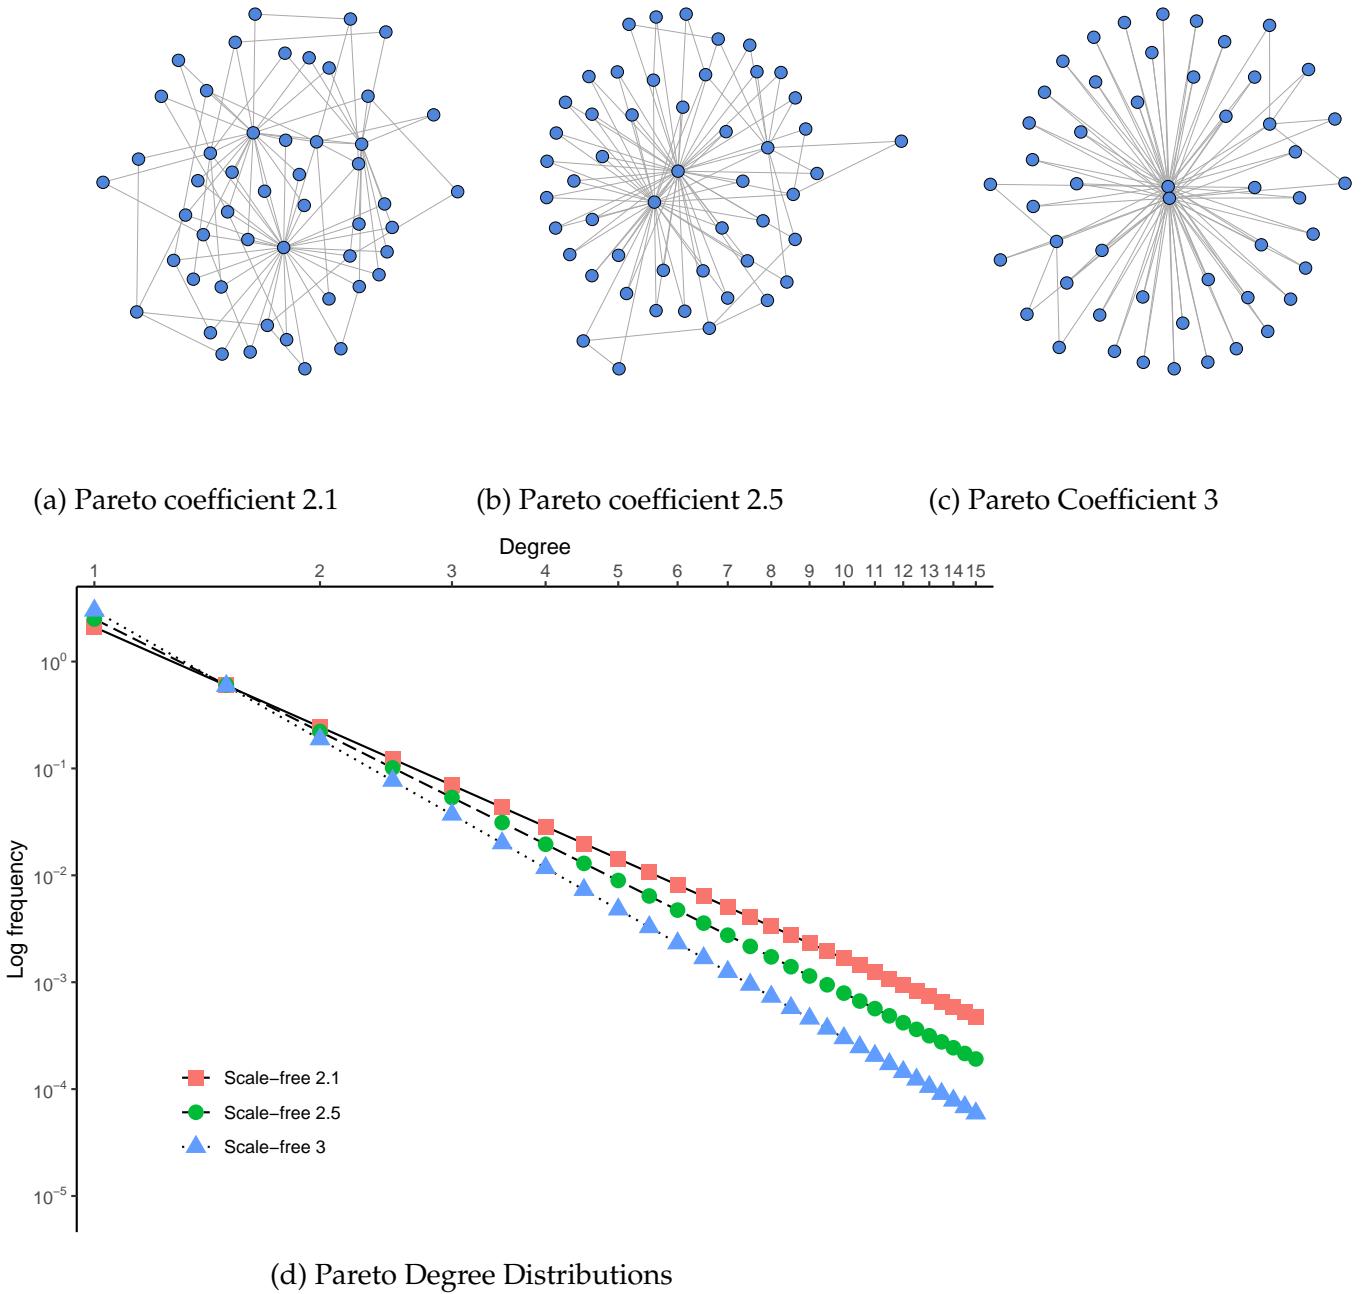

Figure 2.7: Networks with Preferential Attachment

The nodes with degree greater than  $d$  at time  $t$  are simply the nodes which were born before  $i_t(d)$ . This means the fraction of nodes with degree greater than  $d$  is  $(m/d)^2$ , which in turn means that the distribution function is

$$F(d) = 1 - m^2 d^{-2}. \quad (2.16)$$

The frequency of degrees is then simply the derivative and given by:

$$f(d) = 2m^2 d^{-3}. \quad (2.17)$$

The Barabasi-Albert model has a striking simplicity. However, from an empirical point of view, this model is somewhat restrictive as it yields an exact Pareto coefficient of 3. There are a number of directions in which the model has been extended. For instance, we can allow for multiple links being formed by new entering nodes, for the removal of edges, for non-linear preferential attachment, and for nodes being of varying quality. A formal treatment of these extensions is outside the scope of this book; the interested reader is referred to Newman [2018].

The central motivation for the preferential attachment model was the degree distribution. Let us examine the Pareto-coefficient more closely as it offers us a way to tune the degree distribution. A key feature of the degree distribution is the inequality in degrees. We now examine this issue of degree inequality through a study of dispersion in power law networks. Recall that the mean of a degree distribution  $P(d)$  is

$$\langle d \rangle = \sum_{d=1}^{\infty} d p_d \quad (2.18)$$

The second moment is the mean square:

$$\langle d^2 \rangle = \sum_{d=1}^{\infty} d^2 p_d \quad (2.19)$$

More generally, we may write the  $m^{th}$  moment

$$\langle d^m \rangle = \sum_{d=1}^{\infty} d^m p_d \quad (2.20)$$

Suppose the degree distribution obeys a power law with coefficient  $\alpha$  for degrees above  $d_{min}$ . Then we may write the expression for the  $m^{th}$  moment as:

$$\langle d^m \rangle = \sum_{d=1}^{d_{min}-1} d^m p_d + a \sum_{d=d_{min}}^{\infty} d^{m-c} \quad (2.21)$$

As the probability is slowly moving for large  $d$ , we can approximate the second term by an integral so that

$$\langle d^m \rangle = \sum_{d=1}^{d_{min}-1} d^m p_d + a \int_{d=d_{min}}^{\infty} d^{m-c} dd \quad (2.22)$$

$$= \sum_{d=1}^{d_{min}-1} d^m p_d + \frac{a}{m-c+1} [d^{m-c+1}]_{d_{min}}^{\infty} \quad (2.23)$$

The first term is a finite number whose value depends on the (possibly non-power law) probability distribution for low degrees. The second term depends on the values of  $m$  and  $c$ . If  $m - c + 1 < 0$  then the bracketed term has a finite value, if  $m - c + 1 > 0$  then the bracketed sum diverges. Thus  $\langle d^m \rangle$  is finite if and only if  $m + 1 < c$ . So for instance,  $\langle d^2 \rangle$  – the variance in degrees – will be bounded if and only if  $c > 3$ .

The *raison d'être* for the preferential attachment model is on providing a mechanism that can account for empirically observed power law degree distribution. The great power of the model in explaining power laws has led researchers to investigate other properties of the networks, such as connectivity, network diameter and clustering. In networks that exhibit a power law degree distribution, the presence of highly connected hubs brings nodes into closer proximity with each other, suggesting that the network is connected and the diameter is smaller than the diameter in a Poisson random graph with a similar average degree (especially for large networks). The clustering coefficient becomes negligible in large networks (though it declines at a slower rate with respect to number of nodes, as compared to the Poisson graph). The interested reader is referred to Barabási [2016] and Newman [2018] for a thorough study the properties of networks generated by the preferential attachment model.

## 2.4 The Configuration Model

The degree distribution is a very concrete property of a network. Interest in more general degree distributions – that go beyond the Poisson and the power law distributions – has grown with our expanding empirical knowledge of networks. In this section, we present a widely studied model – the configuration model. Early contributions to the study of the

configuration model include Molloy and Reed [1995], Newman, Strogatz, and Watts [2001] and Chung and Lu [2002b]. Our exposition in this section draws on Newman [2018] and Jackson [2008].

The configuration model may be seen as a model of a random graph with a given degree sequence. The exact degree of each individual node in the network is fixed. This in turn means that the number of edges is fixed. Given a sequence of degrees,  $d_1, d_2, \dots, d_n$ , the number of edges is  $m = \sum_{i=1}^n d_i / 2$ . Let us describe the mechanics of how the degree sequence is constructed.

Let us start with an arbitrary degree sequence  $d_1, \dots, d_n$  for the  $n$  nodes. We can create a random graph with this degree sequence as follows. Assign node  $i$ ,  $d_i$  stubs. There are thus a total of  $\sum_i d_i = 2m$  stubs. We choose two stubs at uniformly at random and connect them. We then take two more stubs from the remaining  $2m - 2$  stubs, and so forth. This yields a network in which every node has the degree that we started with. Moreover, as we move across possible matchings of stubs, we will traverse the different possible networks that are all consistent with the original degree sequence. The configuration model is then an ensemble of networks in which each matching of stubs obtains with equal probability. The uniform distribution over matchings has an important implication: each stub is equally likely to be matched with every other stub. This allows us to interpret the resulting network as being random and permits the analysis of a number of interesting questions such as the size of the giant component and its diameter.

There are a couple of technical issues in the construction that need to be noted. First, the network may contain self-edges (if two stubs from the same node are matched) or multiple edges (if multiple pairs of stubs from two nodes are matched). However, as the number of such self-edges and multiple edges are constant, as we raise the number of nodes they become progressively negligible, and can therefore be ignored when we take consider large populations. A final remark pertains to the specification of the model in terms of degree sequence: often our interest is in the degree distribution rather than the degree sequence. If we start with a degree distribution  $p_d$ , that we can compute the probability of a specific degree sequence  $\{d_i\}$  as  $\prod_i p_{d_i}$ . We can then use this definition to study the average value of objects of interest in the network ensemble with a degree distribution  $p_d$ .

The configuration model has attracted a great deal of attention over the past two decades. Due to space constraints, we will restrict ourselves to a discussion of diameter of general random graphs. For a systematic exploration of the configuration model the interested reader should refer to Newman [2010].

We build on the ideas proposed in Newman, Strogatz, and Watts [2001] and Chung and Lu [2002b], to provide approximate estimates for the diameter in general random graphs.

All through, for expositional simplicity, we will consider a tree network with degree distribution  $P(d)$  and mean  $\langle d \rangle$ . Suppose that the degrees of nodes are (at least approximately) independent (this is true in a Poisson random graph when  $n$  is large). How many degrees does a neighbour a node picked at random have?

To answer this question it is useful to consider the following related question: suppose that we randomly pick a link in the network, what is the degree of one of the ends of the link? Consider a simple example in which nodes have either degree 1 or degree 2 and the two degrees are equally likely, i.e.,  $P(1) = P(2) = 1/2$ . In case of 4 nodes, let the network  $g = \{g_{12}, g_{23}, g_{34}\}$ . If we randomly pick a link and then follow through a pick an end of the link, we will pick a node of degree 2 with probability  $2/3$  and a node of degree 1 with probability  $1/3$ . This is intuitive, as nodes with degree 2 are more present in links as compared to nodes with degree 1. Building on this argument, we say that for a network with degree distribution  $P(d)$ , if we were to pick a link at random and then look at the degree of an end of the link (picked with equal probability) the degree distribution of the node picked would be given by

$$\tilde{P}(d) = \frac{P(d)d}{\langle d \rangle} \quad (2.24)$$

This degree distribution is sometimes referred to as the *excess degree* distribution. Note that this excess degree distribution is a property of random graphs when the degrees of neighbours are independent: this means that the degree of the node at the other end does not depend on the degree of the initial starting node.

Applying this excess degree distribution, we may infer that the expected number of (new) neighbours of a neighbour is

$$\sum_d (d - 1)\tilde{P}(d) = \frac{\langle d^2 \rangle - \langle d \rangle}{\langle d \rangle}. \quad (2.25)$$

Before proceeding further, it is worth noting the slightly unexpected nature of this excess degree distribution and its implications. In particular, note that the expected degree of a neighbour is

$$\frac{\langle d^2 \rangle}{\langle d \rangle} \quad (2.26)$$

And the difference between the average neighbour degree and average degree in the network is

$$\frac{\langle d^2 \rangle}{\langle d \rangle} - \langle d \rangle = \frac{1}{\langle d \rangle}(\langle d^2 \rangle - \langle d \rangle^2) \quad (2.27)$$

Thus the average degree of a neighbour is larger than the average degree in the network, so long as there is a positive variance in degrees. This is known as the *friendship paradox*.

Building on (2.25) we can write the expected number of  $i$ 's second neighbours (i.e., the neighbours of neighbours of  $i$ ) is

$$\langle d \rangle \frac{\langle d^2 \rangle - \langle d \rangle}{\langle d \rangle}^2. \quad (2.28)$$

Reasoning as in the simple tree example above, as we reach outward from node  $i$  to distance  $\ell$  we cover

$$\sum_{k=1}^{\ell} \langle d \rangle \left[ \frac{\langle d^2 \rangle - \langle d \rangle}{\langle d \rangle} \right]^{k-1} = \langle d \rangle \left[ \frac{\left( \frac{\langle d^2 \rangle - \langle d \rangle}{\langle d \rangle} \right)^\ell - 1}{\left( \frac{\langle d^2 \rangle - \langle d \rangle}{\langle d \rangle} \right) - 1} \right] \quad (2.29)$$

To get an estimate of the diameter of the graph, we require a number  $\ell$  that covers  $n - 1$  nodes, i.e.,

$$\langle d \rangle \left[ \frac{\left( \frac{\langle d^2 \rangle - \langle d \rangle}{\langle d \rangle} \right)^\ell - 1}{\left( \frac{\langle d^2 \rangle - \langle d \rangle}{\langle d \rangle} \right) - 1} \right] = n - 1 \quad (2.30)$$

Taking logs and simplifying

$$\ell = \frac{\log[(n-1)(\langle d^2 \rangle - 2\langle d \rangle) + \langle d \rangle^2] - \log[\langle d \rangle^2]}{\log[\langle d^2 \rangle - \langle d \rangle] - \log[\langle d \rangle]} \quad (2.31)$$

Recall that in the Poisson degree distribution,  $\langle d^2 \rangle = \langle d \rangle + \langle d \rangle^2$ . we can then rewrite equation (2.31) as follows:

$$\ell = \frac{\log \left( (n-1) \frac{\langle d \rangle - 1}{\langle d \rangle} + 1 \right)}{\log[\langle d \rangle]} \quad (2.32)$$

We see that if expected degree is large, then the expression may be approximated by  $\ell = \log(n-1)/\log(\langle d \rangle)$ , which looks similar to our original derivation for the simplest case of a tree with a unique root. Thus if we abstract from cycles the ratio of logs of number of nodes and average degree offers a rough estimate of  $\ell$  (and also therefore the diameter). While these numbers are approximate, our discussion does suggest that in large random graphs the diameter is likely to be 'small'.

We conclude with the remark that, as in the Poisson random graph, clustering becomes

very small for large  $n$  in networks generated through a configuration model.

## 2.5 Small-World Networks

In the introductory chapter (and earlier on in this chapter) we discussed the network of economics co-authors. In addition to small average distance, the network exhibits a high clustering coefficient. The Poisson Random graph model and the preferential attachment model both generate small distances, but they exhibit negligible clustering. How can we reconcile high clustering and small distances?

To develop a sense of the difficulty of reconciling small path lengths and clustering consider the following simple example. Suppose everyone has 100 friends. As I have 100 friends, and each of my friends has 100 friends, if none of the friends overlap, I will have 10,000 distance 2 friends. Extrapolating on this, I would have 1 million distance 3 friends, and 100 million distance 4 friends. So short distances are natural in this world and indeed would be in any network with reasonable degree that is a tree. But in this example, observe that we are assuming that there is no overlap among friends – in other words no triangles. To see the impact of this assumption in its extreme form, suppose that all my friends are friends of each other. In that case, distance 2 friends will be the same as my immediate friends, as all the friends of my friends are also my friends. Indeed, the circle of friends of 100 will constitute a distinct (and disconnected) clique and will therefore have no paths to other cliques. In other words, the average distance between nodes in the network will be unbounded. While this is a very extreme example, it helps bring out the point that reconciling small average distance and high clustering may be challenging.

In a celebrated paper Watts and Strogatz [1998] proposed a resolution to this tension with the help of the following simple model. Their approach has an initial network of  $n$  nodes arranged around a cycle, which are connected to their nearest 2 neighbors to either side. So there are  $2n$  links in all. The degree distribution is perfectly equal: everyone has degree 4. The diameter in this network is (roughly)  $n/4$  (the average distance is (roughly)  $n/8$ ), and the clustering is  $1/2$ . Observe that as  $n$  grows, the diameter will grow too. The top left panel in Figure 2.8 illustrates this starting point.

The key idea is ‘rewiring’ of links: pick a link  $(A, B)$ , with a very small probability  $p$ , fix one side to node (say)  $A$ , and then pick a new partner selected at random from all other nodes. The surprising finding is that for low and modest values of  $p$ , the average distance falls very sharply, while the clustering remains high and stable.

To get a sense of the numbers here, suppose  $n = 25$ ; so there are a total of 50 links. Let us rewire 6 links; this leads us to the top right panel in Figure 2.8. An inspection of the

network suggests that the average distances have come down rather sharply. When we rewire all links, i.e.,  $p = 1$ , we arrive at the bottom left panel, a random network with very small average distances. Let us examine the changes a little more systematically.

The two objects of interest are the average path length  $L((p))$  and the clustering coefficient  $C(p)$ . Recall,  $L$  is defined as the number of edges in the shortest path between two vertices, averaged over all pairs of vertices. Recall also that the clustering coefficient  $C(p)$  is defined as follows. If a node  $v$  has  $k_v$  neighbours, then they can have at most  $k_v(k_v - 1)/2$  edges between them.  $C_v$  is the fraction of these edges that actually exist in the network. Define  $C(p)$  as the average of  $C_v$  over all  $v$ . The bottom right panel in Figure 2.8 presents a simulation of this thought experiment.

We see that there is a range of values for rewiring of links – ranging from 0.001 to 0.01 – where the average distance comes down sharply, while the clustering remains virtually unchanged. How can we account for this pattern? The intuition for this is that a large number of long paths are shortened through the relocation of a few links from short-range to far-range. Meanwhile, as only 6 out of 50 links are affected, most links remain as before and so the clustering is only marginally lowered. The first figure in the top-left is the original local interaction network with four neighbours. The final figure on the bottom right in Figure 2.8 presents a summary of simulation runs: on the x-axis I we vary the fraction of rewired links all the way from 0 to 1. The y-axis shows that there is a wide range of rewiring probability – ranging from .001 to .01 – for which clustering remains close to the original local interaction network, while the average distance falls precipitously relative to distance in the original network.

We may summarize our short discussion as follows: *The structure of small worlds: starting with a sparse graph on a cycle, the clustering remains stable for a broad range of rewiring probabilities, while the diameter comes down sharply with a small probability of rewiring.*

We conclude this section on a more general note by narrating the history of the idea of small worlds.

### 2.5.1 A brief history of the small-world idea

The origins of the idea may be traced to the Hungarian writer Frigyes Karinthy who wrote a short story called *Lancszemek*, in which two of the characters believed that any two individuals on Earth could be connected to each other through a chain of no more than five acquaintances (Karinthy [1929]). These literary origins were followed by academic research in the 1950's by Ithiel de Sola Pool and Manfred Kochen who wrote a paper titled "Contacts and Influence". The paper proposed a number of ideas relating to social networks and also

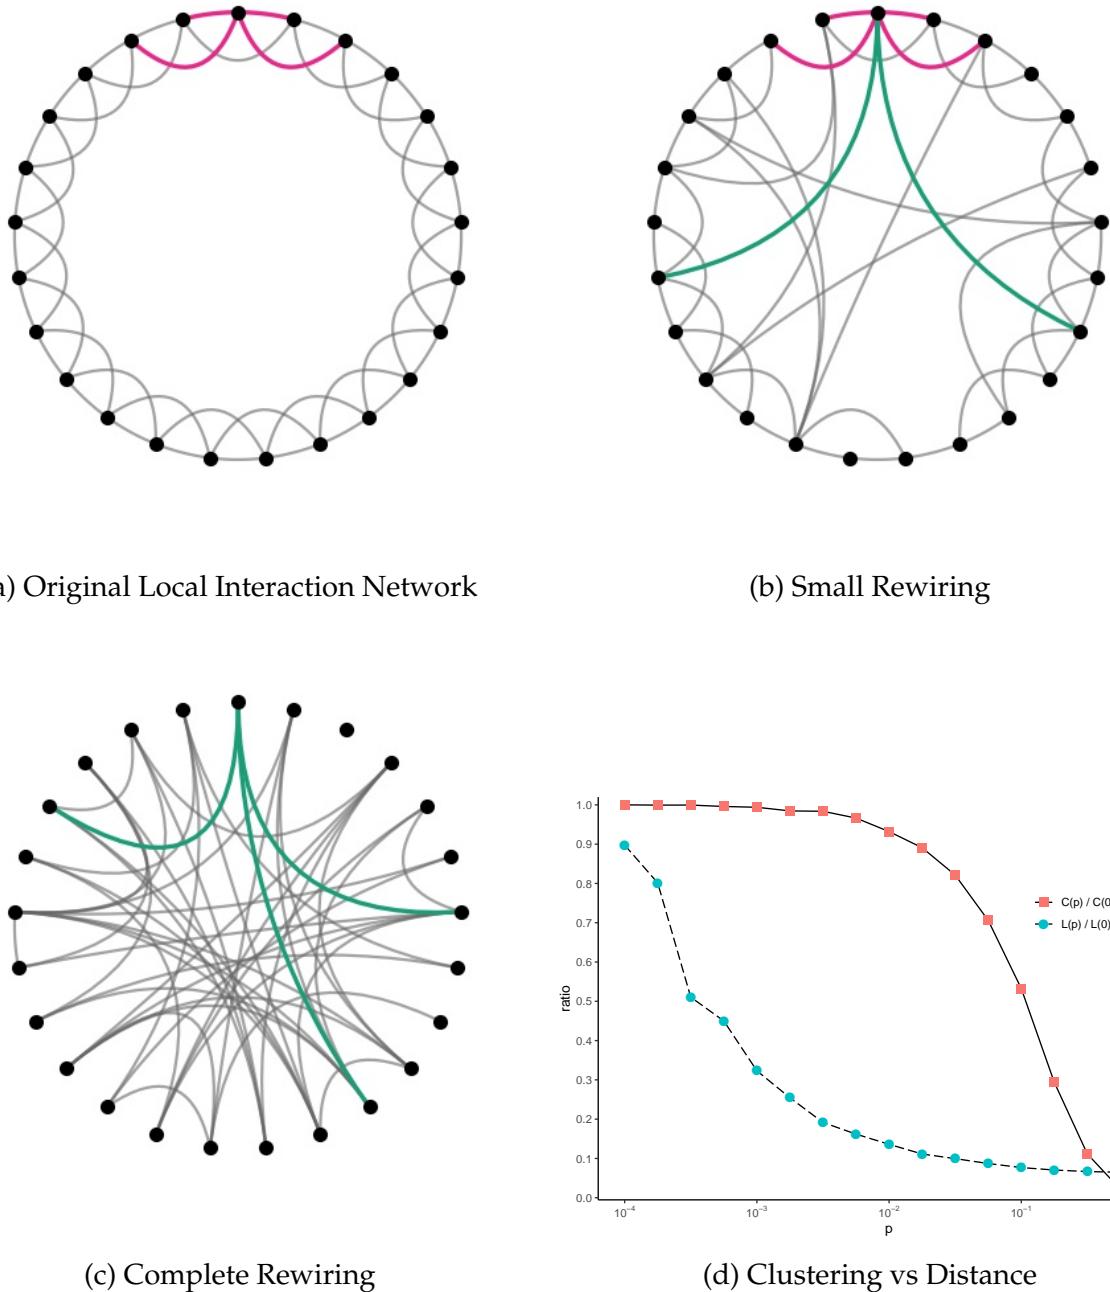

Figure 2.8: Links Rewiring and Small World Networks, based on Watts and Strogatz [1998].

discussed ways of quantifying the distance between people through chains of connections. The article eventually appeared as de Sola Pool and Kochen [1978-79] in the journal *Social Networks*.

The next major development were the experiments undertaken by the social psychologist, Stanley Milgram. In the first experiment, there were 296 randomly chosen starters, typically located in the American state of Nebraska. Each starter was asked to forward a letter to a ‘target’. The personal details of the target – the name and the address (a suburb of Boston, Massachusetts) and the profession (stockbroker) – were provided. The starter was asked to forward the letter to someone known on first name basis, so as to reach target as quickly as possible. The letter therefore passed through a chain of acquaintances until it arrived at target. In all, 64 letters (out of the 296) arrived at the target; the rest did not make it. The path lengths ranged from 1 to 11, with a median value of 6. In the Milgram study, the sample size was small and even within this small sample, the vast majority of the chains did not actually reach the target. These concerns have motivated a number of follow-up empirical studies on small world properties of social networks, see e.g. Dodds, Muhamad, and Watts [2003].

It is worth commenting on the relation between these small world experiments and the network models of small worlds. In the model of small worlds, there exist short paths between individuals that create the possibility of communication across the network using short paths. However, the problem posed in the original Milgram experiments (as well as the follow up experiments) asks an individual to find someone through chains in the network: this requires knowledge of where different people are located in a network. In other words, the Milgram problem is one of navigating a network to find someone whose whereabouts may or may not be known. Networks that have very short average distances may nevertheless may be difficult to navigate. For instance, consider a core-periphery network in which the large core is a clique and every member of the core is linked to a large number of individuals. The diameter in this network is 3, so the average distances are small. However, navigation may be difficult. Suppose every node knows the identity of their neighbours. Now suppose the origin and the target are both peripheral nodes and an individual can search through one link at a time. It could in principle take a very long time for a peripheral node to locate such an anonymous target. The navigation problem would be a lot simpler if the potential target had clear markers of identity and these markers were in turn highly correlated with the corresponding core node that they were linked to.

## 2.6 Network Based Linking

The preferential attachment model delivers skewed degree distributions but fails to account for clustering, while the small world model provides an account for clustering but exhibits relatively similar degrees. We now present a model of a growing network that combines features of preferential attachment with an additional feature – links are formed with neighbours of nodes found at random. This model generates networks with skewed degree distribution as well as significant clustering levels. Our presentation is based on Vazquez [2003] and Jackson and Rogers [2007].

Let us suppose that time proceeds in discrete steps,  $t = 1, 2, 3, \dots$  and at each point  $t > 1$  a new node enters. So  $N_t$  is the set of nodes at time  $t$ . There is a contacting process followed by a linking process. Let us describe the contact process first. At birth, a node picks randomly, and without replacement,  $m_r$  nodes from the set  $N_{t-1}$  and forms links with them. She then picks  $m_n$  nodes randomly, without replacement from the neighbors of the  $m_r$  nodes picked at random. Thus we can say that  $m = m_r + m_n$  is the number of outward links formed by every entering new node. It is important to bear in mind that the neighbor of  $i$  is a node  $j$  such that  $g_{ij} = 1$ . In other words, we are using only incoming links for the indirect linking part of the process.

To make sure that the process is well defined, let us suppose that there are enough nodes and links at the start so that the dynamics are well defined. Suppose that at start of time  $t$  node  $i$  has  $d_i(t)$  incoming links. What is the probability that she gets another link in period  $t$ ? We note that links are formed via random draws uniformly from the population and indirectly by following out-links from other nodes that have been picked uniformly at random. Putting together these two ways of forming links may write the expected number of new links for node  $i$  as

$$\frac{m_r}{t} + \frac{m_r d_i(t)}{t} \left( \frac{m_n}{m_r(m_r + m_n)} \right) \quad (2.33)$$

Substituting for  $m = m_r + m_n$  in (2.33):

$$\frac{m_r}{t} + \frac{m_n d_i(t)}{mt} \quad (2.34)$$

which is increasing linearly in  $d_i(t)$ . Thus the probability of getting a new link is increasing in the number of existing links. This is the preferential attachment aspect of this model.

Turning to a solution, observe that this is a complicated model because the evolution of the network depends on network-based links, and the network is itself stochastic. As

in our study of the preferential attachment models above, we can employ approximation methods used by statistical physicists to solve the model.

Suppose people arrive in continuous time and let the probability of forming new link equal the “deterministic” growth in links. Then we may write the rate of change in links as

$$\frac{d}{dt}d_i(t) = \frac{m_r}{t} + \frac{m_n d_i(t)}{mt} \quad (2.35)$$

This is a differential equation; let us set the initial condition,  $d_i(i) = d_0 \geq 0$ . Define  $r = (m_r)/(m_n)$ , as the ratio of random to network based links.

The solution to the differential equation is given by:

$$d_i(t) = (d_0 + rm) \left( \frac{t}{i} \right)^{1/(1+r)} - rm. \quad (2.36)$$

where  $d_i(t)$  is the in-degree of node  $i$  at time  $t \geq i$ . We use this formula to develop the degree distribution of the network. Using methods similar to those in the preferential attachment model, we can conclude that the in-degree distribution of the above mean-field process has a cumulative distribution function of

$$F_t(d) = 1 - \left( \frac{d_0 + rm}{d + rm} \right)^{1+r}. \quad (2.37)$$

for  $d \geq d_0$  and for each time  $t$ .

Start with in-degree equation (2.36) and with the help of (2.37) we get the formula for the tail distribution:

$$\log(1 - F(d)) = \frac{m}{m_n} [\log(d_0 + rm) - \log(d + rm)]. \quad (2.38)$$

Equation (2.38) permits us to make a number of observations. First, observe that if  $d$  is large relative to  $rm$ , the tail probability is roughly linear in  $\log(d)$ . Second, for small  $r$  the distribution is roughly linear in  $d$  and exhibits a power law. On the other hand, if  $r$  is large, most links are random and the distribution is close to a random linking model with growing number of nodes.

We now next turn to clustering levels in this network. Recall that clustering coefficient in the directed network may be described as the fraction of transitive triples.

$$C^T(g) = \frac{\sum_{i:j \neq i \neq k} g_{ij}g_{jk}g_{ik}}{\sum_{i:j \neq i, k \neq i} g_{ij}g_{jk}} \quad (2.39)$$

A newborn connects to  $m_r$  parent nodes and each of them have  $m$  outgoing links. Thus an upper bound of potential triples (for a single node  $i$ ) is given by  $m^2$ . But each newborn forms  $m_n$  connections with the neighbors of parents, so we get the following expression as a lower bound for clustering:

$$\frac{m_n}{m^2} = \frac{1}{(1+r)m}. \quad (2.40)$$

So, for instance, if  $m = 4$  and  $r = 1$ , then clustering is given by 0.125. Moreover, in line with our intuition, it is falling in the fraction of randomly drawn links.

## 2.7 A concluding remark

This chapter provides a brief introduction to models of random graphs – the Erdos-Renyi model (and its variant the stochastic block model), the configuration model, the preferential attachment model, the small worlds model, and a model of random and neighbor linking. We develop a first impression of how the mechanics of linking give rise to different network properties such as connectivity, degree distributions, small distances, and clustering.

In the rest of this book, we will locate the network concepts introduced in chapter 1 and our understanding of the mechanics of linking introduced in this chapter within a perspective that sees networks as arising out of the goal driven activity of individuals and collective entities (like firms and the state).

## 2.8 Reading Notes

The chapter proposes a number of models of random graphs. At a basic level one may imagine a random graph as specifying a number of nodes,  $n$ , and a number of links/edges,  $m$ . The links may be ordered in different ways and this will give rise to different networks. Say that every possible arrangement of the  $m$  links is equally likely. This model gives rise to an ensemble of networks, denoted by  $G(n, m)$ . We may ask what are the properties of these networks, say, in terms of their connectivity or in terms of distances. As the model describes an ensemble of networks, it is reasonable to ask questions about the average properties of the networks. Some properties of this network such as the average degree are easy to derive, however, it turns out that the others like the connectivity or the diameter are less easy to calculate. Interest has focused on a slightly different model that allows much more complete answers with regard to properties of networks.

This model is known as the  $G(n, p)$  model. In this model, the number of nodes is  $n$  and

there is an (identical and independent) probability  $p$  for the formation of a link between any pair of nodes. Thus the number of links is no longer fixed but will vary depending upon the realization of random draws. As in the original  $G(n, m)$  model, therefore the model describes an ensemble of networks. We can pose questions about degree distribution and connectivity with regard to the average network generated by this process. The  $G(n, p)$  model was first studied in Solomonoff and Rapoport [1951]. However, the model is often referred to as the Erdos-Renyi random graph model due to the three papers published by the two mathematicians in the late 1950's and early 1960's. The Erdos-Renyi model sometimes also called the Poisson random graph model or the Bernoulli random graph model. There is a vast literature on this model and its variants. For excellent overviews of this work see Bollobás [2004] and Bollobás [1998a].

In chapter 1, we drew attention to the presence of very highly connected nodes – also called hubs – in a variety of real world networks. This preponderance of hubs is accompanied at the other end of the distribution by the existence of a very large number of nodes with very small degrees. The degree distribution thus appears to be quite different from a Poisson degree distribution where the vast majority of nodes have degrees close to the mean degree. The study of unequal networks may be traced to an early study by Derek de Solla Price in which he showed that the distribution of citations was similarly very skewed both toward the bottom and at the top end (de Solla Price [1965]: the majority of papers had very few citations and there were a significant number of highly cited papers.

Building on Simon [1955] (and an earlier literature in statistics), de Solla Price proposed a network model of linking that generated a power law degree distribution (de Solla Price [1976]). The work of de Solla Price went relatively unnoticed, until the revival of interest in networks in 1990's when Barabási and Albert [1999] presented a simpler and undirected link version of the original Price model. They also brought it closer to a broad range of empirical applications. For a systematic and wide ranging overview of different aspects of the model see Barabási [2016] and Newman [2010]. For a fascinating experimental study of how information releases can give rise to power laws see Salganik, Dodds, and Watts [2006].

Having studied the Poisson and power law degree distributions, it is only natural that we should consider a framework that allows for general degree distributions. The configuration model is an example of such a framework. A model of specific degree sequence was proposed and studied in the context of the existence of giant components by Molloy and Reed [1995]. Watts, Dodds, and Newman [2002] studied a number of properties of this model such as the phase transition at which a giant component first forms, the mean component size, the size of the giant component (if one exists), properties of excess degree

distributions and average distances. Chung and Lu [2002b] proposed a smoother version of the model with expected degrees and obtained results on the relation between the power law coefficients and average distances in the network. There is a large literature that examines different aspects of the model. For a deeper and more comprehensive overview of these developments, see Newman [2018].

The presence of power laws has been noted in different contexts such as city population size, number of copies of a gene in a genome, firm size (we have already noted distribution of citations). At first sight, it is puzzling that there is a similar macroscopic property in very different contexts. The fact that the rich-gets-richer process can provide a common account is interesting but we should note that there are alternative explanations for such networks. A parallel thread of research argues that power laws may arise due to optimization in the presence of constraints. An early paper by Mandelbrot [1953] introduced this perspective and it has been elaborated upon by a number of authors since then. In chapter 3 (on an economic theory of network formation), in chapter 7 (on network security) and in chapter 11 (on the law of the few) we will present economic models where both the decentralized formation of networks as well as the optimization of networks leads to hubs and highly unequal networks.

The model with rewiring of links giving rise to networks with small average distance and high clustering is due to Watts and Strogatz [1998]. This model has given rise to a vast body of research; see Newman [2010] for an overview of this work. The discussion on small worlds experiments draws on the fascinating early papers by Milgram [1967] and the follow up paper by Travers and Milgram [2011]. With the advances in computing and information technology, the small world problem has been explored by a number of more recent papers; prominent contributions include Dodds, Muhamad, and Watts [2003]. The small worlds experiments have given rise to the study of the problem of navigation in networks. An important element of whether a network is navigable or not lies in the connection between network structure and individual identity. For theoretical investigations on this subject see Kleinberg [2000] and Watts, Dodds, and Newman [2002].

Finally, in an attempt to reconcile unequal degrees with clustering, we present a model that combines growing network with network based linking. The model is taken from Vazquez [2003] and Jackson and Rogers [2007]. For a detailed exposition of this model see Jackson [2008].

I thank Fulin Guo for helpful comments on an earlier draft of the chapter.

## 2.9 Questions

1. Consider the Erdos-Renyi model of random graphs. Let  $P$  be the degree distribution corresponding to a probability of linking  $p$  and  $P'$  be the degree distribution corresponding to a probability of linking  $p'$ . Show that if  $p' > p$  then the degree distribution  $P'$  first order stochastically dominates the degree distribution  $P$  (for definitions of stochastic dominance see chapter 1).
2. Show that  $p(n - 1) = 1$  is a threshold for the emergence of a giant component in the Erdos-Renyi model of random graphs.
3. Consider the Erdos-Renyi model of random graphs. Show that  $t(n) = 1/n^2$  is a threshold function for there being at least one link.
4. The preferential attachment process gives early moving nodes large advantages. Discuss. Hint: suppose that in every period a new node is born. Use the formulae in the chapter to ask how long would it take a node born in period 10 to have the same number of connections as the first born node in period 10?
5. This question is inspired by an experiment on popularity ratings reported in Salganik, Dodds, and Watts [2006]. Prominent news sites like BBC or Guardian present links to their stories; readers can click on these links to access different pieces of news. We may define the popularity of a news item by the number of readers who click on the corresponding link. Suppose that the news company is considering adding a counter next to a news link that would give the number of readers who have already clicked on that link. Discuss the effects of such readership information on the popularity distribution of news items.
6. Consider the model of growing network as in section 2.3. But now suppose that a new born node form  $k$  links with uniform probability with each of the existing nodes. Derive the master equations corresponding to this process for the growth in indegree (for large  $n$ ) and show that (in the limit of large  $n$ ) the indegree distribution have an exponential distribution:  $p(d) = Ce^{-\lambda d}$ , where  $C$  is a normalization constant and  $\lambda = \log(1 + 1/k)$ .
7. Consider the Jackson-Rogers model of growing networks discussed in section 6. Show that as we raise the fraction of random linking from  $r$  to  $r'$ , the corresponding degree distribution is less skewed i.e.,  $P'$  second order stochastically dominates  $P$  (for definitions of stochastic dominance see chapter 1).

# Chapter 3: The Costs and Benefits of Links

## 3.1 Introduction

In a number of the networks presented in the introductory chapter links are chosen by purposeful agents. For example, firms decide on who to source their inputs from and this gives rise to the production networks. Airline companies decide on the routing network they operate. Similarly, individual economists decide on who to co-author with and school pupils choose who to be friends with. It is therefore reasonable to approach the formation of networks through an examination of the motivations that individuals or firms have in forming links. This chapter provides an introduction to the theory of network formation in which purposeful entities create links based on their costs and benefits.

A fundamental dimension of linking is who can decide on a link. For instance, on Twitter an individual user can decide on who to follow, while on Facebook a friendship link requires that both parties agree to the link. We may think of a link on Twitter as being unilateral or one-sided, a link on Facebook is bilateral or two-sided.

We start with a consideration of the following simple scenario: there is a group of individuals who each have some information that is valuable to everyone. Each player can form links with a subset of others. The model is taken from Goyal [1993] and Bala and Goyal [2000a]. In this model, the linking decisions of individuals give rise to a directed network. The benefits to an individual in this network depend on the number of other people that she has a directed path to and the costs depend on the number of links she has formed. Thus an individual's links create paths for others. This potential for a link between two individuals A and B to be used by another individual C is a central feature of the process. One-sided link formation can be formulated as a non-cooperative game. We study the networks that arise in the Nash equilibrium of the game.

We find that economic models of linking lead to sharp transitions in network structure at certain thresholds (that relate to the costs and benefits of links). A second finding is that there exists a tension between strategically stable and efficient networks. The sharp transitions in network architectures and the tension between individual incentives and

collective interests ideas will be a recurring theme in our study of linking and network formation throughout the book.

We then turn to a study of bilateral or two-sided links – a link between A and B requires the assent of both of them. Following Jackson and Wolinsky [1996b], we are led to study the incentives of not just one person but of joint interests. This leads to the notion of pairwise stability. A comparison of pairwise stable networks and Nash networks (from the one-sided model) helps us understand the role of the link formation protocol in shaping network architecture.

The economics literature on network formation has been a very active and fruitful field of research over the past quarter of a century. As linking activity occurs across a very wide range of contexts, the literature has expanded to accommodate a number of issues that include the dynamics of linking, study of linking in combination with assorted activities, weighted graphs, and non-specific networking. We provide an overview of these strands of work and also point to subsequent chapters where these subjects are explored at greater length.

In the previous chapter, our study of random graphs drew attention to thresholds and sharp transitions in networks. These transitions also arise in an economic approach. But perhaps the central distinguishing feature of an economic approach is its attention to goal driven linking by individuals. The central role of individual choice calls for an explicit consideration of the preferences and the knowledge and the rationality of individuals. In particular, our discussion will draw attention to how linking by one individual creates benefits (and costs) for other individuals. This is referred to as an ‘externality’. This externality gives rise to two fundamental issues: the first is multiplicity of equilibrium networks and the second is a tension between what individuals create and what is their collective interest. These two phenomena will be central our study of networks throughout the book. In particular, the tension between equilibrium and collectively desirable networks will give rise the possibility of interventions that make everyone better off. The ideas we explore in this chapter are central to an economic approach to networks. The formal arguments we develop here will be useful throughout this book; in particular, in chapters 5-12 and in chapters 16 and 19.

## 3.2 One-sided links

This section presents an approach to network formation in which individual players can unilaterally decide to form links with others. This approach gives rise to a non-cooperative game that can be solved using the concept of Nash equilibrium. We then introduce ways

of measuring the performance of networks. The model is taken from Goyal [1993] and Bala and Goyal [2000a].

Let  $N = \{1, \dots, n\}$ , with  $n \geq 3$ , be the set of players and let  $i$  and  $j$  be typical members of this set. A strategy of player  $i \in N$  is a (row) vector  $s_i = (s_{i,1}, \dots, s_{i,i-1}, s_{i,i+1}, \dots, s_{i,n})$  where  $s_{i,j} \in \{0, 1\}$  for each  $j \in N \setminus \{i\}$ . Player  $i$  has a *link* with  $j$  if  $s_{i,j} = 1$ . The set of (pure) strategies of player  $i$  is denoted by  $\mathcal{S}_i$ . A strategy profile is denoted by  $s = \{s_1, \dots, s_n\}$ , with the set of all strategies being given by  $\mathcal{S} = \prod_{i=1}^n \mathcal{S}_i$ . There is an equivalence between a strategy profile and a directed network. Let  $\mathcal{G}$  be the set of directed networks on  $n$  nodes. We shall say that  $N_i^d(g) = \{j \in N | g_{ij} = 1\}$  is the set of players with whom player  $i$  forms a link and define  $\eta_i^d(g) = |N_i^d(g)|$  as the number of connections of player  $i$  in network  $g$ . Note that in the definition here the superscript  $d$  refers to the directed nature of the link. Similarly, define  $N_{-i}^d(g) = \{j \in N | g_{j,i} = 1\}$  as the set of players who form a link with player  $i$  and define  $\eta_{-i}^d(g) = |N_{-i}^d(g)|$  as the number of players who form links with player  $i$ . Recall that  $\eta_i^d(g)$  is the out-degree and  $\eta_{-i}^d(g)$  the in-degree of player  $i$  in network  $g$ . In the directed network  $g$ , let  $\mathcal{N}_i(g) = \{k | i \xrightarrow{g} k\}$  be the set of individuals accessed through a directed path by  $i$ . We follow the convention that a player accesses herself, and so the total number of players accessed by player  $i$  in network  $g$ , is given by  $n_i(g) \equiv |\mathcal{N}_i(g)| + 1$ .

Given a strategy profile  $s$ , let  $\Pi(s)$  be the payoff of player  $i$ . A Nash equilibrium is a profile of strategies  $s^* = (s_1^*, \dots, s_n^*)$ , such that for every player  $i \in N$ ,  $\Pi_i(s_i^*, s_{-i}^*) \geq \Pi_i(s_i, s_{-i}^*)$ , for every  $s_i \in \mathcal{S}_i$ , i.e., every player is choosing the highest payoff strategy, given the strategies of the other players. A Nash equilibrium  $s^*$  is said to be strict if all players choose a strict best response, i.e., the inequalities defining the equilibrium are strict for every player.

In the study of network formation an important concern will be the relation between equilibrium/stable networks and socially desirable networks. Two aspects of social desirability will be touched upon: efficiency and equity.

We consider two notions of efficiency are used: Pareto efficiency and aggregate efficiency. A network  $g$  yields a profile of individual payoffs  $\Pi(g) = \{\Pi_1(g), \Pi_2(g), \dots, \Pi_n(g)\}$ . A network  $g$  is said to Pareto-dominate another network  $g'$  if  $\Pi_i(g) \geq \Pi_i(g')$ , for all players and there is some player  $j$  such that  $\Pi_j(g) > \Pi_j(g')$ . A network  $g$  is Pareto efficient if there is no other network  $g' \in \mathcal{G}$  which Pareto dominates it.

In the networks literature, a simpler and more aggregate notion of efficiency has been more widely used. Define aggregate welfare from a network  $g$  as

$$W(g) = \sum_{i \in N} \Pi_i(g) \tag{3.1}$$

A network  $g$  is said to be efficient if  $W(g) \geq W(g')$  for all  $g' \in \mathcal{G}$ .

Consider next the issue of equity. In sociology and political science, social and economic networks have traditionally been associated with the origins and perpetuation of inequality. At different points in this book, we will discuss inequality of network outcomes. Inequality can be measured in different ways; we will draw upon the voluminous literature on economic inequality (for an introduction to the subject see Sen [1997]). Standard measures of inequality include the range, variance and Gini-coefficient. We will sometimes also consider the ratio of maximum versus minimum (or the ratio maximum/median payoffs). The range of the payoffs in a network is given by

$$R(g) = \max_{i \in N} \Pi_i(g) - \min_{j \in N} \Pi_j(g). \quad (3.2)$$

where max refers to the maximum individual payoff and min refers to the minimum payoff level in the network  $g$ . The variance of payoffs in network  $g$  is given by

$$\text{Var}(g) = \frac{\sum_i^n [\Pi_i - \bar{\Pi}]^2}{n} \quad (3.3)$$

where  $\bar{\Pi}$  is the average payoff.

### 3.2.1 The one-way flow model

To illustrate the trade-offs that arise in the one-sided linking approach, we present the one-way flow model taken from Bala and Goyal [2000a]. Denote the set of non-negative integers by  $\mathcal{Z}_+$ . Let  $\phi : \mathcal{Z}_+^2 \rightarrow \mathcal{R}$  be such that  $\phi(x, y)$  is strictly increasing in  $x$  and strictly decreasing in  $y$ . Define each player's payoff function  $\Pi_i : \mathcal{G} \rightarrow \mathbb{R}_+$  as

$$\Pi_i(g) = \phi(n_i(g), \eta_i^d(g)). \quad (3.4)$$

We may interpret  $n_i(g)$  as the "benefit" that player  $i$  receives from the network, while  $\eta_i^d(g)$  measures the "cost" associated with maintaining her links. Note that the assumptions on the payoff function  $\phi(., .)$  allow for both increasing as well as decreasing marginal returns from connections. The linear payoff function is a simple example which satisfies these properties.

$$\Pi_i(g) = n_i(g) - \eta_i^d(g)k. \quad (3.5)$$

In words, player  $i$ 's payoffs are the number of players she observes less the total cost of link formation.

What is the architecture of networks that arise? To answer this question, we will examine Nash equilibria of the game. We start by developing an important property of Nash equilibrium networks: either no one forms any links and the network is empty or every individual accesses everyone else.

Suppose that  $i$  has paths to the most players and suppose that  $i$  does not observe everyone. Then there must exist a player  $j$  who is not observed by  $i$  and who does not observe  $i$  (for otherwise  $j$  would access more players than  $i$ ). We argue that  $j$  can earn strictly higher payoff by forming a single link with  $i$ . To see this in the simplest way, suppose that  $j$  has formed links including a link with (say)  $k$ . By deleting all her current links and forming a single link with  $i$  she will access strictly more players than  $i$ , since she has the additional benefit of observing  $i$ . Since  $j$  was observing (weakly) fewer individuals than  $i$  in his original strategy, and she is forming (weakly) fewer links in this deviation,  $j$  strictly increases her payoff through this deviation. This contradiction means that  $i$  must observe every one in the society.

Building on this property, we can then show that every other agent will have an incentive to either link with  $i$  or to observe him through a sequence of links, i.e., the network is connected. Moreover, the network must be minimally connected: if it is not then there are two paths between a pair of individuals and some player can delete a link and still observe all players, which would contradict the optimality of actions in a Nash equilibrium.

Figure 3.1 presents examples of Nash networks in the linear payoffs in equation (3.5). We see that networks can have a variety of architectures, ranging from a hub-spoke network to a cycle containing all players, and containing a number of intermediate structures with smaller cycles (we refer to them as ‘petals’). We note that a given architecture can be supported in different ways: for instance any of the  $n$  players can occupy the hub place in the hub-spoke network – therefore there are  $n$  equilibria that support that architecture. Similarly, the cycle network can be supported by any permutation of players on the nodes of the cycle, i.e., there are  $n!$  Nash equilibria supporting that architecture. Indeed, the number of Nash networks increases quite rapidly with the number of players; it is possible to show that there are 5, 58, 1069, and in excess of 20,000 Nash networks as  $n$  takes on values of 3, 4, 5, and 6, respectively. Thus Nash equilibrium is a fairly permissive requirement. Is there some way to further restrict the set of networks based on individual incentives alone?

We observe that in the star network the spoke player is indifferent between a link with the central player and any other spoke. In other words, the spoke player has multiple best responses. This multiple best responses creates the possibility that the individual may drift away from the star over time as there are no payoff losses associated with a switch in links. This motivates the study of strict Nash equilibrium. Recall from above that a Nash

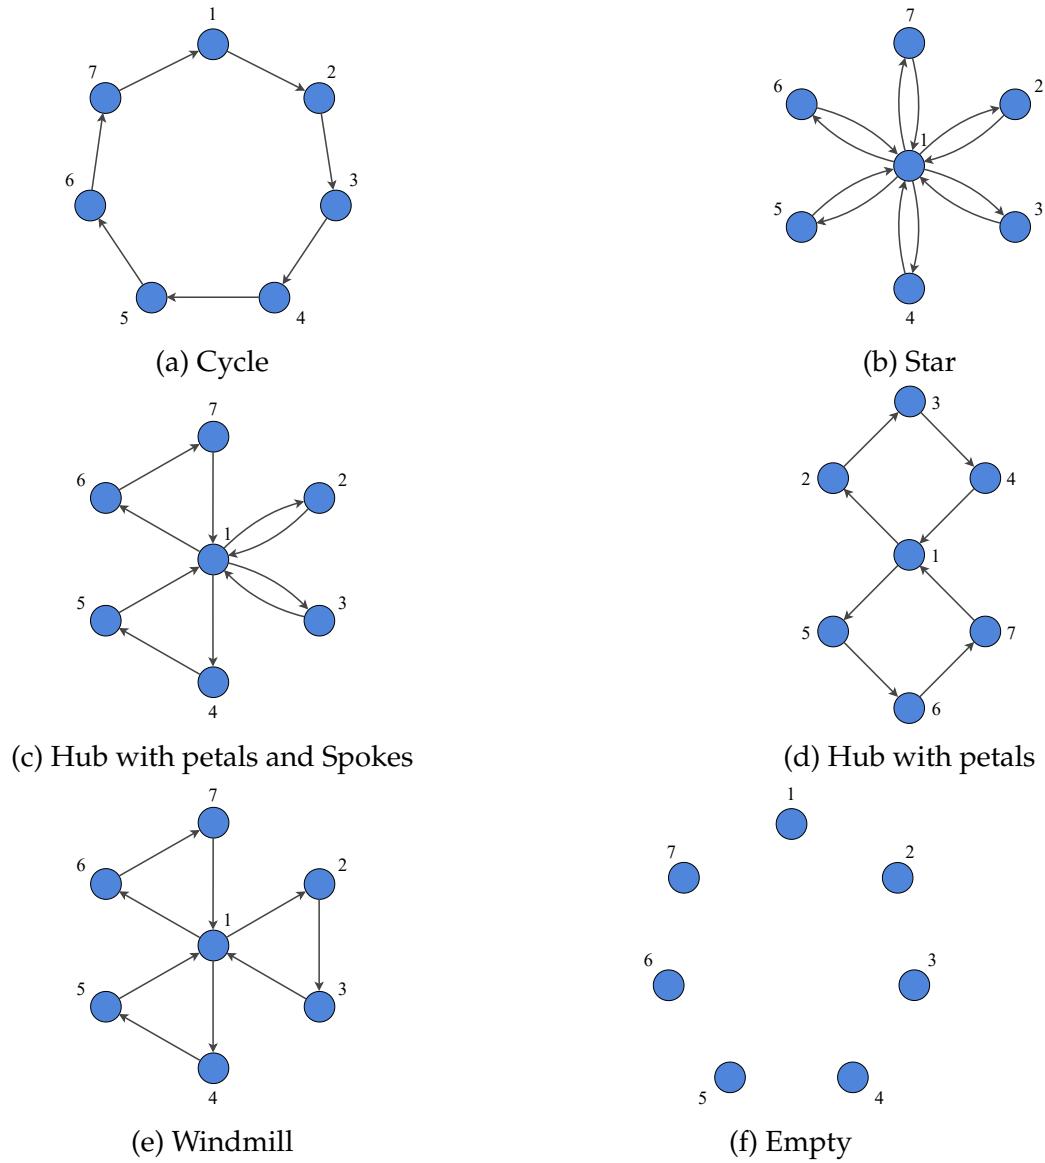

Figure 3.1: Nash Networks: one-sided links model

equilibrium is strict if every player chooses a strict best response. It turns out that the requirement of strictness is powerful and that it eliminates all but two network architectures as candidate networks in our game.

The key step is a simple switching argument: in a Nash equilibrium, if two players  $i$  and  $j$  have a link with the same player  $\ell$ , then player  $i$  will be indifferent between forming a link with  $\ell$  or instead forming a link with  $j$ . This means that every player has one and only one player who initiates a link with her, thus a (non-empty) strict Nash network has exactly  $n$  links. From the first argument in the proof (presented above) we know that a (non-empty) equilibrium network is connected: since the cycle is the only connected (directed) network with exactly  $n$  links we are led to the following result.

**Proposition 3.1.** *In the one way flow model, a Nash equilibrium network is either connected or empty. A strict Nash network is either a cycle containing all players or the empty network. In particular, (a). If  $\phi(\hat{x} + 1, \hat{x}) > \phi(1, 0)$  for some  $\hat{x} \in \{1, \dots, n - 1\}$  then the cycle is the unique strict Nash. (b). If  $\phi(x + 1, x) < \phi(1, 0)$  for all  $x \in \{1, 2, \dots, n - 1\}$  and  $\phi(n, 1) > \phi(1, 0)$  then the empty network and the cycle are both strict Nash. (c). If  $\phi(x + 1, x) < \phi(1, 0)$  holds for all  $x \in \{1, 2, \dots, n - 1\}$  and  $\phi(n, 1) < \phi(1, 0)$  then the empty network is the unique strict Nash.*

For concreteness, let us apply this result to the linear payoffs in equation (3.5). Proposition 3.1 says that the cycle containing all players is the unique strict Nash equilibrium if  $k < 1$ , the cycle and empty network are strict Nash equilibria when  $k \in (1, n - 1)$ , and the empty network is the unique strict Nash equilibrium when  $k > n - 1$ . Figure 3.2 depicts these equilibrium networks for  $n = 8$ . Note that in this figure, a link formed by player  $i$  with player  $j$  is represented by a line joining  $i$  and  $j$  and the arrow points towards  $j$ .

Three aspects of the result are worth highlighting. One, there is an intimate relation between the costs and benefits of links and the architecture of the network: when the costs are smaller than stand-alone benefits the network is connected while when the costs are larger than the benefits of accessing everyone, the network is necessarily empty. In addition, for an intermediate range of values, both empty and connected networks are possible.

Two, there is a sharp threshold that separates the connected from the empty network at  $k = n - 1$ : just below that level of cost we may get a connected network and just above that level, we may get an empty network.

A third point is that in the range  $k \in (1, n - 1)$  there are multiple equilibria and they have extreme properties – one is empty with no links, while the other is connected. This multiplicity is a recurring theme in strategic models of networks because it reflects a fundamental dimension of linking activity: the marginal returns to an individual from forming a

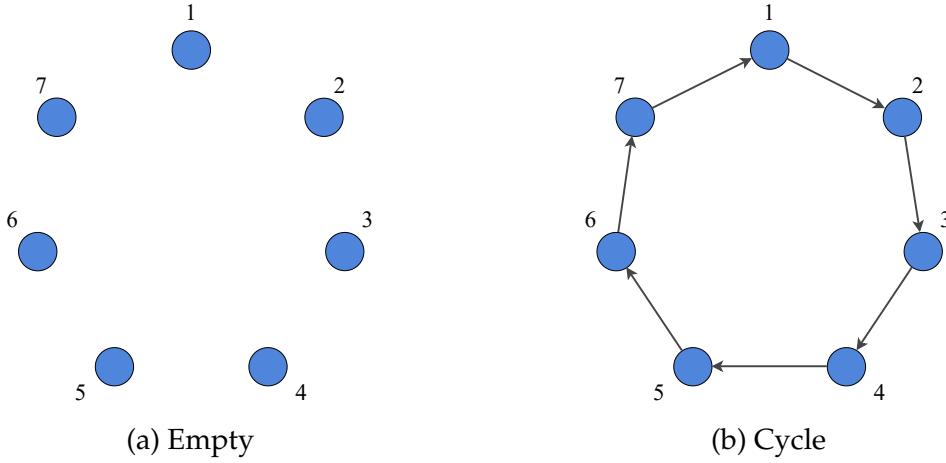

Figure 3.2: Strict Nash Networks: one-sided links model

link depend on how many links others have created. In this example, the marginal returns are 1 in the absence of any links but may equal  $n - 1$  if a player forms a link with someone who accesses everyone else. Thus for a cost  $k \in (1, n - 1)$ , whether a link is profitable or not depends on whether others have formed links.

As economic incentives to form links will be invoked in different contexts throughout the subsequent chapters in the book it is valuable to develop a deeper formal understanding of how to combine graph theoretic concepts with strategic reasoning and so we present a proof of the result here.

**Proof of Proposition 3.1:** The *first* step in the proof is to show that a Nash network is either empty or minimally connected. The focus is on the case  $\phi(n, 1) > \phi(1, 0)$ ; the proof for the case  $\phi(n, 1) \leq \phi(1, 0)$  is straightforward and omitted.

Suppose that  $g$  is a non-empty Nash network. Choose a player  $i \in \operatorname{argmax}_{k \in N} n_k(g)$ . Since  $g$  is non-empty the set of individuals accessed by  $i$   $x_i = n_i(g) \geq 2$  and the number of her links  $y_i = \eta_i^d(g) \geq 1$ . Furthermore since  $g$  is Nash,  $\Pi_i(g) = \phi(x_i, y_i) \geq \phi(1, 0)$ . It is shown that  $x_i = n$ . Suppose instead that  $x_i < n$ . Then there exists  $j \notin \mathcal{N}_i(g)$ . Clearly  $i \notin \mathcal{N}_j(g)$ , for otherwise player  $j$  would access (strictly) more players than player  $i$ . Suppose  $y_j = 0$ : in this case player  $j$  can strictly increase her payoffs by forming a link with  $i$  because  $\phi(x_i + 1, 1) > \phi(x_i, 1) \geq \phi(x_i, y_i) \geq \phi(1, 0)$ . Hence  $y_j \geq 1$ . Now a variant of the same argument can be used to show that player  $j$  can strictly increase her payoffs by deleting all her current links and instead form a direct link with player  $i$ . This contradicts the hypothesis of Nash equilibrium. It also implies that  $j \in \mathcal{N}_i(g)$  and since  $j$  was arbitrary this, in turn, means that  $x_i = n$  in a Nash network.

Let  $i$  be a player with  $x_i = n$  as above. A player  $j$  is critical to player  $i$  if  $n_i(g_{-j}) < n_i(g)$ . Let  $E$  be the set of non-critical players for player  $i$  in network  $g$ . If  $j \in \operatorname{argmax}_{j' \in N} d(i, j'; g)$

then  $j$  is non-critical, so that  $E$  is clearly non-empty. Next it is shown that if  $j \in E$  then  $n_j(g) = n$ . Suppose this is not true. If  $\eta_j^d(g) = 0$  then from the earlier argument above there is a deviation for player  $j$  that increases her payoff strictly. Thus  $\eta_j^d(g) \geq 1$ . If  $x_j = n_j(g) < n$  then player  $j$  can delete all her links and instead form a single link with player  $i$ . The argument in the previous step can be used to show that she benefits strictly from such a deviation. Thus  $g$  is not a Nash network. This contradiction implies that  $n_j(g) = n$ , for all  $j \in E$ .

The next step in the proof of connectedness establishes that for every  $j_1 \notin E \cup \{i\}$ , there exists  $j \in E$  such that  $j \in N_j(g)$ . Since  $j_1$  is critical there exists  $j_2 \in N_{j_1}(g)$  such that every path from  $j_2$  to  $i$  involves  $j_1$ . Hence  $d(i, j_2; g) > d(i, j_1; g)$ . If  $j_2 \in E$  then the claim is proved; otherwise, by a similar argument, there exists a player  $j_3 \in N_{j_2}(g)$  such that  $d(i, j_3; g) > d(i, j_2; g)$ . Since  $i$  accesses every player and  $n$  is finite, repeating the above argument no more than  $n - 2$  times will yield a player  $j \in E$  such that  $j \in N_{j_1}(g)$ . Since  $n_j(g) = n$  from above, it now follows that  $n_{j_1}(g) = n$  as well. Hence  $g$  is connected. If  $g$  is Nash but not minimal then some player can delete a link and the network would still remain connected. This means the player can strictly increase her payoffs by deleting a link, contradicting the definition of Nash equilibrium. We have therefore shown that a non-empty network is minimally connected.

The *second* part of the proof shows the cycle with all players is the unique non-empty strict equilibrium network. Let  $g \in \mathcal{G}$  be a non-empty strict Nash network. It is shown that for every player  $k$  there is one and only one player  $i$  such that  $g_{i,k} = 1$ . First note that since  $g$  is non-empty and an equilibrium it must be minimally connected. So for every player  $k$  there is some player  $i$  such that  $g_{i,k} = 1$ . Suppose there is another player  $j \neq i$  such that  $g_{j,k} = 1$ . Since  $g$  is minimal it follows that  $g_{i,j} = 0$ . Now consider a strategy  $g'_i$  for player  $i$  in which she deletes the link with  $k$  and instead forms a link with  $j$  and define  $g'_i = g_i - g_{ik} + g_{ij}$ . Then  $\eta_i^d(g) = \eta_i^d(g')$ . Furthermore since  $k \in N_j^d(g) = N_j^d(g')$ , clearly  $n_i(g') \geq n_i(g)$ . Hence  $i$  earns weakly higher payoffs from this new strategy,  $g'_i$ , which contradicts the hypothesis that  $g$  is a strict Nash network. As each player has exactly one player forming a link with her, and the network is connected it follows that the network must be a cycle which contains all players. Parts (a)-(c) now follow by direct verification. ■

A central theme in the economic study of networks is the question of performance. We start with a consideration of efficiency. Recall that a network is efficient if it maximizes the sum total of payoffs across the set of all possible networks. Let us make some preliminary observations to delimit the range of possible efficient networks. First consider the class of connected networks: every such network contains least  $n$  links: this is because every

player accesses everyone else in such a network and must therefore form at least one link. The cycle network containing all players has  $n$  links and so it must maximize aggregate payoffs in the class of connected networks. As the cycle is the only connected network with  $n$  links, we know that if a connected network is efficient it must be a cycle. The second observation concerns network externalities: if an efficient network contains some links it must be connected, i.e., a partially connected network with multiple components is never efficient. Thus an efficient network is either empty or the cycle. The following result builds on these observations to provide a complete description of efficient networks.

**Proposition 3.2.** *Suppose the payoffs be given by (3.4). If  $\phi(n, 1) > \phi(1, 0)$  then the unique efficient architecture is the cycle containing all players, while if  $\phi(n, 1) < \phi(1, 0)$  then the unique efficient architecture is the empty network.*

**Proof:** Let  $F$  be the set of values  $(n_i(g), \eta_i(g))$  as  $g$  ranges over  $\mathcal{G}$ . If  $\eta_i(g) = 0$ , then  $n_i(g) = 1$ . If  $\eta_i(g) \in \{1, \dots, n-1\}$ , then  $n_i(g) \in \{\eta_i(g) + 1, n\}$ . Thus,  $F \subset \{1, \dots, n\} \times \{1, \dots, n-1\} \cup \{1, 0\}$ . Given  $(x, y) \in F \setminus \{(1, 0)\}$ , we have  $\phi(n, 1) \geq \phi(n, y) \geq \phi(x, y)$  since  $\phi$  is decreasing in its second argument and increasing in its first. For the cycle network  $g^\ell$ , note that  $n_i(g^{\ell}) = n$  and  $\eta_i = 1$ , for all  $i \in N$ . Next consider any other network  $g \neq g^{\ell}$ : for each  $i \in N$ , if  $\eta_i(g) \geq 1$ , then  $n_i(g) \leq n$ , while if  $\eta_i(g) = 0$ , then  $n_i(g) = 1$ . In either case,

$$\Pi(g^\ell) = \phi(n, 1) \geq \phi(n_i(g), \eta_i(g)) = \pi_i(g), \quad (3.6)$$

where we have used the assumption that  $P(n, 1) > \phi(1, 0)$ . It follows that aggregate payoffs

$$W(g^\ell) = \sum_{i \in N} \phi(n, 1) \geq \sum_{i \in N} \phi(n_i(g), \eta_i(g)) = W(g) \quad (3.7)$$

as well. Thus  $g^w$  is an efficient architecture.

To show uniqueness, note that our assumptions on  $\phi$  imply that (3.6) holds with strict inequality if  $\eta_i(g) \neq 1$  or if  $n_i(g) < n$ . Let  $g \neq g^w$  be given; if  $\eta_i(g) \neq 1$ , for even one player  $i$ , then the inequality in equation (3.6) is strict, and this means that  $W(g^w) > W(g)$ . On the other hand, suppose  $\eta_i(g) = 1$  for all  $i \in N$ . As the cycle is the only connected network with  $n$  agents and  $n$  links, and  $g \neq g^w$ , there must be an agent  $j$  such that  $n_j(g) < n$ . Thus, 3.6 again implies that there is a strict inequality for player  $j$  and  $W(g^w) > W(g)$ , proving uniqueness.

For the case where  $\phi(n, 1) < \phi(1, 0)$ , let  $g$  be different from the empty network,  $g^e$ . Then

there exists some agent  $j$  such that  $\eta_j(g) \geq 1$ . For this player

$$\Pi_i(g^e) = \phi(1, 0) > \phi(n, 1) \geq \phi(n_j(g), \eta_j(g)) = \Pi_j(g) \quad (3.8)$$

while for every other player  $i$ ,

$$\Pi_i(g^e) = \Phi(1, 0) \geq \Phi(n_i(g), \eta_i(g)) = \Pi_i(g) \quad (3.9)$$

The result follows by summation. ■

This results tells us in particular that for the linear payoffs case given by equation (3.5), the unique efficient network for  $0 < k < n - 1$  is the cycle containing all players and for  $k > n - 1$  it is the empty network. Thus efficient and equilibrium networks both exhibit sharp transitions at key threshold points.

The second point is equally fundamental: when we compare Proposition 3.1 with Proposition 3.2 we see that for the cost values in the range  $0 < k < n - 1$  and  $k > n - 1$  an efficient network is sustainable as a Nash equilibrium, but that in the range  $1 < k < n - 1$  an efficient network is a cycle while the empty network is a strict Nash equilibrium. Thus there is a possibility of coordination failure: individuals may create an empty network even though they could create a connected network in equilibrium. Our final remark is that the cycle is perfectly symmetric in terms of number of links as well as payoffs.

In the basic model discussed above, the value of accessing someone remains constant across path length. We now consider a more natural setting in which value declines with distance. To appreciate the implications of this change, we restrict attention to the linear payoffs model in equation (3.5) and introduce a decay parameter that is given by  $\delta \in [0, 1]$ . Given a network  $g$ , if an agent  $i$  has a link with another agent  $j$ , i.e.  $g_{ij} = 1$ , then agent  $i$  receives information of value  $\delta$  from  $j$ . More generally, if the shortest path in the network from  $j$  to  $i$  has  $q > 1$  links, then the value of player  $j$ 's to  $i$  is  $\delta^q$ . The cost of link formation is still taken to be  $c$  per link. The payoff to a player  $i$  in the network  $g$

$$\Pi_i(g) = 1 + \sum_{j \in N \setminus \{i\}} \delta^{d(i,j;g)} - \eta_i^d(g)c \quad (3.10)$$

where  $d(i, j; g)$  is the geodesic distance from  $j$  to  $i$ . The original linear model of equation (3.5) corresponds to  $\delta = 1$ . We will follow the convention that if there is no path between two individuals in a network then the distance between them is set equal to infinity.

The trade-off between the costs of link formation and the benefits of short paths to

overcome transmission losses is key to an understanding of the architecture of networks in this setting. Building on the arguments in Proposition 3.1, it can be shown that a Nash network is connected or empty. A question at the end of the chapter develops the argument for this property. We next turn to other properties of Nash equilibrium networks.

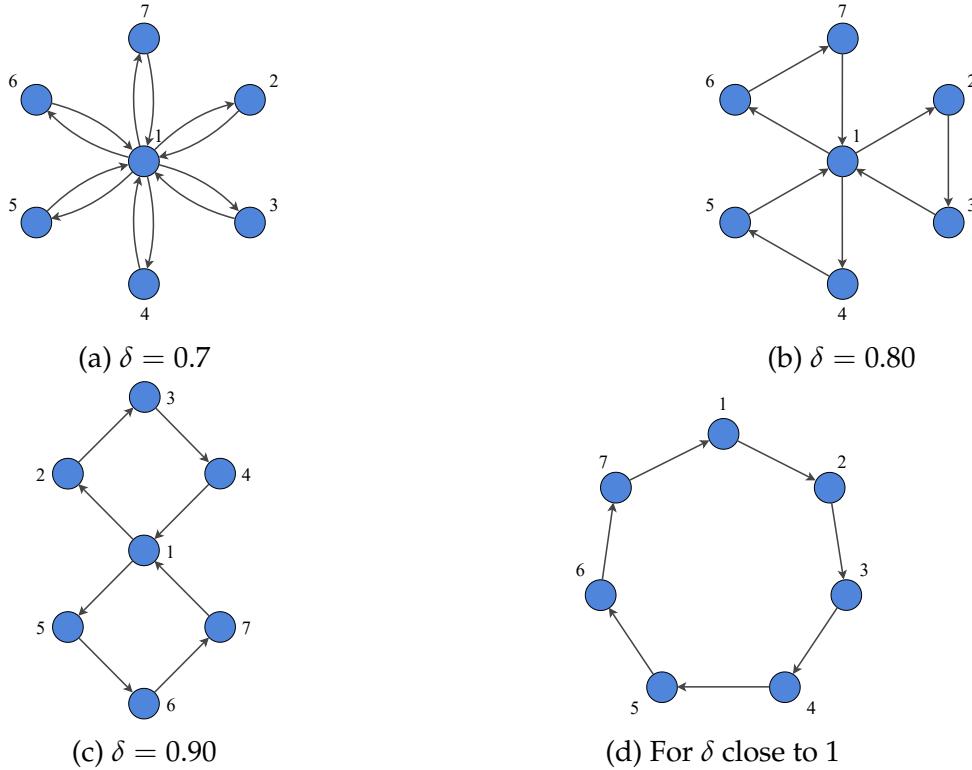

If  $k < \delta - \delta^2$  the marginal return from replacing an indirect link by a direct one exceeds the cost of link formation: it is a dominant strategy for a player to form links with everyone: the complete network is the unique Nash equilibrium. On the other hand, if  $\delta - \delta^2 < k < \delta$ , a player would want to directly or indirectly access everyone, meaning that the network must be connected. And, since  $k > \delta - \delta^2$ , if there exists someone who has links with every other player, then everyone in the society will be content by forming a single link with him, i.e., a star is a Nash equilibrium network. Next observe that if  $k > \delta$  then the empty network is a Nash network, as everyone wishes to form no links if no one has formed any links. However, other non-empty networks like the cycle are equilibrium for  $k > \delta$  and  $\delta$  close to 1, as well. Thus sharp transition thresholds and multiple equilibria remain salient, as in the baseline model with no decay.

We conclude with a brief comment on the role of decay in shaping network architecture. The high level idea here is that smaller decay – higher values of  $\delta$  – pushes towards greater distances. We illustrate this in Figure 3.3 by focusing on networks that range from a single cycle to a hub to whom all are connected. For a fixed cost of linking, the size of the cycle sustainable in a Nash equilibrium expands as we increase the value of  $\delta$  (keeping  $k < \delta$ ).

### 3.3 Two-sided links

This section presents a model of network formation in which a link between two players requires the approval of both the players involved. In such games, for any pair of individuals, it is always a best response for each of them to offer to form no link, if the other does so. There are far too many Nash equilibria; so we need to consider solution concepts that allow for coordination and cooperation between pairs of individuals. We propose the concept of pairwise stability and its elaborations to study games with two-sided links. The discussion will describe pair-wise stable networks and efficient networks and the relation between the two. We will also draw out the role of the linking protocol by comparing the architecture of Nash equilibrium in the one-sided model with pair-wise stable networks in the two-sided links model.

Following Myerson [1991] we consider an link announcement game. Every player announces a set of *intended* links. An intended link is a binary variable,  $s_{i,j} \in \{0, 1\}$  where  $s_{i,j} = 1$  ( $s_{i,j} = 0$ ) means that player  $i$  intends to (does not intend to) form a link with player  $j$ .

Figure 3.3: Nash Networks with Decay:  $n = 7, k = 0.5$ 

A (pure) strategy for player  $i$  is  $s_i = \{s_{i,j}\}_{j \in N \setminus \{i\}}$ , with  $\mathcal{S}_i$  denoting the strategy set of player  $i$ . A strategy profile for all players is denoted by  $s = \{s_1, \dots, s_n\}$ , with the set of all strategies being given by  $\mathcal{S} = \prod_{i=1}^n \mathcal{S}_i$ . Define  $g_{ij} = \min\{s_{i,j}, s_{j,i}\}$ . A strategy profile  $s = \{s_1, s_2, \dots, s_n\}$  therefore induces a corresponding *undirected* network  $g(s)$ . Define  $\Pi_i : \mathcal{S} \rightarrow \mathcal{R}$  as the payoff function of a player  $i$  in network  $g$ .

To develop an appreciation of the linking protocol we will consider linear payoffs as in equation (3.5) (but now in a undirected network setting). Let  $n_i(g)$  be the “benefit” that player  $i$  receives from each player she accesses through an undirected path in the network, and let  $\eta_i(g)$  be the number of links she forms. Given an (undirected) network  $g$  the payoff to individual  $i$  is given by

$$\Pi_i(g) = n_i(g) - \eta_i(g)k. \quad (3.11)$$

In words, player  $i$ ’s payoffs are the number of players she accesses less the cost of the links she forms.

We start the analysis of this game with a consideration of the familiar notion of Nash equilibrium as this will illustrate some of the conceptual issues that arise in the study of network formation with two-sided links. Recall that a strategy profile  $s^* = \{s_1^*, s_2^*, \dots, s_n^*\}$  is

a Nash equilibrium if  $\Pi_i(g(s_i^*, s_{-i}^*)) \geq \Pi_i(g(s_i, s_{-i}^*))$ , for all  $s_i \in S_i$ , and for all  $i \in N$ . This means that if every player announces that she wants to form no links then a best response of player  $i$  is to announce that she wants to form no links also. In other words, the empty network is a Nash equilibrium for any network formation game.

The concept of pairwise stability due to Jackson and Wolinsky [1996b] is designed to overcomes this coordination issue.

**Definition 3.1.** *A network  $g$  is pairwise stable if:*

1. *For every  $g_{ij} = 1$ ,  $\Pi_i(g) \geq \Pi_i(g - g_{ij})$  and  $\Pi_j(g) \geq \Pi_j(g - g_{ij})$*
2. *For  $g_{ij} = 0$ ,  $\Pi_i(g + g_{ij}) > \Pi_i(g) \implies \Pi_j(g + g_{ij}) < \Pi_j(g)$ .*

Pairwise stability looks at the attractiveness of links in a network  $g$  *one at a time*. The first condition requires that every link which is present in a stable network must be (weakly) profitable for the players involved in the link. The second condition requires that for every link which is not present in the network it must be the case that if one player strictly gains from the link then the other player must be strictly worse off.

Let us work through the trade-offs introduced by the two-sided nature of linking. First, observe that there cannot be two paths between any two players in a pairwise stable network. This is because if there were such a link then, since there is no decay and distances don't matter, a player could strictly increase their payoff by deleting a link that retained connectivity of a component. Thus a pairwise stable network must be acyclic.

Next we argue that a pairwise network is either empty or connected. To see why this is true consider a non-empty network that is pairwise stable but that has multiple components. Let  $C_1$  be the largest component. As this is not a singleton and it is acyclic, there is some player  $i$  who has a single link with some player  $j$ : the payoff to this player is  $|C_1| - k$ , and this payoff must exceed 1 (that the player could earn on her own in a singleton component): thus  $|C_1| - k - 1 \geq 0$ . Now consider a player,  $\ell$ , who lies outside component  $C_1$ : such a player can propose a link with  $j$  and that would yield  $|C_1| - k > |C_1| - 1 - k \geq 0$ . In other words player  $\ell$  can strictly increase their payoff by forming a link with player  $j$ . Moreover, player  $j$  would not be worse off with the link as they were happy with the link with player  $i$ . We have therefore shown that  $\ell$  has a strict incentive and  $j$  has at least a weak incentive to form a link. But then the original network  $g$  is not pairwise stable.

Next observe that if  $k < 1$  then every pair of players has an incentive to access each other: a pairwise stable network must be connected. Moreover, if  $k > 1$  then no player would be willing to form a link with an isolated player.

Let us next describe the efficient networks in this model. A preliminary remark is that there cannot exist two paths between any pair of individuals in an efficient network: if there were two paths then a link can be deleted without affecting the connectivity of the component and this new network would yield strictly higher welfare as it would contain one link less without any effect on benefits. So an efficient network must be acyclic. Note that a minimally connected network with  $n$  nodes has exactly  $n - 1$  links. We next establish that an efficient network must be empty or connected.

To see this consider a non-empty network with two components with  $\ell \geq 2$  and  $m \geq 2$  nodes respectively. The aggregate payoffs in the two components are  $\ell^2 - 2(\ell - 1)k$  and  $m^2 - 2(m - 1)k$ , respectively. As the network is efficient it must be the case that the components generate payoffs greater than the corresponding empty networks, i.e.,  $\ell^2 - 2(\ell - 1)k \geq \ell$  and  $m^2 - 2(m - 1)k \geq m$ . If we aggregate the two components to create one minimal component the total payoffs are  $(\ell + m)^2 - 2(\ell + m - 1)k$ . It is clear that

$$(\ell + m)^2 - 2(\ell + m - 1)k > \ell^2 - 2(\ell - 1)k + m^2 - 2(m - 1)k \quad (3.12)$$

given that  $\ell^2 - 2(\ell - 1)k \geq \ell$  and  $m^2 - 2(m - 1)k \geq m$ . Thus an efficient network is either (minimally) connected or it is empty. A minimally connected network yields a total payoff of  $n^2 - 2(n - 1)k$  while the empty network yields total payoffs equal to  $n$ . Thus the connected network dominates the empty network if and only if  $k/2 < n$ .

The following result summarizes our discussion.

**Proposition 3.3.** *Suppose the payoffs be given by (3.11). If  $k < 1$  then a pairwise stable network is minimally connected, if  $k > 1$  then the unique pairwise stable network is empty. If  $k < n/2$  then an efficient architecture is minimally connected, while if  $k > n/2$  then the unique efficient architecture is the empty network.*

Figures 3.4 and 3.5 present pairwise stable and efficient networks in the two-sided links model. The study of two-sided links networks draws attention to the two themes we noted in the one-way flow model: one, there are sharp transitions at thresholds from connected to empty network and two, there is a tension between stability and efficient. However, there are also important differences between Nash equilibrium of the one-sided model and the pairwise stable networks of the two-sided model. In particular, in the one-sided links model, (directed) cycles are a recurring feature of Nash networks, while they do not arise in pairwise stable networks of the two-sided model (cf. Figures 3.1 and 3.4).

Turning to the question of payoffs, observe that in an efficient network like the star the central player earns  $n - (n - 1)k$  while the periphery player earns  $n - k$ . This is a more general feature of efficient networks: even in a line network, the leaves earn  $n - k$  while

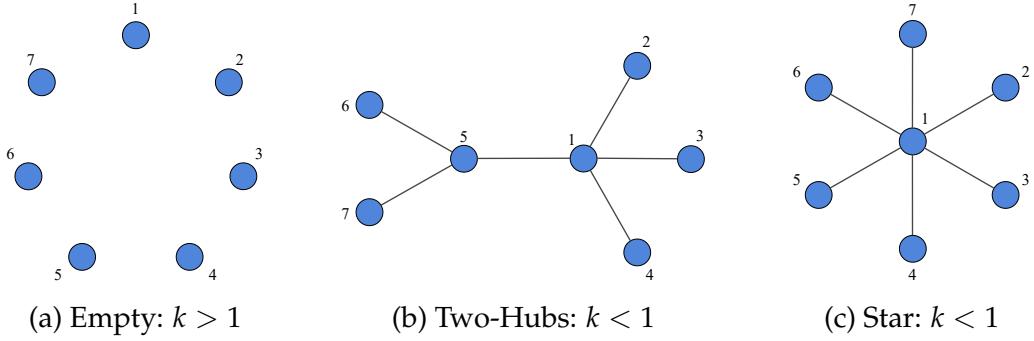

Figure 3.4: Pairwise Stable Networks: two-sided links model

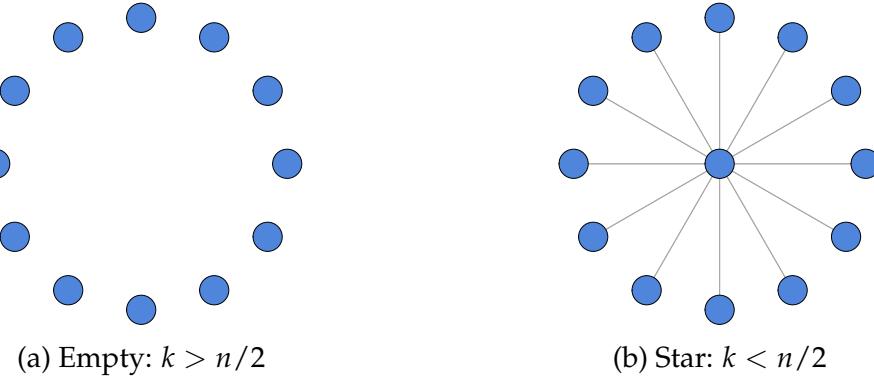

Figure 3.5: Efficient Networks: two-sided links model

all other players  $n - 2k$ . Thus the marginal return to the leaf from a link is significantly larger than the marginal return to the non-leaf from linking with the leaf. In all minimally connected networks, there is this great asymmetry in marginal returns and this goes some way toward understanding why the efficient network is not pairwise stable.

For completeness, we now discuss up the two-sided link model with decay; following Jackson and Wolinsky [1996b], this is known as the “connections model”. Let  $\delta \in [0, 1]$  be the rate of decay in value as it moves across links. Given a strategy profile,  $s$ , the payoffs to player  $i$  in a network  $g(s)$  are:

$$\Pi_i(s) = 1 + \sum_{j \neq i, j \in N_i(g(s))} \delta^{d(i,j,g(s))} - \eta_i(g(s))k. \quad (3.13)$$

where  $k > 0$  is the cost of forming a link (for each player) and  $\delta \in [0, 1]$  is the decay in value as it passes through paths of the network. The value of  $\delta = 0$  reflects full decay and no flow of value, while  $\delta = 1$  indicates the absence of any decay. The existence of decay creates an incentive for players to locate close to others.

**Proposition 3.4.** Suppose payoffs are given by (3.13). A pairwise stable network is either connected

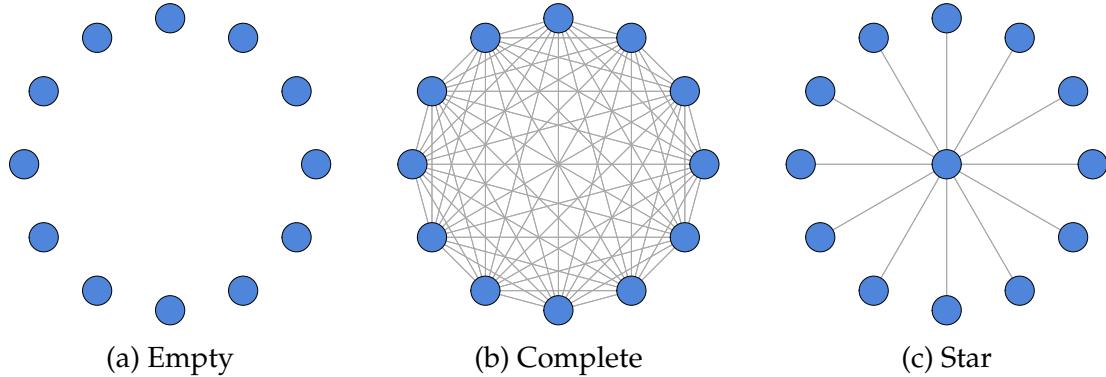

Figure 3.6: Pairwise stable networks: two-sided model with decay

or empty. For  $k < \delta - \delta^2$ , the unique pairwise stable network is the complete network. For  $\delta - \delta^2 < k < \delta$ , a star is a pairwise stable network. For  $\delta < k$ , the empty network is pairwise stable and any pairwise stable network which is non-empty is such that each player has at least two links.

The first part of the proof follows from agglomeration arguments as in the baseline model without decay. The rest of the result follows from straightforward computations. Figure 3.6 illustrates some pairwise stable networks. We note that dense networks like the complete network as well as sparse and small average distance networks like the star can be pair-wise stable networks.

We next turn to an assessment of the performance of networks. Recall that a network is efficient if it maximizes the sum of individual payoffs in the set of all networks. In addition to the trade-offs introduced in Proposition 3.2, the presence of decay creates a further trade-off now. If the costs of linking are very small,  $k < (\delta - \delta^2)$ , it is socially desirable to form a direct link between every pair of individuals. If on the other hand, the costs of links are very large then it is clear that no links would be justifiable. We also note that the star network is attractive because it economises on the number of links and at the same time keeps the average distance between individuals very low (there are  $n - 1$  links in a star, the minimum number of links it takes to connect  $n$  nodes) and the average distance is smaller than 2. These preliminary remarks help us pin down efficient networks very sharply, as the following result confirms.

**Proposition 3.5.** Suppose payoffs are given by (3.13). The unique efficient network in the connections model is (i) the complete network if  $k < \delta - \delta^2$ , (ii) the star if  $\delta - \delta^2 < k < \delta + (n - 2)\delta^2$  and (iii) the empty network if  $k > \delta + (n - 2)\delta^2/2$ .

The arguments underlying this result resurface at different points in subsequent chapters. It is therefore important to develop a thorough understanding of these arguments and so we present a proof of the result in the main text.

**Proof:** The joint marginal gains to players  $i$  and  $j$  from forming a link are bounded from below by  $2[\delta - \delta^2]$ . If  $2k < 2[\delta - \delta^2]$ , then forming a link increases social welfare. Thus any incomplete network is welfare dominated by the complete network so long as  $k < [\delta - \delta^2]$ : the complete network is uniquely efficient.

Next fix a component  $C_1$  in  $g$ , with  $|C_1| = m$ . Suppose  $m \geq 3$ . Let  $l \geq m - 1$  be the number of links in the component. Then the welfare in  $C_1$  is bounded above by

$$m + l(2\delta - 2k) + [m(m - 1) - 2l]\delta^2. \quad (3.14)$$

This is because a link ensures direct benefits of  $2\delta$  to each of the connected pairs, the cost of a link is  $k$ , and the closest all other pairs of individuals could be is at distance 2. If the component is a star then social welfare is

$$m + (m - 1)[2\delta - 2k] + (m - 1)(m - 2)\delta^2 \quad (3.15)$$

where  $m$  reflects stand alone benefits, the second term collects the direct benefits less the costs of links, and the third term reflects benefits of all pairs who are distance two apart.

Under the hypothesis that  $(\delta - \delta^2) < k$ , expression (3.14) can never exceed (3.15), and the two are exactly equal for  $l = m - 1$ . It can be checked that the star is the only network with  $m$  players and  $m - 1$  links in which every pair of players is at distance of 2 or less. Hence any other network with  $m - 1$  links must have at least one pair of players who are at a distance of 3 or more. This implies that social welfare in any other network with  $l = m - 1$  links is strictly less than social welfare in the star. Thus in an efficient network a component must be a star.

Consider next an efficient network with multiple stars, with  $m$  and  $m'$  individuals, respectively. As the network is efficient the component must have non-negative welfare. It can be shown by direct computation that a single component with  $m + m'$  players has higher social welfare than two components with the star structure. Thus a single star maximizes social welfare in the class of all non-empty networks. Social welfare in a star is given by (3.15) where we substitute  $m$  with  $n$ . It can be checked that welfare in the star exceeds welfare in empty network if  $\delta + (n - 2)\delta^2/2 > k$ . This completes the argument. ■

The analysis of the connections model reveals a number of features that are of general interest. We start by noting that a wide range of network architectures are pair-wise stable – they range from the complete network to the empty network and include the star network. We next comment on the role of decay. In the model with no decay, the complete network is never an equilibrium because the equilibrium network cannot be cyclic: thus introducing decay makes denser networks strategically stable. On the other hand, decay also presses

toward bringing individuals closer to each other: this makes the star especially attractive from a payoffs point of view, as it economizes on links and also has small average distances.

The second point pertains to the sharp transition in network structure – both for stability and efficiency – that occurs at critical cost values. This is again reminiscent of the thresholds in the one-way flow model (and in the random graph models).

The third point to note is that there is a tension between individual incentives and collective welfare. The star is efficient for a wide range of parameters – if  $\delta - \delta^2 < k < \delta + (n - 2)\delta^2$  – but it cannot be sustained as a pairwise stable network for  $k > \delta$ . This is reminiscent of the tension we noted in the one-way flow model. It points to the positive externalities created by individual linking: when the hub forms links with the spokes, it creates value for all spokes that it does not take into account.

We conclude our discussion of the two-sided model by drawing attention to the role of linking protocol: in the one-sided model Nash equilibrium (and efficient) networks will generally contain (directed) cycles while in the two-sided linking model both pair-wise stability (and efficiency) push toward acyclic networks.

## 3.4 General Considerations

We have presented the elements of an economic approach to network formation. For expositional reasons, we have concentrated on distinguishing between one-sided and two-sided links and we have focused on a very simple model of benefits and costs. The economics literature on network formation has made major advances over the past two decades in terms of the generality of the theory as well as in terms of the reach of the applications. The aim of this section is to introduce some of the general features of the theoretical models in this literature. In subsequent chapters we will examine the role of linking in a number of application such as production networks, infrastructure, brokerage and intermediaries, security, online social media, social coordination, and networked markets.

### 3.4.1 Dynamics

Networks change as individuals add and delete links over time. This raises the natural question of whether the process of link formation settles down and what are the networks that arise? What is the relation between the networks that arise in the long run and the networks that are Nash equilibria or pairwise stable networks of the static network formation game? To develop a first impression of how dynamics can be used to understand networks, we present the dynamics of the one-sided model of linking.

Perhaps the simplest way to approach the dynamics of networks is to think of a world in which individuals get an opportunity to revise their links, form links with some new players, maintain some of the existing links and delete some of the other links. The structure of the existing network will determine the rewards from linking with different individuals. The possibility that current linking activity will alter incentives for others and hence shape future linking activity may be an important factor as well. The importance of longer term effects will depend on how quickly the network changes as well as on how patient players are.

For expositional simplicity, and in line with most of the research in the field, let us suppose that individuals are perfectly impatient: they care only about the immediate returns and ignore the longer term effects entirely. This leads to the myopic best response model of dynamics.

Time is a discrete variable and indexed by  $t = 1, 2, 3, \dots$ . Let  $g^t$  be the network/strategy profile at the start of time  $t$ . In each period, with probability  $p \in (0, 1)$ , a player gets an opportunity to revise her strategy. She knows the network that exists at that point in time, and she chooses links that maximize her payoff. In making her choices she assumes that the links of all other players do not change. If more than one profile of links is optimal then a player randomly picks one of them. Denote the strategy of a player  $i$  in period  $t$  by  $g_i^t$ . If player  $i$  is not active in period  $t$  then it follows that  $g_i^t = g_i^{t-1}$ . This simple best-response strategy revision rule generates a transition probability function  $P_{gg'} : \mathcal{G} \times \mathcal{G} \rightarrow [0, 1]$ , with  $\sum_{g'} P_{gg'} = 1$ , for every  $g \in \mathcal{G}$ . The dynamics of networks  $g^t$  obey this transition probability function. This defines a Markov chain: a strategy profile (or state),  $g$ , is said to be an absorbing state of the Markov chain if the dynamic process cannot escape from that state i.e.,  $P_{gg} = 1$ .

In some cases the process may not converge; in such cases, we will talk of absorbing set(s) of networks. An absorbing set is a collection of networks such that once the process reaches one of the networks in this set then it remains within this set forever after. Note that the set of all networks is clearly an absorbing set of the process. We will limit ourselves here to a discussion of the dynamics in general terms only.

A preliminary observation is that if the dynamics settle on a network, the absorbing state is a strict Nash equilibrium: clearly the absorbing network must be a Nash network, as otherwise one of the players has an alternative more profitable profile of links and will deviate in due course. In addition, we note that the randomization among best responses also means that a non-strict Nash equilibrium cannot be an absorbing network for the dynamic.

By way of illustration of some of the possibilities, Figure 3.7 presents the dynamics

of linking in the one-sided link formation model. We suppose that payoffs have a linear specification as in equation (3.5) and that  $c \in (0, 1)$ . The initial network (labelled  $t = 1$ ) has been drawn at random from the set of all directed networks with 5 agents. In period  $t \geq 2$ , the choices of agents who exhibit inertia have been drawn with solid lines, while the links of those who are active are drawn with dashed lines. Figure 3.7 suggests that the choices of individuals evolve rapidly and settle down by period 11: the limit network is a cycle.

This simulation motivates a more general question: under what conditions – on the structure of payoffs, the size of the society, and the initial network – does the dynamic process converge? Convergence of the dynamic process would suggest that individuals who are myopically pursuing self-interested goals, without any assistance from a central coordinator, are able to arrive at a stable network over time. It is possible to show that such a decentralized process does converge in the one-way flow model under fairly general circumstances; for the details of the arguments involved the interested reader is referred to Bala and Goyal [2000a].

In this example of the linear model with  $k \in (0, 1)$ , the cycle is the unique strict Nash network but if  $k \in (1, n - 1)$  then there exist two strict Nash networks, the cycle and the empty network. A possible question is whether one of the two networks is more stable or more likely to be picked by the dynamics. The problem of selection among strict Nash equilibria – through the introduction of trembles or noise – has been widely studied in the literature of evolutionary game theory. We will have to leave the subject here; for an elegant introduction to evolutionary approaches to equilibrium selection the interested reader is referred to Young [1998].

So far we have assumed that individual players know the network they located are in and therefore they can calculate the costs and benefits from different links. However, networks are complicated objects and even with a few players a great many structures can arise. Moreover, the fact that networks are subject to subtle transformations that are typically carried out at a local level suggests that it may be difficult for players to keep informed about the details of the evolving network. In chapter 11 below we will present experiments on the dynamics of linking and we will then see that the question of knowledge and the complexity of networks is important for understanding network formation.

### 3.4.2 Richer Models of Links

We have studied models in which links are binary – either a link is present or it is absent. This is in keeping with most of the literature to date. However, it is clear that in many contexts it is not just the existence of a link but the quality of the link that is important.

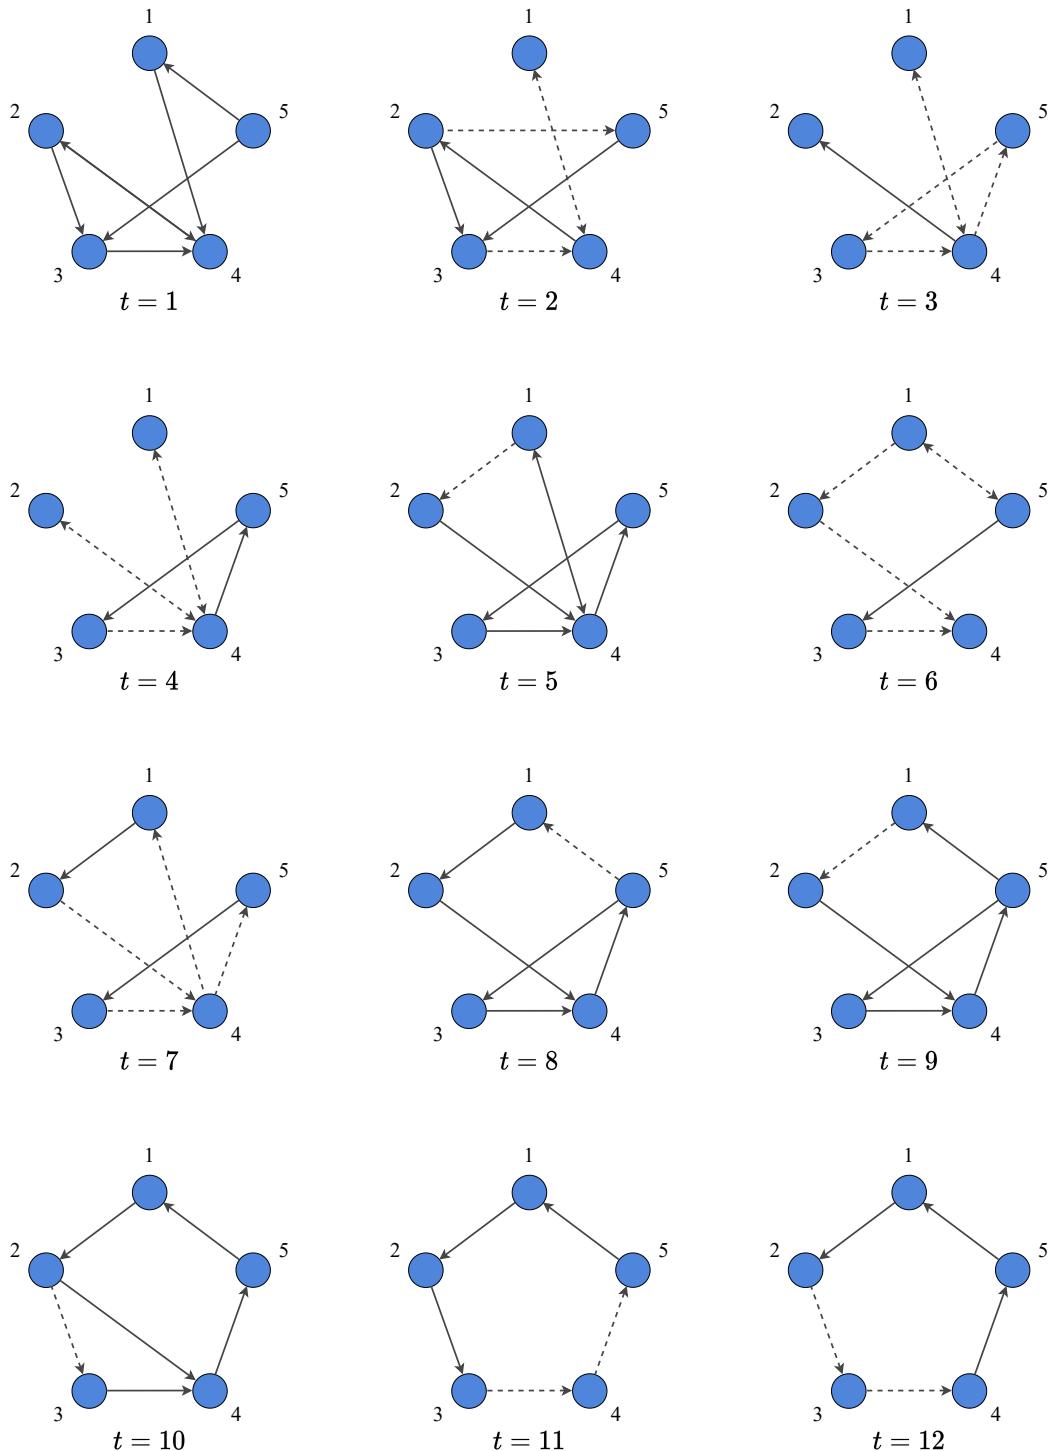

Figure 3.7: Best response network dynamics: taken from Bala and Goyal [2000a]

For instance, take the case of information on jobs. In his classical study, ‘The Strength of weak Ties’, Granovetter [1973] drew attention to the distinct roles of strong and weak ties in shaping the flow of information about jobs in a society. Following on this, Scott Boorman proposed a model of costly investments in strong and weak ties that help communicate information on jobs (Boorman [1975]). However, the modeling of weighted links presents a number of conceptual as well as mathematical challenges and progress has been slow. The discussion in this section draws attention to some of the these challenges.

We start with an approach that builds directly on the basic models of binary links presented in sections 3.2 and 3.3. The model is taken from Bloch and Dutta [2009]. The authors focus on an interpretation of communication networks – networks where agents derive positive benefits from the agents with whom they are connected, with benefits decreasing as the distance increases between two agents. The key point of departure is that links may have different quality depending on the investments that individuals make.. Assume that every individual has resources  $T$  that she can allocate across the links with the other  $n - 1$  individuals. Formally, for investments  $g_{ij}, g_{ji} \in \mathbb{R}_+$  by individuals  $i$  and  $j$ , let the quality of link between them be given by  $q_{ij} : \mathbb{R}_+ \times \mathbb{R}_+ \rightarrow [0, 1]$ . Observe that by suitably varying the nature of the function  $q_{ij}$  we can obtain the one-sided and the two-sided linking models studied earlier as special cases.

To develop intuitions on the forces driving the formation of weighted networks let us focus on a simple special case: suppose that the quality of the link is defined as an additive and separable function of individual investments. Moreover, suppose that the returns to individual investments have increasing returns.

$$q_{ij} = \phi(g_{ij}) + \phi(g_{ji}) \quad (3.16)$$

where  $\phi$  is an increasing and convex function with  $\phi(0) = 0$  and  $\phi(T) < 1/2$ . Thus quality of a link  $q_{ij} \in [0, 1]$ .

We next define the quality of a path as a product of the quality of the links on the path. As an example, the quality of a path consisting of three individuals A, B and C is simply  $q_{AB}q_{BC}$ . In this formulation observe that it is not just the length of a path but also the quality of the links in it that matters. We discuss efficient and equilibrium networks.

Our first observation is that the efficient network is a star. The argument for this result builds on the following intuitions. A star is connected (thus everyone accesses all other individuals), every peripheral agent concentrates their investment on a single link (which enhances quality of the link), and the distance between two nodes which are not directly connected is minimized. All these features contribute to making the star the natural can-

dicate for the efficient network. Turning to Nash equilibrium, if link strength is a strictly convex function of individual investments then the unique Nash equilibrium network is the star where the center of the star invests fully on just one link. The intuition for this result builds on the strict convexity of  $\phi$ : it implies that an individual will invest in at most one link. This more or less rules out all networks other than the star.

This discussion shows how the arguments presented in the context of the baseline binary model need to be modified to understand weighted networks. They also suggest that some of the results on the efficiency and stability of network architecture can be generalized to settings with richer linking possibilities. In this model, the investments of the individuals can be substituted in building up quality of link (as the investments enter in a separable form). We next turn to a setting in which the individual investments are complements in shaping the quality of the link.

We discuss a model taken from Baumann [2021]. Individuals allocate their resource  $T$  between a private/own activity  $t_{ii}$ , and in link specific activities  $t_{ij}$ , for  $j \in N \setminus \{i\}$ . An individual's strategy is given by a vector  $t_i = (t_{i1}, \dots, t_{ii}, \dots, t_{in})$ . A link between two individuals  $i$  and  $j$  exists if both of them make positive investments,  $t_{ij} > 0$  and  $t_{ji} > 0$ . Given a strategy profile  $s = (t_1, \dots, t_n)$  the utility of individual  $i$

$$u_i(t) = \sum_{j \neq i} t_{ij}^\beta t_{ji}^{1-\beta} + f(t_{ii}) \quad (3.17)$$

where  $\beta \in (0, 1)$  and where  $t_{ij}^\beta t_{ji}^{1-\beta}$  refers to returns from relation in which individuals  $i$  and  $j$  contribute  $t_{ij}$  and  $t_{ji}$ , respectively. The term  $f(t_{ii})$  refers to the return from contribution  $t_{ii}$  in own activities. It is assumed that return is increasing and concave, specifically that  $f' > 0$ ,  $f'' < 0$ ,  $f' \rightarrow \infty$  if  $t_{ii} \rightarrow 0$  and  $f'(T)$  is 'low enough'. Note that in this model the payoffs depend only on the quality of links with immediate neighbours. This simplification helps us in obtaining sharp results on patterns of investment in equilibrium.

Given the assumptions on reward function, it follows that in a Nash equilibrium every individual must fully use all his resources allocation

$$\sum_{j \neq i} t_{ij} = T \quad (3.18)$$

Moreover, if  $t_{ji} = 0$  then  $t_{ij} = 0$ . Finally, if  $t_{ji} > 0$ , then  $t_{ij} > 0$  and

$$\beta \left( \frac{t_{ji}}{t_{ij}} \right)^{1-\beta} = f'(t_{ii}). \quad (3.19)$$

In addition, it follows from the assumption  $f'(t) \rightarrow \infty$  for  $t \rightarrow 0$  that  $t_{ii} > 0$ , for all individuals in a Nash equilibrium.

Observe that due to the complementarity in the link quality, there is always an equilibrium in which no one invests in any links with others. Our interest is in equilibria that contain ‘active’ links. In such an equilibrium the marginal returns to investment in own activity must equal the marginal return to investment in any link, i.e,

$$\beta \left( \frac{t_{ji}}{t_{ij}} \right)^{1-\beta} = \beta \left( \frac{t_{ki}}{t_{ik}} \right)^{1-\beta} = f'(t_{ii}). \quad (3.20)$$

This means that the ratio of investments for individual  $i$  must be the same for every link in which he is active: Let us define

$$q_i = \frac{t_{ji}}{t_{ij}} = \frac{t_{ki}}{t_{ik}}. \quad (3.21)$$

In equilibrium a neighbour of  $i$  (say)  $j$  faces a ratio  $q_j$  that is the inverse of  $q_i$ :

$$q_j = \frac{t_{ij}}{t_{ji}} = \frac{1}{q_i}. \quad (3.22)$$

Consider a connected network of active ties. In such an equilibrium network, if the ratio of effort for an individual is different from 1, then the ratios will alternate across neighbours. Therefore in a connected network of active links, the individual ratios must take on two values  $q'$  and  $1/q'$ . This yields a simple characterization of Nash networks

1. reciprocal:  $q_i = 1$  for all  $i$ . Every player chooses same self-investment  $t_b$  where  $\beta = f'(t_b)$ .
2. non-reciprocal: concentrated  $q_i > 1$  for some  $i$  with self-investment  $t_c$  where  $\beta(1/q_i)^{1-\beta} = f'(t_c)$  and diversified  $q_j < 1$  for some  $j$  with self investment  $t_d$   $\beta(q_j)^{1-\beta} = f'(t_d)$

Given a non-reciprocal network  $t$  and a reciprocal network  $t'$

$$\beta \left( \frac{1}{q'} \right)^{1-\beta} = f'(t_c) < \beta = f'(t'_b) < \beta(q')^{1-\beta} = f'(t_d). \quad (3.23)$$

As  $f$  is concave, this yields us the following ranking of investment in links:  $t_d < t'_b < t_c$ . This in turn induces an ordering of utility levels:

$$u_d(t) > u_b(t') > u_c(t) \quad (3.24)$$

Figure 3.8: Weighted Nash Networks

Figure 3.8 presents examples of reciprocal and non-reciprocal Nash networks.

Let us draw out implications of reciprocal and non-reciprocal investments for network topologies. First observe that regular networks are sustainable via reciprocal investments. On the other hand, a network with a ‘leaf’ cannot be sustained in a reciprocal equilibrium in a connected network with 3 or more individuals: this is because reciprocity would mean that  $q = 1$  for leaf and its neighbour. This would in turn rule out investments by the non-leaf individual in other links. Observe that leaves are easily sustained in a non-reciprocal networks.

This brief discussion does not do justice to the large literature on the subject of weighted networks. The aim has been much more modest: to draw attention to some of the challenges involved in moving from binary to weighted links. We see that results on network topologies obtained in the binary link model can sometimes be extended to weighted counterparts (though the arguments are significantly more complicated) but that there arise interesting asymmetries in patterns of investment between neighbours that are intimately connected to the network topology. The area of weighted networks remains a very active field of research; the readings section provides references.

### 3.4.3 Generic investments and random linking

In the models presented we took the view that individuals make decisions on individual links and in computing their benefits and costs they were informed about the details of the links in the entire network. In some contexts – examples include parent teacher associations, neighbourhood groups, and professional conferences – it is perhaps more plausible to think of the ‘network’ in a more generic sense and imagine that individuals contemplate the issue in terms of how much time or resources they will allocate to interacting with different groups of individuals (such as friends, neighbours, professional colleagues and sports contacts). In these contexts, we are interested in the amount of time/resources that different groups of individuals spend in these forums and how that would affect the

returns to taking part in them oneself. In this approach the exact details of who links with whom no longer occupy central stage. Rather we are interested in the ‘thickness’ of interaction or the macroscopic level of the network. These considerations suggest a simpler and more direct approach to the problem of network formation. This section discusses a strand of the literature that takes this ‘social investments’ perspective.

We start with a model taken from Cabrales, Calvo-Armengol, and Zenou [2011]. In this model, individuals take two decisions that pertain to ‘production’ and ‘socialization’. Individual payoffs depend on own and others’ production efforts and these spill-overs are mediated through the social links between individuals.

There are  $n$  players with types/values  $0 < b_1 < \dots < b_n$ . Player  $i$  chooses a strategy,  $s_i = (e_i, g_i)$  comprising of productive effort  $e_i$  and a synergy effort  $g_i$ . Both socialization and effort are costly and the returns depend on the synergy strength between individuals. Given a profile of strategies  $s = (s_1, \dots, s_n)$  the payoffs to player  $i$  are:

$$u_i(s) = b_i e_i + \sum_j g_{ij} e_i e_j - \frac{c}{2} e_i^2 - \frac{1}{2} g_i^2 \quad (3.25)$$

where  $c > 0$  refers to the relative cost of productive effort. The link quality or intensity is constructed as follows: for a profile of investments  $g = (g_1, \dots, g_n)$  for any pair  $i, j$  the link intensity

$$g_{ij}(g) = \frac{g_i g_j}{\sum_k g_k} \quad (3.26)$$

This formula captures two intuitive ideas: one, that weight of a link between two individuals is increasing in each of their investments and two, that it is decreasing in the sum total of all investments of everyone.

As in the earlier models with two-sided links, there is a coordination aspect to investing in social interaction: specifically, if everyone else chooses zero social interaction then there is no return to investing in social interaction and so zero investment is always an equilibrium. The more interesting case concerns positive social investments. An important feature of the model is the complementarity between social interaction and efforts – reflected in the term  $\sum_j g_{ij} e_i e_j$  – and this can give rise to multiple (interior) equilibria. In other words, there exists a low interaction plus modest effort equilibrium and a high interaction plus high effort equilibrium. As the game exhibits complementarities, the effects of changes in parameters can be studied classical methods (as for instance in Topkis [1998]).

A second strand of the literature examines models of linking in which individuals propose a single scalar number, as in the model above, but the payoffs depend on the macro-

scopic properties – such as connectedness and giant component – of the random graph that they create. We will present a model taken from a recent paper by Dasaratha [2021].

Suppose there are  $N = \{1, \dots, n\}$ ,  $n \geq 3$  individuals. Every individual has a distinct idea  $a_i \in \mathbb{N}$ . An individual can earn payoffs only if she has access to a technology: a technology consists of  $L > 1$  ideas. Moreover, due to the competitive nature of the setting an individual earns this payoff only if she is the only person to have these  $L$  ideas. We may think of the size of  $L$  as a measure of the complexity of the technology.

The goal of a firm is to form connections so as to access  $L$  distinct ideas. The firm accesses ideas from others by choosing a level of openness,  $q_i \in [0, 1]$ . The level of openness refers to the how secretive or collaborative it will be, e.g., should it locate near or far from other firms, should it be liberal in sharing its intellectual advances with employees and encouraging informal interactions of its employees.

Greater openness is, however, a double edged sword: it facilitates access to other firms' ideas but also makes it's own idea more easily accessible to other firms. Given openness  $q_i$  and  $q_j$ , we say that a firm  $i$  learns the idea of firm  $j$  with probability

$$p_i(q_i, q_j) = q_i q_j \quad (3.27)$$

A key element of the process is that the learning is directed: so firm  $i$  may learn from firm  $j$  without the converse being true, i.e., the random variable  $p_{ij}$  is realized independently of  $p_{ji}$ . Importantly, however, notice that increasing  $q_i$  leads to a higher learning probability for both firms  $i$  and  $j$ .

The next important element is indirect learning: when  $i$  learns from  $j$ , it also gains access to the ideas that  $j$  has learnt from other firms. Conditional on connecting with  $j$  there is a probability  $\delta \in [0, 1]$  that it learns the ideas that firm  $j$  has learnt directly or indirectly through its connections. To complete the description of the learning process, we note that the realizations with respect to learning are independent and occur simultaneously.

Let us say a few words on the on the notion of a 'technology' here. A technology,  $t$ , is defined as a set of  $L$  distinct ideas. We will say that individual  $i$  has exclusive access to technology  $t$  if it contains  $i$ 's idea,  $a_i \in t$ , individual knows all the ideas contained in  $t$ , and no other individual knows all these ideas. Figure 3.9 illustrates the exclusive access of individual  $i$  to a technology consisting of ideas from three individuals. An individual earns 1 from every technology to which it has exclusive access. We can consider these as proprietary technologies for  $i$ . On the other hand,  $i$  receives zero payoff from those technologies that it knows along with other individuals. Given a profile of openness choices  $q$ , the expected earnings of firm  $i$  are simply the expected number of exclusive technologies, i.e.,

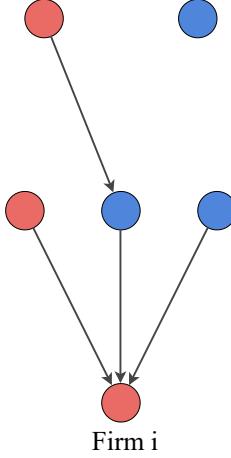

Figure 3.9: Exclusive Technology for firm  $i$ :  $L = 3$

$$U_i(q) = E[PT_{ij}] \quad (3.28)$$

where  $PT_i$  is the number of exclusive technologies of individual  $i$ . We study Nash equilibria in openness levels and comment on their social efficiency.

Let us start by drawing out some of the economic forces at work. First note that a profile  $q$  gives rise to a directed graph that tells us who will have access to which ideas. The value of openness to a firm will depend on how open other firms are. Greater openness of other individuals creates two conflicting pressures: one the one hand, it makes them more likely to have more ideas to share and this increases the value of accessing them, but on the other hand, as each of them have access to many ideas it is not necessary to access many of them and this lowers the value of openness. This conflicting impact of openness of others is central to an understanding of equilibrium.

The analysis will build on our discussion of random graphs and in particular on the thresholds of sharp transitions (that were identified in the chapter on random graphs). As in the case of random graphs, the arguments will apply as the number of individuals,  $n$ , gets large. We will say that (the symmetric level of) openness  $q$  is sub-critical if expected number of links where an individual learns indirectly is less than 1 (i.e.,  $p(q, q)\delta n < 1$ ), it is critical if the other ideas learnt is 1, and it is super-critical if expected number of new ideas learnt is greater than 1.

These thresholds are helpful as we can apply methods from random graph theory (see the discussion on transition thresholds in the chapter on random origins) to infer that the number of ideas learnt by an individual in each region can be pinned down as follows. In the sub-critical region all firms learn at most  $o(n)$  ideas (i.e., the number of ideas is

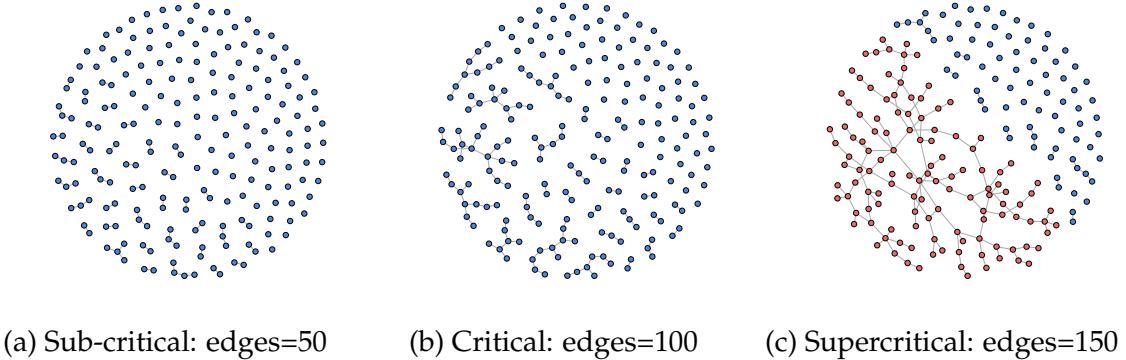

Figure 3.10: Regions and component sizes:  $n=200$

negligible relative to value of  $n$  when  $n$  is large); in the critical region individuals learn an intermediate number of ideas, while in the super-critical a positive fraction of individuals learn  $\gamma n$  ideas, for  $\gamma \in (0, 1)$ , while all other firms learn  $o(n)$  ideas. Figure 3.10 illustrates the role of openness – and number of links – in shaping access to others' ideas.

In this setting, it can be shown that for *large enough  $n$  a symmetric equilibrium has a critical level of openness*.

Let us discuss the intuition underlying this result as it gives us a first glimpse of the forces driving knife-edge properties of equilibrium networks that also obtain in other applications such as financial networks and supply chains. By definition, at the optimal level of openness,  $q$ , it must be the case that the marginal cost of raising openness must be equal to the marginal return from openness. The marginal cost comes in the form of giving up possible exclusivity to technologies, while the marginal return takes the form of exclusive access to new technologies. Marginal costs to links increase in 'number' of links as an individual has more to lose from their idea leaking through the increased openness of everyone. So to sustain a high interaction rate equilibrium, marginal returns to links must also increase in overall openness. In other words, we need openness of different individuals to be complements. However, in the supercritical region the network will contain a giant component and adding openness serves to lower exclusivity, i.e., the levels of openness of individuals are substitutes. On the other hand, in the sub-critical region, the marginal cost of losing access to exclusive technologies is small as there are no large components. This pushes up the openness level. In this way, economic pressures push individuals to create networks at the critical threshold.

In these models, individuals choose a single level of interaction that helps define a probability of being connected to any other individual. It is possible to take this one step further and to say that individuals choose a number of links. This is the approach proposed

in Goyal and Sadler [2021]. In their model, choices on number of links are mapped on to a degree distribution using the configuration model (for a discussion of the configuration model see the chapter on random origins). The motivation is similar to the model of linking and assorted activity discussed above. Players can invest effort to obtain a discrete piece of information and they can also invest in costly links that can transmit information. Individuals choose the probability of obtaining the information  $x \in X = [0, 1]$  and the number of links  $d \in \mathbb{N}_+$ . The types of individuals lie in the set  $T = \mathbb{R}_+$ ; we assume that the distribution of types  $F$  is continuous with full support. We interpret  $x \in X$  as the probability with which a player independently obtains the information and  $t \in T$  as the cost of a link. A player learns the information either if she discovers it herself or if she is path-connected to a player who learns it. Learning the information yields a payoff of 1, but choosing strategy  $(x, d)$  incurs the cost  $x^2 + td$ . Hence, player  $i$  earns the expected payoff

$$u_i = \mathbb{P}(i \text{ learns the information}) - x_i^2 - t_i d_i. \quad (3.29)$$

The game proceeds as follows: players realize their private costs, make investments  $x$  and link requests  $d$ , the network forms, and payoffs are realized. A symmetric strategy profile  $\sigma(t) = (d(t), x(t))$  specify how many links to request and how much to invest in information as a function of the link cost parameter  $t$ . It is possible to show that given a type distribution there exists a symmetric equilibrium (in which a player's strategy is only a function of her type). This equilibrium generates a degree distribution and also a probability of learning the information and the corresponding payoffs. Lower cost types form more links and exert less personal effort and have a higher probability of learning the true state and they earn higher payoffs. We leave the discussion of this model here; the interested reader is referred to Goyal and Sadler [2021] for further details.

### 3.4.4 Combining linking with assorted activity

In the baseline models individuals choose links with each other. In many of the examples we studied in Chapter 1 individual entities choose links and also make choices on related activities. For instance, on Twitter, they choose links as well as the level of tweeting and retweeting; on Facebook, they choose friendship links and different types of participation. Similarly, a researcher or a firm chooses who to collaborate with and also chooses how much effort/investment to put in these collaborations. If we reflect on these examples we see that the level of activity will affect the rewards of linking and vice-versa. This consideration motivates a large and very active economics literature that explores models of network formation alongside related activities. In this section, we illustrate the interaction

between linking and related activity by adding an activity alongside linking in the one-sided link model from section 3.2. We will then comment briefly on a range of assorted activities and discuss the potential role of linking.

Let us begin by adding an effort dimension to the one-sided linking model in section 3.2. An individual chooses links with a subset of others,  $g_i$ , and an effort level  $x_i \in \mathbb{R}_+$ . A strategy of individual  $i$  is given by  $s_i = (g_i, x_i)$  and the profile of strategies is denoted by  $s = (s_1, \dots, s_n)$ . We set  $N_i^l(g)$  as the set of individuals who lie at distance  $l$  of  $i$  in the (directed) network  $g$ . Following Galeotti and Goyal [2010], we shall say that given a strategy profile  $s$  the payoffs of an individual  $i$

$$\Pi_i(s) = f(x_i + \sum_{l=1}^{l=n-1} a_l \sum_{j \in N_i^l} x_j) - cx_i - d_i(g)k \quad (3.30)$$

where  $a_l \geq 0$ , and  $a_{l+1} \leq a_l$ , for all  $l \geq 1$ ,  $c > 0$  and  $k > 0$ , and  $d_i$  is the number of links created and paid for by individual  $i$ . To see how activity and linking can powerfully shape networks, we use a specific functional form for the reward function (Goyal, Rosenkranz, Weitzel, and Buskens [2017]):

$$f(y) = \begin{cases} y(29 - y) & \text{if } y \leq 14 \\ 196 + y & \text{else} \end{cases} \quad (3.31)$$

Suppose to fix ideas that the per unit cost of information  $c = 11$  and that  $a_l = 1$  for all  $l \geq 1$ , i.e., there is no decay. Recall that in the one-sided model with no decay, the cycle containing all nodes in the unique non-empty equilibrium network (see 3.1). Let us see how adding an effort level alters this prediction.

Consider an individual in isolation who chooses 9. Observe that this is the optimal effort level for someone in isolation under reward function  $f$ . What would be the response of the other individuals? To fix ideas, consider an individual and label him ‘B’: how much effort should she exert and should she link with A? B accesses 9 units if she links with A. The cost of this effort is  $11 \times 9 = 99$  and it costs  $k$  to access A. So it is in her interest to link with A if  $k < 99$ . Observe that once an individual links with A, she has access to 9 units of effort, so the incremental value of additional information is smaller than the cost of information: she will choose personal effort level 0. The same reasoning applies to all individuals other than A. Therefore, the star network with A choosing effort 9, all other individuals choosing effort 0, and forming a link with A constitutes an equilibrium.

This argument helps bring out the dramatic impact of adding an effort dimension to the basic linking problem: we move from a cycle containing all individuals to a star network

in which the spokes form a link with the hub and make zero effort while the hub forms no links and makes effort 9. The chapter on the Law of the Few will develop the theoretical arguments more fully and will also present an experiment.

The economics literature has developed a range of models to explore the interplay between linking and assortative activity. We next present some of the important lines of enquiry – that deal with coordination, cooperation, exchange and intermediation, and collaboration and competition and we point to chapters where they are discussed at length.

**The problem of coordination:** The problem of coordination arises in its simplest form when the optimal course of action for an individual is to conform to what others are doing. If there is more than one possible course of action then individuals have to coordinate on one of these actions. One simple example is the choice of software to draft documents or to communicate. As we work with colleagues, we have a preference to choose the software that they are using. This suggests that the network of interaction could shape the ways in which individuals solve their coordination problems; in a highly integrated group individuals may opt for a common course of action, while in fragmented groups, segments might follow different courses of action. The reasoning can well flow the other way: individuals may organize into different segments and choose different actions if they have different preferences over these actions. What are the circumstances under which we expect to see social conformism and diversity? Can societies get locked into inefficient courses of action? How does the network shape the openness of a society to change and movement from an inefficient to an efficient norm? The chapter on social coordination studies the role of linking in shaping social coordination.

**The problem of cooperation:** This arises in its simplest form when we consider situations that arise over time: an individual has need for support at a point in time that can be provided by another individual. The key point to note is that the benefit to the recipient is greater than the cost of support to the provider. To the extent that different individuals need support over time it is in their collective interest to provide mutual support. However, at any instant in time an individual who is asked to provide support is better off by not offering it. As is clear from this description, the potential provider may be persuaded to provide support through an appeal to enlightened self-interest: by refusing to provide support today she forgoes the chance of receiving help in the future from the person currently in need. This bilateral cost-benefit may however not be sufficient as such opportunities may arise insufficiently often. This brings into play the possibility that connections with other individuals may be brought into play. This points to the role of networks of mutual support. A large body of work has studied the role of social structure in sustaining coop-

eration. More recent work has incorporated the idea that the network itself is evolving and endogenous. Economists have traditionally studied questions of cooperation, norms and trust using models of repeated games. The chapters on trust and on scaling up present models of networks, repeated games, trust and cooperation.

**Exchange, intermediation, and brokerage:** The terms on which individuals carry out exchange with each other will depend on the outside options they have. Here exchange may be direct when a buyer purchases an object from a seller or it may be indirect when a buyer purchases something from a seller but through intermediaries. In the first case, for example, a buyer who has links with many potential sellers is likely to have greater bargaining power. In the second case of indirect exchange, a pair of buyer and seller are likely to pay less to intermediaries if there are multiple (paths of) intermediaries available to them. These observations have led to a study of the ways in which networks shape the terms of exchange among individuals. As networks can have powerful effects on terms of trade and earnings, it is natural for individuals to try and shape the networks within which they conduct exchange. The formation of exchange networks has been the subject of an extensive body of research in economics (and in computer science and sociology). The problem of exchange in networks is studied in the chapter on networked markets while brokerage rents are studied in the chapter on market power and intermediation.

**Collaboration and competition:** Firms collaborate to share knowledge and innovate and to become more competitive in the market; similarly, individual researchers collaborate to explore ideas and to conduct research. An important feature of such collaborations is that they are extensive and that they are non-exclusive (A may collaborate with B who may collaborate with C, but A and C do not collaborate with each other). These collaborations shape the speed and the level of innovation and can have a decisive impact on the relative performance of individuals. Discussions on empirical aspects of scientific collaboration networks are spread across different chapters of the book; the chapter on networked markets takes up formal models of oligopolists forming research collaboration networks to compete in a market.

### 3.5 Appendix: Advanced Material on Solution Concepts

An important part of the appeal of pairwise stability is its great simplicity. In this section we elaborate on some aspects of the concept and develop conditions for its existence. We also discuss elaborations on the concept. The results are taken from Jackson and Watts [2001] and the exposition is based on Goyal [2007a].

Recall the definition of a pairwise stable network:

**Definition 3.2.** A network  $g$  is pairwise stable if:

1. For every  $g_{ij} = 1$ ,  $\Pi_i(g) \geq \Pi_i(g - g_{ij})$  and  $\Pi_j(g) \geq \Pi_j(g - g_{ij})$
2. For  $g_{ij} = 0$ ,  $\Pi_i(g + g_{ij}) > \Pi_i(g) \implies \Pi_j(g + g_{ij}) < \Pi_j(g)$ .

We will exploit the ideas of improving paths and cycles, due to Jackson and Watts [2001]. An improving path is a sequence of networks that can emerge when individuals form or sever links based on individual payoff considerations.

**Definition 3.3.** An improving path from a network  $g$  to a network  $g'$  is a finite sequence of networks  $g^1, g^2, \dots, g^k$ , with  $g^1 = g$  and  $g^k = g'$  such that for every  $l \in \{1, 2, \dots, k-1\}$ , either

1.  $g^{l+1} = g^l - g_{ij}$  for some  $g_{i,j}^l = 1$  and  $\Pi_k(g^l - g_{ij}) > \Pi_k(g^l)$  for  $k \in \{i, j\}$ , or
2.  $g^{l+1} = g^l + g_{ij}$  for some  $g_{i,j}^l = 0$  and  $\Pi_i(g^l + g_{ij}) > \Pi_i(g^l)$  and  $\Pi_j(g^l + g_{ij}) \geq \Pi_j(g^l)$ .

A set of networks  $\hat{\mathcal{G}}$  forms a *cycle* if for any  $g, g' \in \hat{\mathcal{G}}$  (which includes  $g = g'$ ), there exists an improving path from  $g$  to  $g'$ . A cycle  $\hat{\mathcal{G}}$  is *maximal* if it is not a proper subset of any other cycle, while a cycle  $\hat{\mathcal{G}}$  is *closed* if no network in  $\hat{\mathcal{G}}$  lies on an improving path leading to a network which does not lie in  $\hat{\mathcal{G}}$ .

A sufficient condition for the existence of pairwise stable network is that there does not exist an improving path starting from every network; in a game with finite number of players (and therefore also a finite number of networks) a sufficient condition for this is that there are no cycles of improving paths in the network. We develop conditions on payoff functions in network formation games which rule out cycles. These conditions suggest that payoffs should exhibit a form of monotonicity.

It is convenient to write a network formation game slightly more generally as follows. There is a set of players  $N = \{1, 2, \dots, n\}$ , a value function  $V : \mathcal{G} \rightarrow \mathbb{R}$ , which defines the aggregate value generated by any network  $g$ , and an allocation function  $\Pi : \mathcal{G} \rightarrow \mathbb{R}^n$ , which specifies, for each network  $g$ , the payoff accruing to every player in the network.

The following result, due to Jackson and Watts [2001], provides a result on existence.

**Proposition 3.6.** For any value function  $V$  and any allocation function  $\Pi$ , there exists at least one pairwise stable network or a closed cycle of networks.

*Proof:* Start with a network  $g$ . If it is pairwise stable then the proof is done. So suppose it is not pairwise stable. This means there exists an improving path leading away from it. If

this improving path ends at some network that network is pairwise stable network, and the proof is done. So suppose that there is no end network: given the finiteness of the game there must exist a cycle. So suppose there exists no pairwise stable network. First, note that since  $G$  is finite there must exist a maximal cycle. Second, consider the set of maximal cycles, and note that at least one of them must have no path leaving it. If all maximal cycles had paths leaving them then there would be a larger cycle containing two or more of such cycles, which would be a contradiction to the hypothesis that these cycles are maximal. Thus at least one maximal cycle must be closed. ■

Ruling out closed cycles is one simple way to guarantee the existence of pairwise stable networks. The following terminology is used in the next result. For a given game of network formation, denote the existence of an improving path from  $g$  to  $g'$  by  $g \rightarrow g'$ . Clearly  $\rightarrow$  is a transitive relation, and so it follows that there are no cycles if and only if  $\rightarrow$  is asymmetric. Two networks  $g$  and  $g'$  are *adjacent* if they differ by one link only.  $V$  and  $\Pi$  exhibit no indifference if for any two adjacent networks  $g$  and  $g'$ , either  $g$  defeats  $g'$  or vice-versa. Note that a network  $g$  defeats another network  $g'$  if there is an improving path from  $g'$  to  $g$ . Our next result provides a useful characterization result on the existence of cycles.

**Proposition 3.7.** *Fix a value function  $V$  and an allocation function  $\Pi$ . If there exists a function  $\mathcal{W} : \mathcal{G} \rightarrow \mathcal{R}$  such that  $[g' \text{ defeats } g] \Leftrightarrow [\mathcal{W}(g') > \mathcal{W}(g) \text{ and } g \text{ and } g' \text{ are adjacent}]$  then there are no cycles. Conversely, if  $V$  and  $\Pi$  exhibit no indifference, then there are no cycles only if there exists a function,  $\mathcal{W} : \mathcal{G} \rightarrow \mathcal{R}$  such that  $[g' \text{ defeats } g] \Leftrightarrow [\mathcal{W}(g') > \mathcal{W}(g) \text{ and } g' \text{ and } g \text{ are adjacent}]$ .*

**Proof:** Consider the first statement. This is equivalent to saying that if there exists a cycle then there cannot exist such a  $\mathcal{W}$ . Suppose not and there exists such a  $\mathcal{W}$  function. Then by transitivity of  $>$ , it follows that  $\mathcal{W}(g) > \mathcal{W}(g)$ , which is impossible. So the existence of cycles precludes any  $\mathcal{W}$  function which satisfies the mentioned properties.

Consider the second statement. Assume that there are no cycles and also that for any adjacent pair of networks  $g$  and  $g'$ , either  $g$  defeats  $g'$  or vice-versa. The proof shows that there exists such a  $\mathcal{W}$  satisfying the desired properties. This step exploits Proposition 3.2 in Kreps [2018], which is stated below for easy reference. A binary relation  $b$  is negative transitive if the converse relation  $\text{not-}b$  is transitive.

**Lemma 3.1.** *If  $X$  is a finite set and  $b$  is a binary relation, then there exists  $\mathcal{W} : X \rightarrow \mathcal{R}$  such that  $\mathcal{W}(x) > \mathcal{W}(y) \Leftrightarrow xby$ , if and only if  $b$  is asymmetric and negatively transitive.*

Since there are no cycles, the binary relation  $\rightarrow$  is acyclic and therefore asymmetric. The relation  $\rightarrow$  is transitive by the definition of an improving path. However, the relation  $\text{not-}\rightarrow$  is not necessarily transitive.

Here is an example: let  $n = 5$  and start with a cycle network,  $g^{cycle}$ . Suppose that in the network  $g^{cycle} + g_{12}$  the payoffs of players one and two fall by 1 each while all other payoffs remain the same, relative to  $g^{cycle}$ . Proceed next to a network  $g^{cycle} + g_{12} + g_{34}$ , in which the payoffs of players three and four fall by 1 each, relative to network  $g^{cycle} + g_{12}$ . Finally, consider the network  $g^{cycle} + g_{34}$ , in which the payoffs of players one and two fall by 1 each while the payoffs of players three and four increase by 2 each, relative to  $g^{cycle} + g_{12} + g_{34}$ . The payoff of player five remains unchanged throughout. So we have a situation in which  $g^{cycle} + g_{12} \not\rightarrow g^{cycle} + g_{12} + g_{34} \not\rightarrow g^{cycle} + g_{34}$  but  $g^{cycle} + g_{12} \not\rightarrow g^{cycle} + g_{34}$  does not hold, since there is an improving path  $g^{cycle} + g_{12} \rightarrow g^{cycle} \rightarrow g^{cycle} + g_{34}$ .

Therefore a relation  $b$  has to be constructed such that (i)  $g \rightarrow g'$  implies that  $g' b g$ , (ii) if  $g$  and  $g'$  are adjacent, then  $g \rightarrow g'$  if and only if  $g' b g$ , and (iii)  $b$  is asymmetric and negatively transitive. Then the above Lemma can be applied to obtain a  $\mathcal{W}$ , and the Theorem 3.7 follows from property (ii). The construction of  $b$  is now presented.

**Case 1:** For every distinct pair of networks,  $g$  and  $g'$ , at least one of the following holds:  $g \rightarrow g'$  or  $g' \rightarrow g$ . Set  $g' b g$  if and only if  $g \rightarrow g'$ . We show that this relation is negatively transitive. Define  $g \text{ nb } g'$  if  $g \not b g'$  fails to obtain. Suppose that  $g \text{ nb } g'$  and  $g' \text{ nb } g''$ . Given the definition of  $b$ , this means that  $g' b g$  and  $g'' b g'$ . It then follows from the transitivity of  $b$  that  $g'' b g$ , which in turn implies, by asymmetry of  $b$  and definition of  $\text{nb}$ , that  $g \text{ nb } g''$ .

**Case 2:** There exist distinct  $g$  and  $g'$  (which are not adjacent) such that  $g \not\rightarrow g'$  and  $g' \not\rightarrow g$ . Define the binary relation  $b_1$  as follows. Let  $g'' b_1 g'''$  if and only if  $g''' \rightarrow g''$ , except on  $g$  and  $g'$  where set  $g' b_1 g$ . Note that by construction (i) and (ii) are satisfied and also note that  $b_1$  is acyclic (and hence asymmetric). To see the acyclicity of  $b_1$ , note that if there is a cycle then it would have to include  $g$  and  $g'$ , as this is the only point at which  $b_1$  and  $\rightarrow$  disagree. However, the existence of such a cycle would imply that  $g' \rightarrow g$ , which is a contradiction. Next define  $b_2$  by taking all the transitive implications of  $b_1$ . Again, (i) and (ii) are true of  $b_2$ . By construction  $b_2$  is transitive. Next it is shown that  $b_2$  is acyclic. This is shown by construction. Add one implication from  $b_1$  and transitivity at a time and verify acyclicity at each step. Consider the first new implication that is added and suppose that there exists a cycle. Let  $g'''$  and  $g''$  be the networks in question. So  $g'' b_1 g'''$  and  $g''' \text{ nb}_1 g''$ , but  $g'' b_2 g''$ , and there exist a sequence of networks  $\{g_0, g_1, \dots, g_r\}$  such that  $g''' b_1 g_0 b_1 g_1 \dots b_1 g_r b_1 g''$ . This implies that there exists a cycle under  $b_1$ , which is a contradiction. Iterating this argument implies that  $b_2$  is acyclic.

Now consider cases 1 and 2, when  $b_2$  is substituted for  $\rightarrow$ . Iterations on this process lead to a case where  $b_k$  has been constructed and relative to  $b_k$  this is then Case 1. Iterating on the argument under case 2 it follows that (i) and (ii) will be true of  $b_k$  and  $b_k$  will be transitive and asymmetric. Then by the argument under Case 1,  $b_k$  will be negatively transitive. Set

$b = b_k$  and the proof is complete. ■

While pairwise stability is a useful first check for strategic stability, only a relatively small set of possible deviations are ruled out – for instance, the deletion of only one link is contemplated, and the simultaneous addition and deletion of links is not allowed. We briefly discuss ways in which these considerations can be taken into account.

Let us consider an example in which the deletion or an addition of a link by itself is not profitable, but the deviation in which several links are deleted together is profitable.

**Example 3.1.** Deleting a subset of links.

Suppose  $n = 4$ . Assume that the payoffs satisfy  $\Pi_i(g^c) = 10$  for all players, while  $\Pi_i(g) = 15$  in every network  $g$  in which player  $i$  has no links. In a network  $g$  where two players have 3 links each and two players have 2 links each, the payoffs to players with 3 links are 9 while the payoffs with 2 links are 8, respectively. The complete network is clearly pairwise stable, since no player has an incentive to delete a single link. However, a player would strictly profit from deleting all links. ■

The notion of pairwise equilibrium addresses this concern directly by supplementing the idea of Nash equilibrium with the requirement that no pair of players wishes to form an additional link.

**Definition 3.4.** A network  $g^*$  can be sustained in a pairwise equilibrium if:

1. There is a Nash equilibrium  $s^*$  which yields  $g^*$ .
2. For any  $g_{ij}(s^*) = 0$ ,  $\Pi_i(g(s^*) + g_{ij}) > \Pi_i(g(s^*)) \implies \Pi_j(g(s^*) + g_{ij}) < \Pi_j(g(s^*))$ .

A feature of pairwise stability is that deviations in which a pair of players each deletes one or more links *and/or* add a link in a coordinated manner are not allowed. In some games it is possible that deleting a subset of links is not profitable for any single player *and* adding a link is not profitable for any pair of players either, but it is profitable for a pair of players to simultaneously delete a subset of their current links and add a link. The following example illustrates this possibility.

**Example 3.2.** Simultaneous deletion and addition of a link.

Consider a game with  $n = 4$ . Assume the following payoffs: any isolated player earns 0; in a line network, the two central players earn 25 each while the end players earn 10 each; in a cycle network every player earns 20 each; in a network with a cycle and an additional

link the payoffs of the players with two links each is 20, while the payoffs of the three link players is 15 each. Then it follows that the cycle is a pairwise equilibrium. However, if players can delete links and add a link at the same time then two players in the cycle can make a coordinated move – which yields a line network with themselves as the central players – and thereby increase their payoffs. Thus the cycle is not stable with respect to coordinated deviations. ■

The notion of bilateral equilibrium addresses these concerns. Define  $s_{-i-j}$  as the strategy profile  $s$  less the strategies of players  $i$  and  $j$ , i.e.,  $s_{-i-j} = \{s_1, \dots, s_{i-1}, s_{i+1}, \dots, s_{j-1}, s_{j+1}, \dots, s_n\}$ .

**Definition 3.5.** A network  $g^*$  is a bilateral equilibrium if:

1. There is a Nash equilibrium strategy profile  $s^*$  which yields  $g^*$ .
2. For any pair of players  $i, j \in N$ , and every strategy pair  $(s_i, s_j)$ ,

$$\Pi_i(g(s_i, s_j, s_{-i-j}^*)) > \Pi_i(g(s_i^*, s_j^*, s_{-i-j}^*)) \Rightarrow \Pi_j(g(s_i, s_j, s_{-i-j}^*)) < \Pi_j(g(s_i^*, s_j^*, s_{-i-j}^*)). \quad (3.32)$$

Thus a given network can be supported in a ‘bilateral equilibrium’ if no player or pair of players can deviate (unilaterally or bilaterally, respectively) and benefit from the deviation (at least one of them strictly). We note that bilateral equilibrium is a special case of the well known concept of strong equilibrium – it is special in the sense that only two player subsets are allowed (strong equilibrium was introduced in Aumann [1959]). The characterization of conditions on payoffs for the existence of bilateral equilibrium appears to be an open problem.

## 3.6 Reading Notes

The beginnings of an economic approach to network formation can be traced to Boorman [1975] who studied workers in a labour market. The model captures two key ideas in the theory of network formation: link formation has costs and benefits for the individual and it also generates externalities on others (we give a brief overview of the Boorman model in the chapter on social ties and markets below).

In an early paper, Myerson [1977b] studied a variation of Shapley Value for games when players in a component can form coalitions. This is now referred to as Myerson value. In a subsequent paper, Aumann and Myerson [1988] introduced an explicit extensive form game of link formation with the following rules: pairs of players are ordered and in each period one pair is given the opportunity to form a link. Linking is irreversible. Once every

pair of players has had a chance and decided on whether to form a link the game ends. The paper examined some examples to illustrate that sub-game perfect equilibrium networks of this process may be socially inefficient. In his game theory text book, Myerson [1991] proposed a simultaneous link formation model: every player announces a subset of links which she intends to form and a link between two players is formed if and only if both players involved express a wish to form a link.

Following these early attempts at network formation, in recent years, the study of network formation has been a very active field of study in economics and a number of different questions have been systematically explored. For extended surveys of this work see the interested reader is referred to Demange and Wooders [2005] and Dutta and Jackson [2003], Goyal [2007a], Jackson [2008], Mauleon and Vannetelbosch [2016] and Bramoule, Galeotti, and Rogers [2016].

The chapter starts with a discussion of a model of network formation in which individuals can unilaterally decide to form links. Unilateral link formation has the advantage that it allows us to use the tools of non-cooperative game theory to analyze the games of linking. This facilitates a study of a number of questions using familiar methods. This approach was introduced in Goyal [1993] and was systematically explored systematically in Bala and Goyal [2000a]. In many contexts – friendships and coauthorships are examples – it is more natural to consider link formation as a two-sided process: both individuals must agree to the link. In our discussion, we follow Jackson and Wolinsky [1996a] who proposed the solution concept of pairwise stability and offer a general introduction to this approach. The study of pairwise stability has been developed in a large literature. Richer solution concepts have been explored by this literature and we briefly discussed some of the more widely used notions. Pairwise equilibrium was formally defined in Goyal and Joshi [2006b] and Belleflamme and Bloch [2004]. The existence of pairwise stable networks is established in Jackson and Watts [2001]. The basic ideas underlying the proof of the efficiency result in the two-sided model with decay were provided in a paper on airlines by Hendricks, Piccione, and Tan [1995]. An overview of solution concepts for network formation games is presented in Gilles and Sarangi [2004], Gilles, Chakrabarti, and Sarangi [2012], Bloch and Jackson [2006] and Bloch and Dutta [2011]. For discussions on ways to reconcile ones-sided and two-sided linking protocols also see Ding [2021] and Olaizola and Valenciano [2015].

In the basic models studied in sections 3.2 and 3.3 we assumed that individuals were symmetric: everyone had the same payoff function. Differences across individuals may be important both with regard to costs and benefits. These heterogeneities can shape networks in important ways. For an early examination of network formation with heteroge-

neous individuals see Galeotti, Goyal, and Kamphorst [2006], Galeotti [2006], and Gilles and Johnson [2000]. A prominent development in this line of work is the incorporation of homophily in linking; for an early model of network formation with homophily see Currarini, Jackson, and Pin [2009].

A recurring theme is the tension between pairwise stability (and equilibrium) networks and efficiency. The literature has explored the scope of this tension and proposed ways of mitigating it. We mention the work of Jackson and Wolinsky [1996a] and Dutta and Mutuswami [1997] on centralized mechanisms and the work of Bloch and Jackson [2007] on decentralized transfers between the players. For overviews of this work see Jackson [2008] and Goyal [2007a].

As the literature on network formation has grown greatly over the past twenty five years and so a number of variations on the basic models presented in sections 3.2 and 3.3 have been developed. The chapter discusses four themes in the literature: dynamics, weighted links, generic social investments, and linking and assortative activity. The dynamics of linking were studied early on by Bala and Goyal [2000a] and Jackson and Watts [2002a]. For an early overview of the research in this field see Goyal [2007a] and Jackson [2008]; for more recent surveys see the handbooks Bramoullé, Galeotti, and Rogers [2016] and Benhabib, Bisin, and Jackson [2011].

Turning to weighted links, an early discussion of the issues is presented in Goyal [2005]. A number of papers have examined formation of weighted networks and they have also been applied to study specific empirical contexts, see e.g., Bloch and Dutta [2009], Deroian [2009], Rogers [2006], Brueckner [2006], Goyal, Moraga-González, and Konovalov [2008], Van der Leij and Goyal [2011b], and Skyrms and Pemantle [2009]. Recent contributions include Baumann [2021] Ding [2021], Salonen [2015], and Griffith [2020].

Fairly early, a number of researchers realized that non-specific linking may offer a more tractable framework to study network formation in large populations and it would also help in obtaining more realistic network architectures. Early contributions using this approach include Durieu, Haller, and Sola [2011] and Cabrales, Calvo-Armengol, and Zenou [2011]. This line of work has been recently elaborated upon by Albornoz, Cabrales, and Hauk [2019] and Canen, Jackson, and Trebbi [2020]. One part of this literature examines the consequences of generic investments for macroscopic properties of the network. The early papers using this approach are Golub and Livne [2010] and Blume, Easley, Kleinberg, Kleinberg, and Tardos [2013], recent contributions include Dasaratha [2021] and Goyal and Sadler [2021].

A strand of the literature examines models of linking in which individuals propose a single scalar number, as in the model above, but the payoffs depend on the macroscopic

properties – such as connectedness and giant component – of the random graph that they create. A number of other papers have explored a similar approach and drawn attention to the economic incentives for creating networks that exist at the knife-edge of macroscopic properties like connectedness (or the existence of a giant component), see e.g., Dasaratha [2021], Blume, Easley, Kleinberg, Kleinberg, and Tardos [2013], Elliott, Golub, and Leduc [2020b], and Golub and Livne [2010].

There is a very large literature on linking and assorted activity. For a survey of the theoretical aspects of the interplay between linking and related activity see Vega-Redondo [2016]. The chapter discussed contexts relating to coordination, cooperation and trust, co-operation and competition among firms, and brokerage and intermediation where this perspective has been further developed. Later chapters in the book will study these applications in detail.

The solution concepts discussed in the chapter focus on one and two player deviations. The ideas can be extended further to include groups of players to shape pairwise links and allowing for many-player links. Consider first the issue of larger group deviations within a pairwise link context. Suppose that a group of players of any size can determine the nature of networks among them, as well as determine the links between members of the group and the players who are not in the group. Group-level incentives are traditionally studied using notions of strong equilibrium and coalition equilibrium. Jackson and Van den Nouweland [2005] study strongly stable networks and derive conditions for the existence of such networks. Building on the early work of Chwe [1994] there is also a strand of research that examines far-sighted network formation. The interested reader is referred to Dutta and Mutuswami [1997], Bloch and Jackson [2006] and Herings et al. [2009] for alternative solution concepts in the context of network formation.

At a more fundamental level, however, there is the issue of why links should be bilateral. Indeed, in well known applications, such as co-authoring, collaboration between firms, and free trade agreements between countries, links often involve more than two players. This suggests that the level of linking should itself be viewed as endogenous. Allowing for larger groups in network formation brings the framework closer to the coalitions framework, with one major difference: a distinctive feature of the coalitions model is that membership is exclusive. A player can be a member of one or the other group but not of several groups. By contrast, the network literature restricts group formation to be at the level of pairs of players, but allows for a player to be a member of any number of two-player groups at the same time. Extending the networks framework to allow links between general many player groups as well as allowing for non-exclusive membership of groups would therefore yield a general framework for studying coalitions as well as networks.

We may generalize coalitions and networks using the concept of *hypergraphs*: in hypergraph generalizes a network or a graph to allows for formed between multiple nodes. This general framework would also permit a study of endogenous group size and exclusivity. Hypergraphs are used in Dziubiński and Goyal [2017] in the context of network defence (see the chapter on network security below). For studies of the formation of hypergraphs see Page Jr and Wooders [2010], Chen et al. [2020], Martinez et al. [2019], Ding, Dziubinski, and Goyal [2021] and Fershtman and Persitz [2021].

The formation of networks is subject to a variety of technological, economic and social forces. It is therefore only natural that network formation is studied across a number of disciplines. Early work on network formation in mathematics and bibliometrics used the metaphor of random graphs; the previous chapter presented an introduction to this work. There is a rich body of work in mathematical sociology that studies network formation and dynamics (for an introduction to this literature see Wasserman and Faust [1994]). More recently, network formation has been the subject of research in computer science (Fabrikant et al. [2003], Roughgarden [2005] and Easley and Kleinberg [2010]), physics (Barabási and Albert [1999], Watts and Strogatz [1998]) and business strategy (Gulati [2007]).

I thank Antonio Cabrales, Krishna Dasaratha, and Yves Zenou for useful comments on this chapter.

## 3.7 Questions

1. Consider the one-way flow model with decay from section 3.2. Show that a Nash equilibrium network is either connected or empty.
2. Recall that social welfare of a network is the sum of utility of players. In a game, define the price of anarchy as the ratio of first best social welfare to the social welfare attained in the worst Nash equilibrium. Define the price of stability as the ratio of first best social welfare to the social welfare attained in the best Nash equilibrium
  - Show that in the two-sided linking model the price of anarchy is unbounded for a wide range of cost parameters.
  - Show that in the one-sided linking model with one-way of benefits the price of anarchy is unbounded for a wide range of cost parameters.
  - Comment on the price of stability in the different models.
3. (Jackson and Wolinsky [1996b]) Consider a group of researchers who each have a fixed amount of time available which they can allocate across projects. The payoffs to

a player  $i$  in network  $g$  are given by,

$$\Pi_i(g) = \sum_{j \in N_i(g)} \left[ \frac{1}{d_i(g)} + \frac{1}{d_j(g)} + \frac{1}{d_i(g)d_j(g)} \right] = 1 + \left( 1 + \frac{1}{d_i(g)} \right) \sum_{j \in N_i(g)} \frac{1}{d_j(g)}. \quad (3.33)$$

if  $d_i(g) > 0$ , and  $\Pi_i(g) = 0$ , if  $d_i(g) = 0$ . A researcher allocates equal time across projects and productivity depends on the time spent on the project  $1/d_i(g) + 1/d_j(g)$  and on a synergy in the production process captured by the interactive term  $1/(d_i(g).d_j(g))$ .

- Show that in the network constituted of distinct pairs every player earns a payoff of 3.
  - Next consider the effects of an author commencing a new project. Show that a coauthor with two links earns  $[1/2 + 1 + 1/2]$  from old and  $[1/2 + 1/2 + 1/4]$  from new project. Show that if everyone has two projects then the payoffs for each player would be  $5/2$ .
  - Let  $n$  be an even number. Show that the network with  $n/2$  separate pairs maximizes social welfare.
  - Any pairwise stable network can be partitioned into complete components of unequal size. In particular, if  $m$  is the size of a component and  $m'$  is the size of the next larger component then  $m' > m^2$ .
4. (Bala and Goyal [2000b]) Suppose every individual has information of value 1. Individuals can access each other's information via direct or indirect links. A link is costly. However, in contrast to the models in the chapter, suppose that the reliability of a link is uncertain and given by  $p \in [0, 1]$ .
- Discuss the trade-offs that arise as we vary  $p$ ,  $c$  and  $n$ . A network is super-connected if deleting a link leaves the network connected. Show that for fixed  $c$  and  $p \in (0, 1)$ , as we increase  $n$ , an efficient network must be super-connected.
  - Next suppose that reliability can be increased through investments. Discuss how convexity/concavity of costs of increasing reliability will shape the architecture of efficient networks.
5. (Galeotti, Goyal, and Kamphorst [2006], Jackson and Rogers [2005]). Consider a model of network formation in which agents belong to groups: individuals are alike except that the costs of forming links within groups are lower as compared to costs of linking across groups and there is decay in value as it flows through paths of the

network. Building on the arguments in the chapter show how these group based cost differences and decay can give rise to a core-periphery network in which a few agents from different groups constitute hubs.

6. Ductor, Goyal, and Prummer [2021] show that male and female economists have different coauthor networks: women have fewer coauthors, form stronger ties, and have higher clustering. Using the ideas of purposeful linking introduced in this chapter, reason about the role of preferences and the environment in explaining these network differences.
7. Bearman, Moody, and Stovel [2004] show that romantic and sexual networks are heterophilous and contain a large component with long cycles. Propose a model of relationship formation and use it to reason about the role of preferences and constraints in shaping such a network.
8. Currarini, Jackson, and Pin [2009] present empirical evidence on school friendships: pupils from larger communities have more friends and there is inbreeding homophily (see chapter 1 for a definition). Propose a model of friendship formation and use it to reason about the factors that could account for these friendship patterns.

# **Chapter 4: Network Structure and Human Behaviour**

## **4.1 Introduction**

In a democracy a citizen votes in city, provincial and national elections. To inform herself on the issues and the competing candidates she reads newspapers and magazines and she also exchanges views with his family, friends and colleagues. As the range of problems is broad and the issues are often complex who she talks to will play a role in determining how well informed she is and how she votes. Families decide on whether to vaccinate their children against infectious diseases such as measles and mumps. The risk of contacting a disease depends on its prevalence in the neighbourhood, something that is determined by the vaccination decisions of friends and neighbours. A young man decides on whether to take up a life of crime; he will be more likely to succeed if he learns tricks from others who are engaged in crime. The skills of others in turn depend on their connections with other criminals. The quality of research a scientist undertakes depends on her efforts and the efforts of collaborators. The quality of ideas and the availability of collaborators will in turn depend on the other collaborations they are engaged in.

In each of these instances, an enquiry into individual behaviour pushes us toward a study of a broader set of relationships within which they and their contacts are embedded. We are led to questions such as: what are the effects of connections on individual behavior, how does behaviour respond to changes in a network, are some networks better for the attainment of socially desirable outcomes, and how can policy interventions raise welfare in a network? This aim of this chapter is to develop a theoretical framework that helps formulate these questions precisely and to introduce concepts that will help us in understanding how embeddedness shapes human behaviour.

The framework we propose will have two ingredients – one, a formal description of the pattern of relationships among individual entities and two, a description of the cross

effects that an individual's actions create for other individuals and how these are mediated by the pattern of ties between them. We introduced networks in the first three chapters. In this chapter, we will introduce a number of concepts that help us in organizing the different ways in which networks mediate the effects of others' actions on individual payoffs.

The key idea is that the same action carried out by two individuals, A and B, will have a different effect on C depending on their locations vis-a-vis C. A simple way of formalizing this point is to think of effects as being either *local* or *global*: an individual  $j$  is said to be a *neighbor* of  $i$  if  $i$  and  $j$  have a tie. In this case the actions of  $j$  have a local effect on  $i$ . All players who are not neighbors are referred to as *non-neighbors* and are treated alike and their effects on  $i$  are said to be global.

We will be especially interested in two dimensions of such effects. The effect of  $j$ 's action on  $i$ 's total payoffs: actions of others are said to create a *positive externality* if an increase in their value raises an individual's payoffs; they are said to create *negative externality* if an increase in other's actions lowers an individual's payoff. A second dimension of effect is intimately connected to individual incentives: if an increase in other's actions raises the marginal returns from own actions, the actions are said to be *strategic complements*; if an increase in other's actions lowers the marginal returns from own actions then the actions are said to be *strategic substitutes*. The effects of others' actions can be mixed, depending on their location in the network: the actions of neighbors may generate positive effects while actions of non-neighbors may generate negative effects, and vice-versa. This points to the potentially complex interplay between action externalities and network location. We will refer to these payoff effects as the *content* of interaction. We present a number of examples that help us appreciate the rich possibilities with regard to the content of interaction.

Our analysis of games on networks begins with two classical binary action games: the *best-shot* game and the *weakest-link* game. The analysis of these games helps us in appreciating an important general point about embedded human activity: individual behaviour are shaped both by the structure of the network and the content of interaction. In the best-shot game, individual activity can be understood in terms of *maximal independent sets* of the network; in the weakest-link game, activity can be understood in terms of the  $q$ -core of the network. The difference between these two network properties shows how the content of interaction – strategic substitutes vs complements – is decisive for identifying a network dimension that defines individual behaviour.

In our study of best-shot and weakest-link game we assume that individuals know all details of network. In large networks, it is unlikely that individuals will have complete knowledge of all details of the network. Rather, we expect individuals to know some aspects of their local environment (such as their own degree) and some global aspects of the

network (such as its overall connectivity) but not other features, such as for example the links between other nodes in the network. In this setting, it is natural to define the strategy of an individual as a function of their degree. We study the Bayes-Nash equilibria of games of incomplete information. The analysis yields sharp predictions: equilibrium strategy is monotonically decreasing (increasing) in best-shot (weakest link) games. Earnings are increasing in degree in both games. The framework also allows us to study effects of changes in networks measured in terms of the degree distribution.

We then turn to games with a continuum of actions. In this context networks have smoother effects on behaviour. Take a game of complements: if an individual raises her action, then her neighbours will best respond by raising their action. This will in turn affect their neighbours and so forth. These raised efforts will feed back on the original individual, the magnitude of the positive pressure depending on the number and length of ‘walks’ of the initial player. Recall from chapter 1 that the *Bonacich centrality* of a node is a summary statistic of the number and length of all walks from a node to all other nodes. The analysis tells us that equilibrium action of an individual is proportional to her Bonacich centrality in the network. However, the content of interaction is again key: in games with strategic complements the hub of a star network chooses the largest effort, while in a game of strategic substitutes the hub chooses the lowest effort.

A central feature of the games on networks that we have discussed so far is the presence of externalities: in an equilibrium of the game, individual actions will therefore generally not be socially optimal. The tension between what individuals do and what is in their collective interest is an important motivation for intervening in a network. Our study of the intervention problem draws attention to the value of targeting nodes in proportion to their presence in different principal components/ eigenvectors of the matrix of interactions.

## 4.2 Choice in networks

This section presents a framework for the study of individual choice in networked environments. There are two essential ingredients. The first is the content of interaction: what is the form of activity being contemplated? More precisely, we are interested in incentives of individuals to undertake different actions and so by the content of interaction we will mean how actions of others affect an individual’s total and marginal returns to activity. The second is the structure of interaction: who is connected to whom? We start by laying out some basic notation on individuals, their actions and the network they are embedded in. Our discussion draws on Goyal [2007a].

Consider a set of individuals  $N = \{1, 2, \dots, n\}$ , where  $n \geq 2$ . Individuals make their

choices simultaneously: let the strategy of individual  $i$  be given by  $s_i \in S$ . It will be assumed that  $0, 1 \in S$  and both discrete and ‘continuous’ action sets are allowed. The vector of strategies is denoted by  $\mathbf{s} \in S^n$ . In what follows,  $s_{-i} = (s_1, s_2, \dots, s_{i-1}, s_{i+1}, \dots, s_n)$  refers to the profile of strategies of all players other than player  $i$ . The payoff (utility or reward) to player  $i$  under the profile of actions  $\mathbf{s} = (s_1, \dots, s_n)$  is given by

$$\Pi_i : S^n \times \mathcal{G} \rightarrow \mathbb{R}$$

In the games where the action set is continuous, we assume that  $S$  is also convex (recall that a set  $S$  is said to be convex if for every pair of elements  $x, y \in S$ , and for any  $\lambda \in [0, 1]$ ,  $\lambda x + (1 - \lambda)y \in S$ ).

Individuals are located in a network,  $g$ . Recall that the neighbours of  $i$ ,  $N_i(g)$ , are individuals with whom she has a link, i.e.,  $N_i(g) = \{j \in N | g_{ij} = 1\}$ . We define  $d_i(g) = |N_i(g)|$  as the degree or number of neighbours of  $i$  in network  $g$ . An individual’s payoffs depend on her action and the actions of others. Given a profile of strategies,  $\mathbf{s}$ , and a network  $g$ , let  $s_{N_i(g)}$  refer to the strategies of  $i$ ’s neighbours in network  $g$ . It will be useful to define higher and lower actions of neighbours: we will say that a vector  $s'_{N_i(g)}$  is greater than the vector  $s_{N_i(g)}$ ,  $s'_{N_i(g)} > s_{N_i(g)}$ , if for every neighbour  $j \in N_i(g)$ ,  $s'_j \geq s_j$ , and for some neighbour,  $k$ ,  $s'_k > s_k$ .

In the examples mentioned in the introduction it is reasonable to suppose that the action of a neighbour has a greater impact on an individual as compared to the action of non-neighbours. This leads us to classify ‘others’ into two groups, the *neighbors* and the *non-neighbors*, and to treat members in each group alike. This distinction between neighbours and non-neighbours naturally suggests a corresponding distinction between *local* and *global* spillovers. In a game of local spillovers, the payoffs of an individual depend only on her own actions and the actions of her neighbours. Given a strategy profile  $\mathbf{s}$ , individual  $i$ ’s payoff

$$\Pi_i(s|g) = \Phi(s_i, s_{N_i(g)}) \tag{4.1}$$

where  $\Phi(\cdot, \cdot) : S^{d_i(g)+1} \rightarrow \mathbb{R}$  and  $d_i(g) = |N_i(g)|$  is the degree of individual  $i$  in network  $g$ .

We assume that the payoff function of two players with the same degree are identical: so payoffs do not depend on the identity of the player. This simplifying assumption is reasonable as our primary interest is in network effects. At a later point, specific forms of individual heterogeneity – such as gender and race or age – can be introduced depending on the particular application under study. We will also assume that payoffs are anonymous with regard to choices of neighbours’ actions. This means that if  $s'_{N_i(g)}$  is a permutation of

actions in  $s_{N_i(g)}$  then  $\Phi(s_i, s'_{N_i(g)}) = \Phi(s_i, s_{N_i(g)})$ .

Going beyond the pure local case, we will also be interested in situations where neighbours as well as non-neighbours matter. An important special case arises when an individual's payoff depends only on own action, the sum of neighbors' actions, and the sum of non-neighbors' actions. Given a profile  $s = (s_1, \dots, s_n)$ , and a network  $g$ , an individual  $i$ 's payoff

$$\Pi_i(s|g) = \Phi(s_i, \sum_{j \in N_i(g)} s_j, \sum_{k \notin N_i(g) \cup \{i\}} s_k) \quad (4.2)$$

In this chapter we will restrict attention to the cases where we treat all neighbours and all non-neighbours respectively alike. It is possible to generalize this formulation so as to allow for individuals at different distances in a network. In the chapter on the law of few we will present an example of such a general case.

We now turn to how others' actions matter for payoffs. A game of local effects exhibits *positive externality* if the payoffs are increasing in actions of neighbors, and it exhibits *negative externality* if they are decreasing in actions of neighbors. We will assume symmetry of payoff functions across players and we will also assume anonymity of neighbours. With this in mind we state the following externality definition.

**Definition 4.1.** *A game with pure local effects exhibits positive externality if for every  $d \in \{0, 1, 2, \dots, n-1\}$ , for every  $s_i \in S$ , and for every pair of neighbors' strategies  $s_d, s'_d \in S^d$ ,  $s_d \geq s'_d$  implies  $\Phi(s_i, s_d) \geq \Phi(s_i, s'_d)$ .*

*A game with pure local effects exhibits negative externality if for every  $d \in \{0, 1, 2, \dots, n-1\}$ , for every  $s_i \in S$ , and for every pair of neighbors' strategies  $s_d, s'_d \in S^d$ ,  $s_d \geq s'_d$  implies  $\Phi(s_i, s_d) \leq \Phi(s_i, s'_d)$ .*

The game exhibits strict externality (positive or negative) if the corresponding payoff inequalities are strict whenever  $s_d > s'_d$ .

We now turn to the effects of neighbours' actions on incentives of an individuals. The incentives will depend on how an individual's marginal returns are affected by the neighbours' actions. Building on Bulow, Geanakoplos, and Klemperer [1985], we shall say that a game with pure local effects exhibits *strategic complements* or *strategic substitutes* depending on whether the marginal returns to own action for player  $i$  are increasing or decreasing in the efforts of her neighbors.

**Definition 4.2.** *A game with pure local effects exhibits strategic complements if for every  $d \in \{0, 1, 2, \dots, n-1\}$ , every pair of own strategies  $s_i > s'_i$ , and for every pair of neighbors' strategies  $s_d, s'_d \in S^d$ ,  $s_d \geq s'_d$  implies that  $\Phi(s_i, s_d) - \Phi(s'_i, s_d) \geq \Phi(s_i, s'_d) - \Phi(s'_i, s'_d)$ .*

A game with pure local effects exhibits strategic substitutes if for every  $d \in \{0, 1, 2, \dots, n - 1\}$ , every pair of own strategies  $s_i > s'_i$ , and for every pair of neighbors' strategies  $s_d, s'_d \in S^d$ ,  $s_d \geq s'_d$  implies that  $\Phi(s_i, s_d) - \Phi(s'_i, s_d) \leq \Phi(s_i, s'_d) - \Phi(s'_i, s'_d)$ .

The payoffs exhibit strict complements and substitutes if the above payoff inequalities are strict whenever  $s_d \geq s'_d$ .

Games on networks are solved using the concept of Nash equilibrium (or its variants). A strategy profile  $s^* = \{s_1^*, \dots, s_n^*\}$  is a Nash equilibrium of a network game if, for each player  $i$ , given the strategies of other players  $s_{-i}^*$ ,  $s_i^*$  maximizes her payoffs. Formally, a strategy profile  $s^* = \{s_i^*, s_{-i}^*\}$  is a Nash equilibrium in network  $g$  if for all  $i \in N$ :

$$\Pi_i(s_i^*, s_{-i}^* | g) \geq \Pi_i(s_i, s_{-i}^* | g), \forall s_i \in S. \quad (4.3)$$

The conditions for the existence of Nash equilibrium have been studied extensively; we refer the interested reader to Osborne and Rubinstein [1994].

We now present examples to bring out the scope of this framework.

### 4.2.1 Examples

The aim of this section is to formally represent social and economic situations where connections matter and to map them into the concepts of strategic complements and substitutes.

We start with binary games and then turn to continuous action games. The binary action games – the *best-shot* game and the *weakest-link* game – are taken from Hirshleifer [1983].

#### **Example 4.1.** Best-shot game]

There are two actions, 0 and 1. Action 0 denotes inactivity that is costless. Action 1 denotes a costly activity. Examples of action 1 include collecting information on best route to a destination, the availability and location of a product, and facts about a political candidate. Individual utility is 1 if and only if the sum of her action and her neighbours actions adds up to 1 or more. For simplicity suppose that action 1 costs  $c \in (0, 1)$ . Observe that if an individual is choosing 0, an increase in action of the other player raises her payoff from 0 to 1. If she is choosing 1, such an increase in action by another player leaves her payoff unaffected. Thus an increase in action by other player raises her payoffs or leaves them unchanged. Next observe that in this game there is a return to choosing a costly action 1 if, and only if, the neighbours do not choose 1. Thus the marginal returns to choosing 1 are falling in the choice of the other player – i.e., individual action and the actions of

neighbours are strategic substitutes. Following Galeotti, Goyal, Jackson, Vega-Redondo, and Yariv [2010], we locate this game in a network. Given a network  $g$ , and a strategy profile  $s$ , the payoffs of individual  $i$ :

$$\Pi_i(s|g) = \begin{cases} 1 - c & \text{if } s_i = 1 \\ 1 & \text{if } s_i = 0 \text{ and } \sum_{j \in N_i(g)} s_j \geq 1 \\ 0 & \text{if } s_i = 0 \text{ and } \sum_{j \in N_i(g)} s_j = 0. \end{cases} \quad (4.4)$$

Observe that it does not matter who among my neighbours chooses which action, only the sum of actions matters. This is an instance of a general feature of such contexts: these payoffs are ‘anonymous’. All individuals with the same degree have the same payoff function and this payoff function is symmetric with regard to the actions of different neighbours. We also see that individual payoffs are increasing in actions of others; so this is a game with positive externalities. ■

#### **Example 4.2 ((Variant on the) Weakest-link game).**

In a classroom, the returns from learning a new computer language depend on how many others learn the same language. Learning a language takes time and effort and is costly. The returns depend on whether the other player also learns the language. Observe that if an individual chooses not to learn (i.e., action 0), then an increase in action of another player has no effect on her payoffs. If she chooses learn a new language, the action 1, then such an increase in the action by other player raises her payoffs from  $-c$  to  $1 - c$ . Also note that there is a return to choosing a costly action 1 if, and only if, the other player also chooses 1. Thus the marginal returns to choosing action 1 are increasing in the choice of the other player – so actions of an individual and her classmates are complements. Following Galeotti, Goyal, Jackson, Vega-Redondo, and Yariv [2010] we locate this interaction within a network. Given a network  $g$ , and a strategy profile  $s$ , the payoffs of an individual  $i$  are

$$\Pi_i(s|g) = s_i \sum_{j \in N_i(g)} s_j - cs_i \quad (4.5)$$

We see that this is a game of positive externalities and strategic complements. ■

We next present a number of examples of games where the action set is continuous.

#### **Example 4.3. Local public goods**

In a wide class of situations an individual makes a costly contribution that brings her closer to her ideal level of a ‘good’ but it also raises the ‘goods’ enjoyed by her neighbors. Prominent examples include (i) the case of an individual who reads extensively on public affairs and shares her information with her friends and colleagues, (ii) contributions to improve physical neighborhoods such as residents clearing snow or improving their garden, (iii) Protection measures against infectious disease such as vaccination or wearing masks. These examples motivate a widely studied model of local public goods proposed by Bramoullé and Kranton [2007]; for elaborations on this model see Galeotti and Goyal [2010] and Allouch [2015].

Suppose that if each  $i$  contributes effort  $s_i$  to the public good, then the amount of public good  $i$  experiences is

$$x_i = \tilde{b}_i + s_i + \tilde{\beta} \sum_{j \in N_i(g)} g_{ij} s_j,$$

where  $0 < \tilde{\beta} < 1$ . The utility of  $i$  is

$$U_i(s, g) = -\frac{1}{2}(\tau - x_i)^2 - \frac{1}{2}s_i^2,$$

where  $\tilde{b}_i < \tau$ .

The optimal level of public good in the absence of any costs is  $\tau$ ; this can be thought of as the maximum that can be provided (thus  $x_i \leq \tau$ ). Individual  $i$  has access to a base level  $\tilde{b}_i$  of the public good. Each agent can expend costly effort,  $s_i$ , to augment this base level to  $\tilde{b}_i + s_i$ . If  $i$ ’s neighbor  $j$  expends effort,  $s_j$ , then  $i$  has access to an additional  $\tilde{\beta}g_{ij}s_j$  units of the public good, where  $\tilde{\beta} < 1$ .

As higher effort of others raises an individual’s utility this is a game of positive externality. Simple computations also reveal that greater effort by neighbours lowers an individual’s marginal returns from higher effort, so this is a game of strategic substitutes.

#### Example 4.4. Crime

There exist very large differences in rates of crime across space (this holds true across countries, across cities within the same country and indeed also across precincts within the same city). Glaeser, Sacerdote, and Scheinkman [1996] show that these differences cannot be accounted for by differences in local social and economic conditions. This leads them to argue that positive covariance across agents’ decisions about crime must be an important part of the explanation for such dispersion in crime.

Building on the rational actor approach to crime introduced in Becker [1968], we propose the following model of criminal activity. As criminal activity is illegal, individuals acquire proficiency in it through personal interaction with trusted others. This suggests that the level of criminal activity exhibits a form of “complementarity”: individual incentives to engage in it are increasing in the criminal activity of “close by” others. Developing this reasoning a next step we are led to the view that level of criminal activity will depend on the direct and indirect connections of individuals. We present a model of crime taken from Ballester, Calvó-Armengol, and Zenou [2006].

There are  $n$  individuals, who each choose a level of criminal activity  $s_i$ . The payoffs to player  $i$  faced under strategy profile  $s$ , are given by:

$$\Pi_i(s) = \alpha s_i - \frac{1}{2} s_i^2 + \rho \sum_{j \neq i} g_{ij} s_i s_j \quad (4.6)$$

Assume that  $\alpha > 0$  and  $\rho > 0$ . We can see that an increase in actions of neighbours raises an individual’s payoffs implying that this a game of positive spillovers. Taking derivatives with respect to own action and then cross partial derivative with respect to a neighbor’s action reveals that this is a game of strategic complements.

■

#### Example 4.5. Research Collaboration Among Firms

Firms collaborate with each other to create new products and cost reducing processes. The study of business management provides extensive evidence on the role of such collaborations (see Hagedoorn [2002] and Gulati [2007]). Two features of this collaboration activity are worth noting. The first feature is that firms enter into a number of relationships with non-overlapping sets of firms: in other words, that the relations are non-exclusive. The second feature is that firms often collaborate with other firms within the same market, giving rise to a complex relation which combines cooperation and competition giving rise to a form of *coopetition* (Nalebuff and Brandenburger [1997]). We present a model of research collaboration among firms taken from Goyal and Moraga-Gonzalez [2001] which embodies this perspective.

Suppose that demand is linear and given by  $Q = 1 - p$  and that the initial marginal cost of production in a firm is  $\bar{c}$  and assume that  $n\bar{c} < 1$ . Each firm  $i$  chooses a level of research effort given by  $s_i \in S = [0, \bar{c}]$ . The marginal costs of production of a firm  $i$ , in a network  $g$ , facing a profile of efforts  $s$ , are given by:

$$c_i(s|g) = \bar{c} - (s_i + \sum_{j \in N_i(g)} s_j). \quad (4.7)$$

Efforts involve allocation of scarce resources; let us suppose that this cost is given by  $Z(s_i) = \alpha s_i^2/2$ , where  $\alpha > 0$ . Given costs  $c = \{c_1, c_2, \dots, c_n\}$ , firms choose quantities to maximize profits. The costs of firms are positive so long as  $\alpha$  is sufficiently large.

Firms choose quantities  $(\{q_i\}_{i \in N})$ , with  $Q = \sum_{i \in N} q_i$ . Thus, the profits of firm  $i$  in a collaboration network  $g$  are given by

$$\Pi_i(s|g) = \left[ 1 - q_i(g) - \sum_{j \neq i} q_j(g) - c_i(g) \right] q_i(g) - \alpha \frac{s_i^2(g)}{2}. \quad (4.8)$$

From the theory of oligopoly, we know that given a cost vector  $c = (c_1, \dots, c_n)$ , firm  $i$  will choose

$$q_i = (1 - nc_i + \sum_{j \neq i} c_j) / (n + 1)$$

Bearing this in mind, the payoffs of a firm  $i$ , located in network  $g$ , faced with a research profile  $s$ , are given by:

$$\Pi_i(s|g) = \left[ \frac{1 - \bar{c} + s_i[n - \eta_i] + \sum_{j \in N_i(g)} s_j[n - \eta_j(g)] - \sum_{l \in N \setminus \{i\} \cup N_i} s_l[1 + \eta_l(g)]}{n + 1} \right]^2 - \alpha \frac{s_i^2(g)}{2}.$$

It can be checked that this payoff function exhibits positive externality across neighbors and negative externality across non-neighbors actions. Moreover, actions of neighbors are strategic complements, while the actions of non-neighbors are strategic substitutes. We see how a rather simple game of collaboration can generate a very rich set of externalities and strategic effects. ■

#### Example 4.6. Competition among Firms

Consider the classical problem of a set of firms that each produce a distinct good and choose a price for their good. Following Singh and Vives [1984] let us say that the demand for good  $i$  is

$$Q_i(p) = a - \beta p_i + \sum_{j \neq i} \gamma_{ij} p_j \quad (4.9)$$

where  $p = (p_1, \dots, p_n)$  is the price vector,  $\beta$  is own price effect, and  $\gamma_{ij}$  is the effect of price  $j$  on the demand for good  $i$ . Given a price vector  $p$ , the profit for firm  $i$  is

$$\Pi_i(p) = p_i Q_i(p) = p_i(a - \beta p_i + \sum_{j \neq i} \gamma_{ij} p_j) \quad (4.10)$$

We may summarize the parameters of the demand system  $\beta$  and  $\gamma_{ij}$  in an adjacency matrix  $D$ , where  $\beta$  occupies the diagonal cells and  $\gamma_{ij}$  is the element in cell  $ij$  of the matrix. The adjacency matrix  $D$  may be seen reflecting a network of demand cross-dependencies across the different goods. Let us assume that  $\gamma_{ij} = \gamma_{ji}$ . We notice that the nature of effects between firm  $i$  and  $j$  will depend on the sign and magnitude of the parameter  $\gamma_{ij}$ :  $\gamma_{ij} > 0$  will imply that raising price of  $i$  confers a positive externality on  $j$ ,  $\gamma_{ij} < 0$  implies that a higher price of  $i$  confers a negative externality on firm  $j$ . Similarly,  $\gamma_{ij} > 0$  signifies a relation of strategic complements between the prices of  $i$  and  $j$ ,  $\gamma_{ij} < 0$  signifies a strategic substitutes relation.

■

#### Example 4.7. Keeping up with the Joneses

Individuals and families often define the quality of their lives in relation to the standard of living of their relatives and neighbours. A distinguished strand of literature starting with the celebrated work of Torsten Veblen (Veblen [1973]) studies the consequences of the “keeping up with the Joneses effect” (see Duesenberry [1949] for an early discussion of the implications of such effects. For empirical evidence on the presence of relative consumption effects see Luttmer [2005] and Kuhn, Kooreman, Soetevent, and Kapteyn [2011]). We present a model of consumer choice where individuals care about the consumption relative to that of their neighbours. The model is taken from Ghiglino and Goyal [2010].

We consider a group of households who have the same income,  $\omega$ , and spend it on two goods  $x$  and  $y$ . The households have Cobb-Douglas preferences; the novel feature of the preferences is that the good  $y$  is a relative consumption good. Utility of individual  $i$  facing a consumption profile  $(x_i, y_i)_{i \in N}$  is:

$$u_i(x_i, y_i, y_{-i}) = x_i^\sigma [y_i + \alpha \eta_i (y_i - \frac{1}{d_i} \sum_{j \in N_i(g)} y_j)]^{1-\sigma} \quad (4.11)$$

where  $y_{-i}$  is the consumption of all households other than household  $i$ ,  $\sigma \in (0, 1)$  and  $\alpha > 0$  is strength of social comparisons,  $N_i(g)$  is the neighbors of  $i$  in network  $g$  and  $d_i$  is the number of neighbors. We can check that the consumption of good  $y$  is a strategic complement across neighbours.

■

We now turn to the study of how network structure and the content of interaction shape behaviour.

### 4.3 Binary Games

We commence our analysis of behaviour in networks with a study of two simple games: the best-shot game and the weakest-link game. This binary choice environment offers us a basic framework within which we can develop a general message – behaviour is jointly shaped by the content of interaction (as reflected in the payoff externalities in an activity) and the structure of the network.

Let us consider the best-shot game; the discussion here is based on Bramoullé and Kranton [2007]. A preliminary observation is that, since  $c \in (0, 1)$ , in a (Nash) equilibrium it must be the case that an individual either chooses 1 himself or one of his neighbours must choose 1. Moreover, the strong substitutability of actions between neighbours implies that an individual will choose 1 if, and only if, all her neighbours will choose 0. So in any network, a Nash equilibrium can be constructed using the following algorithm: number the players from 1 to  $n$ . Say that player 1 chooses 1; assign 1 to the set of active players  $A$ . Next consider players starting from 2 onward: check if 2 is a neighbour of 1, if not then add him to the set of players  $A$  who chooses 1. If 2 is a neighbour put him in the set,  $B$ , that chooses 0. Proceed next to 3: check if she is a neighbour of anyone in the set  $A$ . If she is not then place her in set  $A$ ; if she is a neighbour of someone in set  $A$  then place her in set  $B$ . Proceed next to player 4, and so forth. Once we complete this procedure with player  $n$ , we would have partitioned the players into two sets  $A$  and  $B$  (every player lies either in  $A$  or in  $B$  but never in both). Indeed, the set of active individuals correspond to a *maximally independent set* of the network. Formally, an independent set is a collection of nodes  $N'$  such as no pair of nodes  $i, j \in N'$  has a link. An independent set is maximal is it is not a strict subset of any other independent set in the network. A question at the end of the chapter works through some properties of such sets.

Every player in set  $A$  chooses 1, while every player in the set  $B$  chooses 0. By construction of the sets  $A$  and  $B$ , observe that these actions are optimal for every individual. Consider a player  $i \in A$ : every neighbour lies in set  $B$ , and chooses 0: so it is optimal for her to choose 1. Similarly, for any player  $j \in B$ , there must be a neighbour in set  $A$ , otherwise she would be in set  $A$  herself. But everyone in set  $A$  chooses 1, so it is optimal for everyone in set  $B$  to choose 0. This simple process thus yields a Nash equilibrium for the best shot game. By suitably reordering the players, we can in fact trace any Nash equilibrium on a given network. Finally, note that as we have not invoked any special feature of a network,

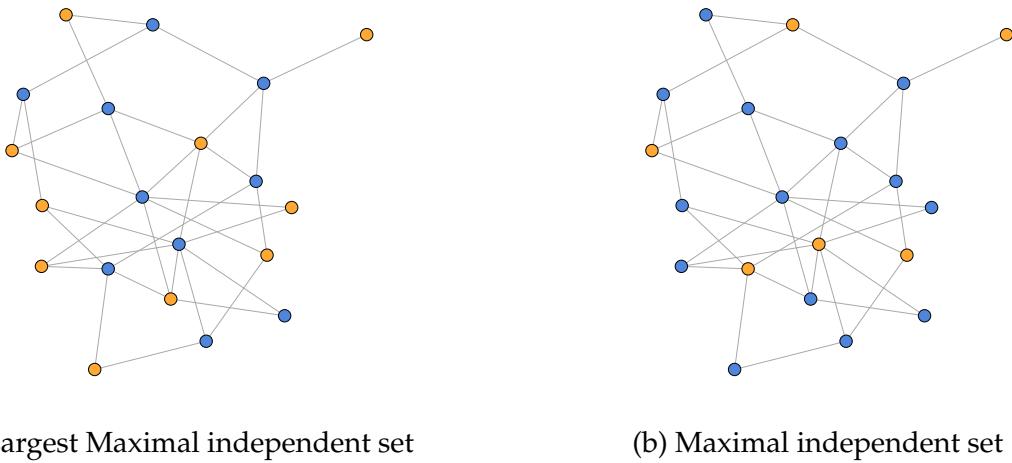

Figure 4.1: Maximal Independent Sets in Erdos-Renyi Graphs:  $n = 20$  and  $p = 0.20$ .

the same procedure would apply to any network.

Figures 4.1 and 4.2 provide examples of maximally independent sets. In Figure 4.1 we consider Erdos-Renyi graphs and see that the number of nodes in the maximal independent set can vary widely: in this case from 6 to 10. This is a more general feature of maximal independent sets. Figure 4.2 presents two simple networks – the star and the circle – and their corresponding maximal independent sets. In the star, the maximal independent sets vary from size 1 to  $n - 1$ , while in the circle the number varies from  $n/3$  to  $n/2$ . It is clear that maximal independent sets have a rich structure and that they vary widely within the same network and across networks.

Some features of maximal independent sets are worth noting. There is no simple relation between an individual's connections and her presence in a maximal independent set: behaviour in the best-shot game thus depends on the social structure broadly construed. The multiplicity of maximal independent sets gives rise to the problem of multiple Nash equilibria.

The multiplicity of equilibria poses a challenge when we wish to understand the effects of changes in a network. To see this consider let us start from a network that contains two distinct stars, and add a link that connected the two hubs. The effect of this change can be radically different depending on which maximally independent set is active. Figure 4.3 illustrates this point: in the top left panel 4.3a, there is a network with two stars, in each star the hub (represented in red) is active and the spokes (represented in blue) are passive. A link is added between the two hubs to create a connected network. The figure on the right, Figure 4.3b, presents an equilibrium in the connected network in which spokes are

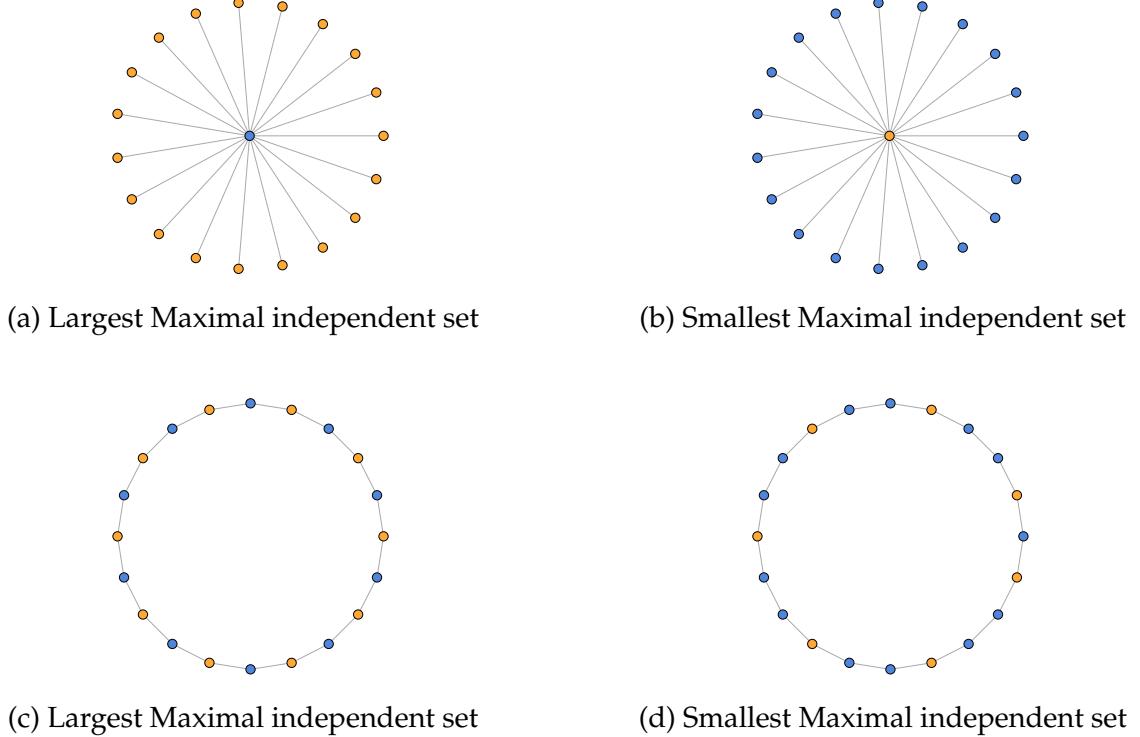

Figure 4.2: Maximal Independent Sets in Simple Networks

active (represented in red) and both the hubs are passive (represented in blue). This shows that a link can lead to significant increase in activity. By contrast, consider the bottom panel: on the left 4.3c there is an equilibrium in which the hubs are passive (represented in blue) while the spokes are active (represented in red). In the bottom right panel, after the addition of the links the equilibrium changes, one hub is active and the corresponding spokes are passive, while the other hub is passive but the corresponding spokes are active (active in red and passive in blue). Thus the effects of adding a link – whether it increases aggregate activity or decreases it – depends very much on the initial starting situation. It is easy to see that this ambiguity is also true if we look at the effects of additional links on payoffs.

We summarize our discussion of the best-shot game as follows.

**Proposition 4.1.** *Consider the best-shot game played on a network. In an equilibrium the set of active players is given by a maximal independent set of the network. Starting from any network  $g$ , adding links may increase or decrease the level of activity. Similarly, adding links may increase or lower payoffs of individuals.*

We conclude our discussion of best-shot games with some remarks on social welfare.

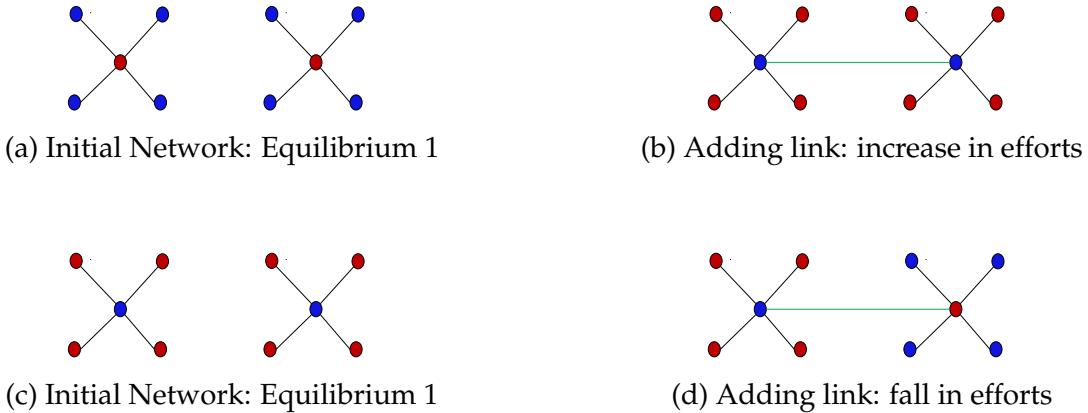

Figure 4.3: Adding links: multiplicity in outcomes (active players in red)

As in chapter 1, let us define social welfare as the sum of individual utilities. Observe that since  $c \in (0, 1)$ , in an equilibrium every individual must have access to at least one unit of activity. Thus any variations that arise in social welfare must be due to the number of active players. Indeed, it follows that social welfare is falling in the size of the maximal independent set. In the star network differences in social welfare across equilibria can therefore be very large: 1 vs.  $n - 1$ .

We next take up weakest link games: our discussion is based on Gagnon and Goyal [2017]. The first point to note is that everyone choosing action 0 is always an equilibrium. However, there will typically also exist other equilibria. To develop a sense for how equilibria and networks are related let us fix the cost of action 1 to be  $c = 4/1$ . So an individual will only choose action 1 if the returns of choosing 1 cover the cost  $4/1$ . From the payoff given in equation (12.4), this means that at least 5 of her neighbours must also choose action 1. However, these neighbours will choose action 1 only if each of them have at least 4 other neighbours choosing 1 (in addition to the player who started with). Thus for an individual to choose 1, she must be part of a set of nodes in a network each of whom have at least 5 links with others who have 5 links, and so on. This discussion motivates the study of the  $q$ -core of a network.

**Definition 4.3.** *The  $q$ -core of a network  $\mathbf{g}$ , denoted by  $\mathbf{g}^q$ , is the largest subgraph of  $\mathbf{g}$  such that all individuals in  $\mathbf{g}^q$  have strictly more than  $q$  links to other individuals in  $\mathbf{g}^q$ .*

Here is a simple procedure for obtaining the  $q$ -core of a network. Start with a network  $\mathbf{g}$ . In step 1, delete all the nodes (and their links) in  $\mathbf{g}$  for which degree  $k \leq q$ . Label the residual graph  $\mathbf{g}_1$ . In step 2, delete all the nodes (and their links) in  $\mathbf{g}_1$  for which  $k \leq q$ .

Iterate until no node with  $k \leq q$  remains (i.e. when  $\mathbf{g}_t = \mathbf{g}_{t+1}$ ). The residual graph in this last step is the  $q$ -core.

By way of illustration, consider the network on Figure 4.4. Suppose that we want to find the 4-core. First, find all the nodes with  $k \leq 4$ , and delete them and their links. In step 2, delete the nodes with 4 or less links in the residual network from step 1. Proceed likewise unless no node with  $k \leq 4$  remains. The remaining nodes form the 4-core. A question at the end of the chapter works through some properties of the  $q$ -core.

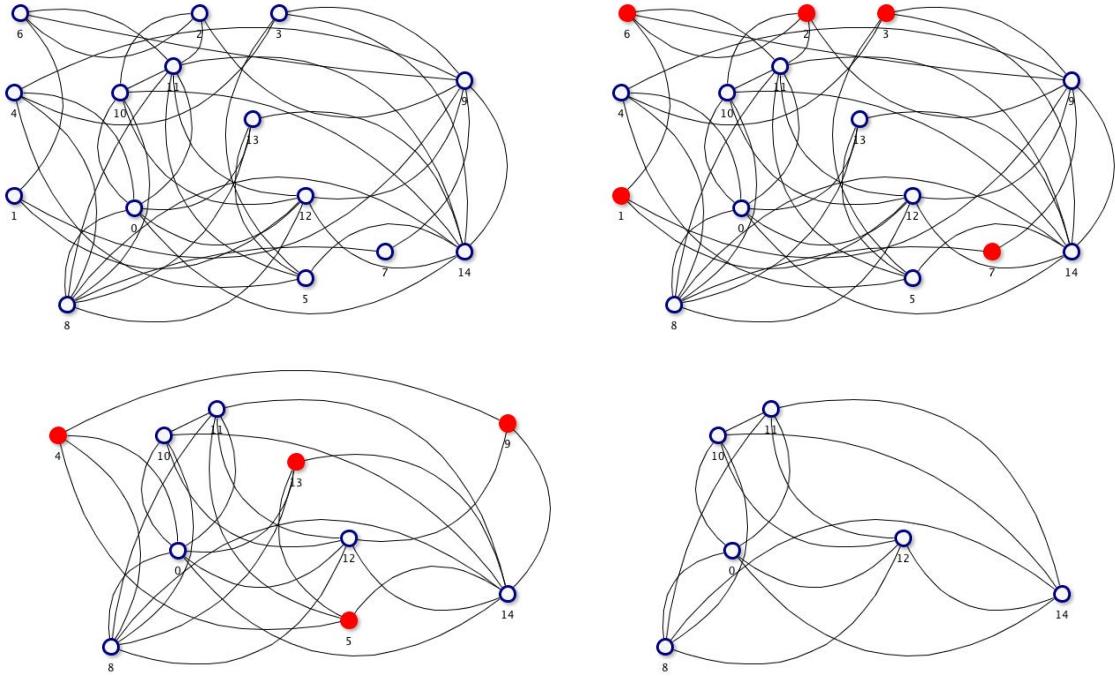

Figure 4.4: The 4-core. Taken from Gagnon and Goyal [2017].

**Top left:** initial graph. **Top right:** delete all nodes with  $k \leq 4$ . **Bottom left:** among the nodes remaining, delete all nodes with  $k \leq 4$ .  
**Bottom right:** the 4-core obtains when no further iteration is possible.

To return to our example with  $c = 4.1$ , observe that everyone in the 4-core choosing action 1 and everyone outside choosing action 0 constitutes a Nash equilibrium of the weakest-link game. By definition, everyone in the 4-core has at least 5 neighbours and so their return from choosing action 1 is at least  $5 - 4.1 = 0.9$ . By definition of the 4-core, no one outside the set has five or more neighbours who belong to the 4-core. Finally, we note that, by definition of the 4-core, this is also the largest set of individuals who can choose action 1 in an equilibrium in this network.

Observe that the zero activity outcome remains an equilibrium for every network. Taken together, the zero equilibrium and the equilibrium corresponding to the  $q$ -core define the minimal and the maximal level of activity in a network. Figure 4.5 illustrates the 1-core

and 2-core in an Erdos-Renyi network and in a Stochastic Block random graph with two communities (and equal average degree). We observe that in Erdos-Renyi graphs the  $q$ -core is either extensive and covers much of the graph or it is very small. This is because Erdos-Renyi graphs have a fairly homogenous structure with most nodes having a degree close to the average degree. As we move from the Erdos-Renyi to the Stochastic Random graph model, this changes slightly and we see that a part of one community constitutes a  $q$ -core, while the other one lies outside the  $q$ -core. To see how this homogeneity matters let us consider another classical network: the core-periphery network. Figure 4.6 shows that the  $q$ -core in this network has a very different reach as compared to the Erdos-Renyi graph. On the effects of changes in a network, note that adding a link to a network will either leave the  $q$ -core unaffected or it will expand it: so adding a link to a network can only weakly raise the maximal equilibrium.

A final remark concerns utility: the payoffs to an individual who chooses 0 are zero, while the potential payoffs of an active agent are increasing in the number of neighbours choosing action 1. So given a positive cost  $c$ , it follows that payoffs are larger for nodes in the  $q$ -core as compared to those outside it. It then follows as a simple corollary that, for any network, aggregate social welfare is maximized in the equilibrium corresponding to the  $q$ -core. Hence, adding links to a network has the potential to raise social welfare (that is therefore maximized in the complete network).

We summarize our discussion of the weakest-link game as follows:

**Proposition 4.2.** *Consider the weakest-link game played on a network. In every network, there exists a zero activity equilibrium. The maximal activity equilibrium is defined by the  $q$ -core, where  $q = \lceil c - 1 \rceil$ , of the network. Starting from any network  $g$ , adding links expands the  $q$ -core and has the potential to increase level of activity. The payoffs of players are larger in more active equilibria – thus adding links can potentially increase payoffs.*

A comparison of Propositions 4.1 and 4.2 brings out the general point – individual behaviour and utility are jointly shaped by the content of interaction and the structure of the network. In particular, in the best-shot game, the strategic substitutes property leads us to maximal independent sets; in the weakest-link games, the strategic complements property leads us to the  $q$ -core of the network.

A feature of both types of games is that, even in simple networks, there exist multiple equilibria. This means that it is often difficult to clearly relate an individual's location with her behaviour and her utility. So, for instance, we cannot say whether highly connected individuals choose higher or lower actions and earn more or less than less connected individuals. This multiplicity also places limits on what we can say on the effects of network change.

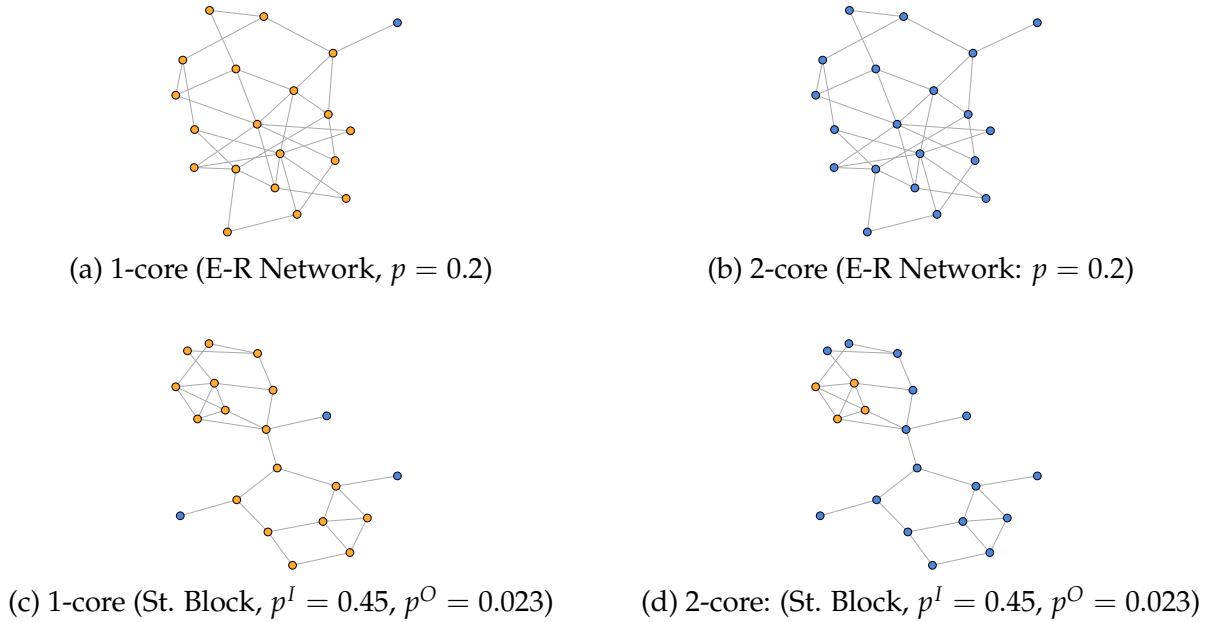

Figure 4.5: Cores (in orange):  $n = 20$ .

A key assumption underlying the analysis in this section has been that individuals know the entire network. This is a reasonable assumption in small networks but unlikely to hold in large network. The next section takes up the study of human behaviour in large networks.

## 4.4 Binary Games on Random Networks

Many networks of interest (such as online social media) are large – containing several hundred to several million nodes. In these networks it is more reasonable to suppose that individuals will have limited information on the details of who is connected to whom. An individual may know who her friends are and she may have a rough idea about the overall distribution of connections. This section explores human behaviour when individuals have limited knowledge of the network. Our discussion is based on Galeotti, Goyal, Jackson, Vega-Redondo, and Yariv [2010]. Let us revisit the best-shot game. Now suppose that an individual has degree  $d$  and knows that this is her degree. Should she choose action 0 or action 1? The returns to choosing 1 remain the same as before ( $1 - c$ ), but the returns from choosing 0 are less clear: they depend on whether her neighbours choose 1 or 0. If any of her neighbours chooses 1 then her best choice is 0; if all her neighbours choose 0 then her best action is 1. To make her decision, she therefore needs to have a view on what actions

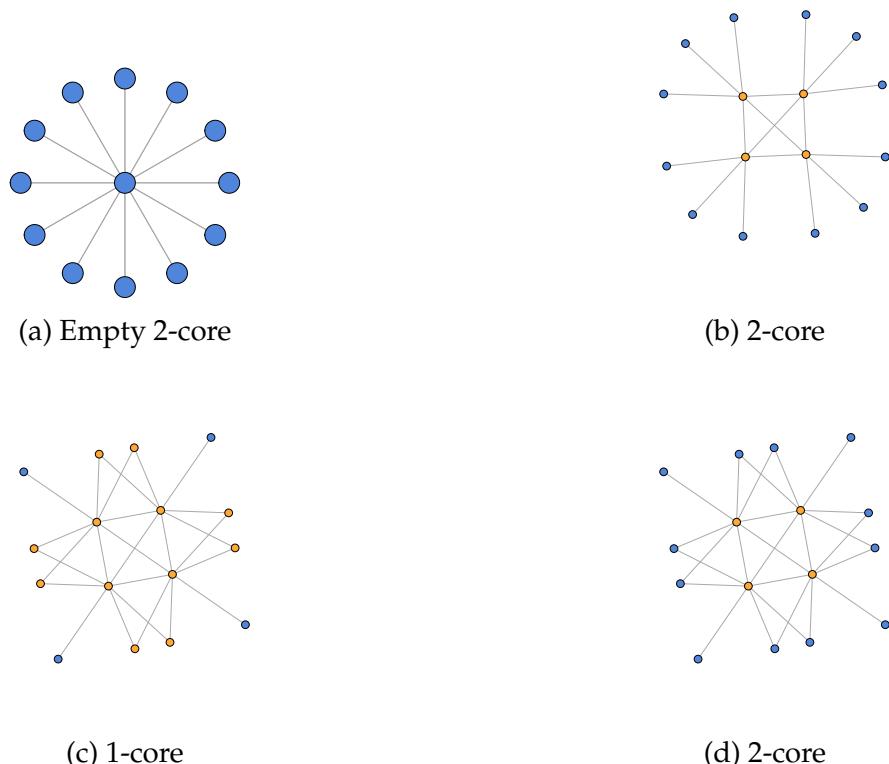

Figure 4.6: Cores (in orange)

her neighbours are choosing. Their choices will depend on the number of connections they have. To make progress in this problem one way to proceed is as follows: we define individual strategy as a function of her degree,  $s_i : \mathbb{N} \rightarrow \{0, 1\}$ . Next we need to consider an individual's perspective on the behaviour of her neighbours: as their behaviour depends on their degree, she needs to have a view on the degrees of each of her neighbours. To fix ideas let us suppose that she believes that the network arises out of an Erdos-Renyi random linking process with probability  $p \in (0, 1)$ . With this belief, she believes that the probability that any randomly selected neighbor is of degree  $k$  is the probability the neighbor is connected to  $k - 1$  additional agents of the remaining  $N - 2$  agents. This probability may be written as

$$Q(k; p) = \binom{N-2}{k-1} p^{k-1} (1-p)^{N-k-1}. \quad (4.12)$$

In principle, since the network is undirected, an individual's own degree is related to the degree of others and in particular to the degrees of her neighbours. However, as  $n$  gets large, this correlation becomes progressively smaller. Let us make one final assumption: suppose that everyone with the same degree chooses the same action. We now have all the ingredients to fully solve for the optimal individual strategy.

We show that the optimal strategy has a threshold property: there is a cut-off value  $d^*$ , such that everyone below  $d^*$  chooses 1 and everyone above  $d^*$  chooses 0. To see why this must be true, suppose it is optimal for someone with degree  $k$  to choose action 1. As degrees of neighbours are uncorrelated, it follows that each of the neighbours of someone with degree  $k - 1$  has the same degree distribution as a neighbour of someone with degree  $k$ . As a neighbour's degree is independent of an individual's own degree this means that someone with degree  $k - 1$  must expect less activity in the aggregate from her neighbourhood as compared to someone with  $k$  neighbours. As this is a game of strategic substitutes, it follows that the marginal returns to choosing action 1 are higher for the individual with degree  $k - 1$ , as compared to the individual with degree  $k$ . If action 1 is optimal for degree  $k$ , it must also be optimal for individual with degree  $k - 1$ . Thus there is a threshold property to optimal choice.

Suppose every individual is following the threshold strategy with a threshold  $t$ . Let us compute this threshold: first note that individual payoff from action 1 is  $1 - c$ . The payoff from action 0 depends on whether one of the neighbours chooses action 1. What is the probability that at least one of the neighbour chooses 1? This is one minus the probability that none of the neighbours chooses 1:

$$1 - \left[ 1 - \sum_{k=1}^t Q(k; p) \right]^t. \quad (4.13)$$

To compute  $t$  we equate the expected payoff from action 0, given in equation (4.13), with the payoff from action 1,  $1 - c$ . In other words, we are looking for  $t$  such that  $1 - c$  lies between the values of 4.13 evaluated at  $t$  vs.  $t + 1$ . It is possible to show that this equilibrium is the only equilibrium in strategies that condition only on degree. Moreover, the strategy is (monotonically) decreasing in degree: degrees below the threshold choose action 1, and degrees above the threshold choose action 0.

We now turn to the issue of how changes in the network affect behaviour. An individual conditions their behaviour on their own degree, so it is natural to study changes in the network in terms of changes in the degree distribution. Let us again consider the Erdos-Renyi random graph: here changes in the degree distribution can be studied in terms of an increase in the probability of linking,  $p$ . Let us consider an increase from  $p$  to a higher  $p'$ . Note that a higher  $p$  means that for every  $t$ ,

$$\sum_{k=1}^t Q(k; p') \leq \sum_{k=1}^t Q(k; p)$$

Recall from chapter 1, that a change from  $p$  to  $p'$  therefore induces a first order stochastic shift in the degree distribution.

Consider the threshold that we computed under  $p$ . Under a first order stochastic dominant shift the term  $\sum_{k=1}^t Q(k; p')$  is smaller and the expected payoff from action 0 at threshold  $t$  is strictly smaller than the payoff from action 1. This means that the new threshold  $t'$  under  $p'$  will be higher,  $t' \geq t$ .

To develop a feel for these features of behaviour, it is helpful to compute thresholds. Table 4.1 presents thresholds in an Erdos-Renyi network with  $n = 20$  and the probability of linking  $p = 0.1$ . The threshold is 2: so degrees 1 and 2 choose action 1, and all degrees above 2 choose 0. Table 4.2 presents thresholds for different levels of  $p$  in the best-shot game: we see that the threshold is increasing in connectivity level  $p$ .

The increase in threshold means that effort remains unchanged for individuals with degrees lower than  $t$  or greater than  $t'$ , and *increases* for all individuals with degrees between  $t$  and  $t'$ . The change in threshold also has another implication: the probability that any randomly selected neighbour chooses effort falls, in other words,  $\sum_{k=1}^{t'} Q(k; p') \leq \sum_{k=1}^t Q(k; p)$ . Thus the threshold only increases if, for a given degree, the total of neighbors' equilibrium efforts is greater under the original  $p$  than under  $p'$ , which implies that

Number of nodes	20
Probability of link	0.1
Cost of action	0.5
Threshold	2
Prob. at least 1 neigh. chooses 1:	0.70
Expected Utility of threshold degree (s=0)	0.70
Expected Utility (s=1)	.50

Table 4.1: Best-Shot Game on Erdos-Renyi Network:  $p = 0.1$ 

Prob. of link, $p$	0.1	0.2	0.3	0.4	0.5
Best-shot Threshold	2	3	4	6	7

Table 4.2: Thresholds: Erdos-Renyi Networks with Varying  $p$ 

the probability of any selected neighbor choosing effort must be lower under  $p'$ .

The computations above were made in the context of Erdos-Renyi networks. However, nothing essential in these computations rests on the details of the Erdos-Renyi network. Recall from chapter 2, that starting from some degree distribution  $P$ , using the configuration model, the approximate degree distribution for neighbours is

$$\tilde{P}(d) = \frac{P(d)d}{E[d]}, \quad (4.14)$$

where  $E(d)$  is the expected degree under distribution  $P$ . The probability that a neighbour who uses strategy  $s(\cdot)$  chooses 1 is given by

$$p_s = \sum_d s(d)\tilde{P}(d). \quad (4.15)$$

The probability that  $m$  out of  $d$  neighbours choose action 1 is given by

$$\binom{d}{m} p_s^m (1 - p_s)^{d-m}. \quad (4.16)$$

The expected utility of a player choosing action  $x_i$  is then given by

$$U_{d_i}(x_i, s(\cdot)) = \sum_{m=0}^{d_i} u_{d_i}(x_i, m) \binom{d}{m} p_s^m (1 - p_s)^{d-m}. \quad (4.17)$$

The arguments used to derive the thresholds in the Erdos-Renyi network can easily be used to derive thresholds for an arbitrary degree distribution  $P$  (simply by substituting the above formulae in the place of the expressions corresponding to the Erdos-Renyi degree distribution). With these remarks in mind, we may summarize our discussion as follows.

**Proposition 4.3.** Consider the best-shot game played on a random network. There exists a unique equilibrium in threshold strategies. Degrees below the threshold degree choose action 1 while degrees above the threshold choose 0. Thus activity level is (weakly) falling and therefore utility is (weakly) increasing in degree.

A first order stochastic shift in neighbours' degree distribution from  $P$  to  $P'$  leads to a (weak) increase in degree threshold in the equilibrium strategy. Thus more connected networks exhibit (weakly) higher level of activity, for every degree. This implies that for every degree the expected level of activity of a neighbour must go down.

We provide a sketch of the argument for uniqueness here; the interested reader is referred to Galeotti, Goyal, Jackson, Vega-Redondo, and Yariv [2010] for the details of the proof. Suppose there exist two equilibria with distinct thresholds  $t > t'$ . So there is a degree  $t' + 1$  that is weakly lower than  $t$ : this degree chooses action 0 under  $t'$  and chooses 1 under threshold  $t$ . However, that degree  $t' + 1$  expects higher sum of activity in the  $t$  equilibria and so her marginal returns from action 1 will be lower than the marginal returns from action 1 for the same degree under the threshold  $t'$ . Given that  $t' + 1$  finds it optimal to choose action 0, this contradicts the optimality of choosing action 1 under threshold  $t$ .

We conclude our discussion of best-shot game on random graphs with some remarks on social welfare. Let us say that social welfare is given by the expected payoff of a randomly chosen player (according to the prevailing degree distribution). The above result tells us that every degree does weakly less well under the more connected network. However, utility is increasing in degree and there is a higher fraction of individuals in the more connected network. It is therefore possible that even though every degree does less well, the average individual does better in the more connected network.

We next turn to weakest-link game played by individuals located in a large random graph. Recall that payoffs in the weakest-link game are given by

$$s_i \sum_{j \in N_i(g)} s_j - cs_i \tag{4.18}$$

We will show that equilibrium is characterized by a unique threshold. As before, suppose that individuals inhabit a Erdös-Renyi model with link probability given by  $p$ . If the number of nodes is large enough, the degrees of neighbours are independent. This means that the probability of a neighbour choosing action 1 is independent of own degree: in turn, this implies that expected activity is increasing in the number of neighbours, i.e.,  $\sum_{j \in N_i} x_j$  is increasing in degree of  $i$ . If someone with degree  $t$  chooses action 1 then the property of strategic complements tells us that the marginal returns to action 1 are strictly larger for individuals with degree greater than  $t$ . In other words, optimal action obeys a threshold:

there is some  $t$ , individuals with degree lower than  $t$  choose 0, while those with degree greater than  $t$  choose 1.

Building on this argument, we can say that for sufficiently large  $p$  there exists  $t < N - 1$ , for which

$$(t - 1) \sum_{k=t}^{N-1} Q(k; p) < c \text{ and } t \sum_{k=t}^{N-1} Q(k; p) \geq c. \quad (4.19)$$

Marginal returns are increasing in expected activity in neighbourhood. As own degree is independent of neighbour's degree, higher degree means higher expected activity level in neighbourhood. This means that the optimal strategy is monotonically increasing in the degree of an individual. As individuals can always earn 0 by choosing action 0, it follows that expected payoffs are increasing in degree as well.

Let us now take up the effects of changes in the network: consider an increase in probability of linking from  $p$  to  $p'$ , where  $p' > p$ . This means that the degree distribution under  $p'$  first order dominates the degree distribution under  $p$ , i.e., for any  $t$ ,  $\sum_{k=t}^{N-1} Q(k; p') > \sum_{k=t}^{N-1} Q(k; p)$ . Intuitively, the shift from  $p$  to  $p'$  increases connectivity of neighbours and this raises the probability that a neighbour would choose 1. From the property of strategic complements, this raises the returns from action 1 and lowers the threshold. Iterating on this process, we generate a new threshold  $t' < t$ . A lower threshold means that, the probability that a neighbor chooses 1 increases: this is because for any  $t$ , the probability of degree greater than  $t$  is higher under  $p'$ .

To develop a feel for these features of behaviour, we compute thresholds in Erdos-Renyi networks. Table 4.3 presents the computation of active equilibrium threshold for a network with twenty nodes,  $n = 20$ , and with probability of linking  $p = 0.2$ . The threshold is 3: this means that all those with degrees 1 and 2 choose action 0, while players with degree 3 and higher choose action 1. Table 4.4 presents thresholds for different levels of  $p$  in the weakest-link game: we see that the threshold is declining in connectivity level  $p$ .

Number of nodes	20
Probability of link	0.2
Cost of action	2
threshold	3
Prob. a neigh's degree $\geq 3$ :	0.72
Expected Utility (s=0)	0
Expected Utility of threshold degree (s=1)	0.19

Table 4.3: Equilibrium in Weakest-Link Game on Erdos-Renyi Networks

We summarize our discussion of weakest-link games on random graphs as follows:

Prob. of link, $p$	0.1	0.2	0.3	0.4	0.5
Weakest-Link Threshold	3	2	2	2	2

Table 4.4: Thresholds in Erdos-Renyi Networks with Varying Connectivity

**Proposition 4.4.** Consider the weakest-link game played on a random network. There exists a zero activity equilibrium in every network. In addition, there may exist an equilibrium with positive activity. A positive activity equilibrium strategy exhibits a threshold property: degrees below the threshold degree choose action 0, while degrees above the threshold choose 1. Thus activity level is (weakly) rising in the degree of an individual.

A first order shift in degree distribution of neighbours leads to a (weak) decrease in the degree threshold. Thus more connected networks exhibit (weakly) higher level of activity, for every degree.

We conclude our discussion of the weakest-link game with some remarks on social welfare. As before, we will measure social welfare by the expected payoff of a randomly chosen player. The above result tells us that every degree does weakly better under the more connected network. Moreover, utility is increasing in degree and there is a higher fraction of higher degree individuals in the more connected network. It therefore follows that in the active equilibrium of the weakest-link game, the average individual does better in the more connected network.

Our study of best-shot and weakest-link games in random graphs provides a nice illustration of how the content of interaction interacts with networks to shape behaviour. The structure of interaction is reflected in own degree and degree distribution, while the content of interaction is captured in whether the game is one of substitutes or complements. Equilibrium strategy is monotonically decreasing in degree under strategic substitutes, while it is monotonically increasing under strategic complements. Higher degree individuals earn higher payoffs in both cases. Increases in connectivity of neighbours have contrasting implications for behavior: under strategic substitutes, there is a fall in expected efforts of each neighbour, while under strategic complements, there is an increase in expected efforts from each neighbour.

#### 4.4.1 Experimental Evidence

The discussion above derives a simple rule for behaviour in large networks when individuals have limited information on the network. We found that equilibria involve simple thresholds that determine whether to be active or passive. The level of the threshold depends on the degree distribution of the network, on the costs of activity, and on whether the game is one of substitutes or complements. In this section, we present a laboratory

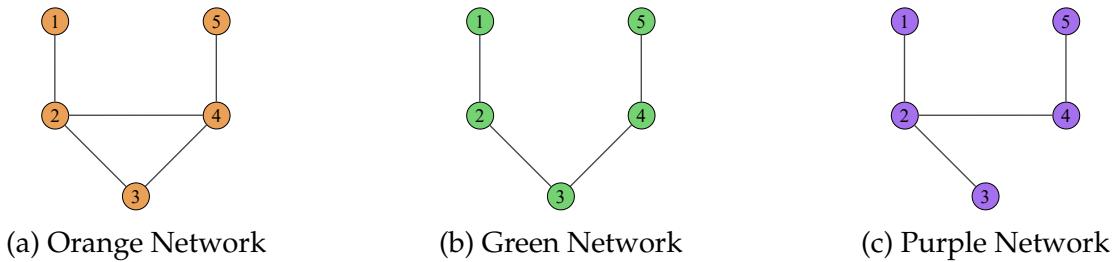

Figure 4.7: Networks for Experiment 1. Taken from Charness, Feri, Meléndez-Jiménez, and Sutter [2014]

experiment that tests these predictions: do experimental subjects use threshold rules and do the thresholds adapt as the underlying network is changed? Our discussion is based on Charness, Feri, Meléndez-Jiménez, and Sutter [2014].

At the outset, it is worth drawing attention to a few potential difficulties faced by subjects. Subjects need to work their way to understanding how degrees and strategic considerations interact. In addition, there is the potential challenge of choosing the right threshold. In the best-shot game there is a unique threshold; in the weakest-link game there typically exist multiple equilibria, ranging from the zero activity outcome to the positive activity outcome. As actions are costly there is a difference in the level of security/risk associated with the different equilibrium: choosing action 0 guarantees a payoff, while choosing action 1 exposes the individual to an uncertain payoff that depends on how many neighbours choose action 1. Thus attitudes toward uncertainty may also come into play, in addition to the thresholds.

We consider three networks that are displayed in Figure 4.7. Let  $p$  be the probability that the Orange network is picked, the other two networks being picked with equal probability given by  $(1 - p)/2$ . Observe that the Orange network has a higher connectivity than the other two networks (the Orange network is obtained by adding link 24 to the Green network, and it is obtained from the Purple network by adding the link 34). An increase in  $p$  can therefore be interpreted as an increase in connectivity of the networks. Two values of  $p$  are considered:  $p = 0.2$  and  $p = 0.8$ . So there were four treatments in all, two for substitutes and two for complements. There were two sessions per treatment and 20 subjects per session, so there were 160 subjects in all. The experiment was conducted at the University of Innsbruck.

The theoretical analysis tells us that the equilibria are defined by a threshold. In the best-shot game, the parameters are as follows: a player earns 100 if either he or one of his neighbours is active, and earns zero otherwise. Action 1 costs 50. In the weakest-link game, if a player is inactive she earns 50, and if she is active, she earns 33.33 times the number of

neighbours who are active. Thus she requires at least two neighbours to be active to justify choosing action 1 herself.

Table 4.5 summarizes the theoretical analysis for these parameters. In the case of strategic substitutes, the theoretical prediction is that players with degree 1 (degree 3) are active (inactive) in both treatments with  $p = 0.2$  and  $p = 0.8$ . Players with degree 2 are active when  $p = 0.8$  and inactive when  $p = 0.2$ . With strategic complements, the unique theoretical prediction is zero activity with  $p = 0.2$ . With  $p = 0.8$ , in addition to the zero activity, there is also a positive action equilibrium in which degrees 2 and 3 are active, while degree 1 is inactive (it is worth bearing in mind that the degrees of neighbours may be correlated due to the size of networks; a question at the end of the chapter explores this issue further).

Figure 4.8 (top panel) shows the evolution of behaviour across networks and across the 40 periods in the game of strategic substitutes (the best-shot game). For strategic substitutes we observe that subjects behave very much line with the (unique) threshold equilibrium: this is especially true for degrees 1 and 3, but slightly less so for degree 2.

Next, let us consider the effect of degree on behavior. Subjects with degree 2 are much less likely to choose activity than those with degree 1; this decrease is large when  $p = 0.2$  and somewhat smaller when  $p = 0.8$ . Comparing degree 3 to degree 2, the probability of choosing 1 is significantly lower for subjects with degree 3; this difference is large when  $p = 0.8$ , and the difference is smaller when  $p = 0.2$ . Overall, the behaviour in the laboratory is in line with the theoretical prediction.

Turning to the effects of greater connectivity (recall that higher values of  $p$  imply higher connectivity), there is no significant change for degree 1. The degree 2 individuals do increase activity with a move from  $p = 0.2$  to  $p = 0.8$ . For subjects with degree 3, there is a slight increase in the probability of action 1.

To summarize, *in the best-shot game, subjects consistently choose the unique equilibrium and the probability of activity is decreasing with the degree and increasing with network connectivity.*

We now report on the game of strategic complements (the weakest-link game). When  $p = 0.2$ , the zero action outcome is the unique equilibrium. Play by subjects with degrees 1 and 2 is strongly consistent with the equilibrium prediction. Subjects with degree 3 are inactive with significant probability. When  $p = 0.8$ , in addition to the zero action outcome, there is also the activity equilibrium – in which subjects with degrees 2 and 3 are active. The behavior of subjects with degree 1 is strongly consistent, but the evidence on the behavior of degree 2 and 3 subjects is mixed.

Turning to the effects of changing  $p$ , the behavior of subjects with degree 1 does not change significantly, but subjects with degrees 2 and 3 are significantly more likely to

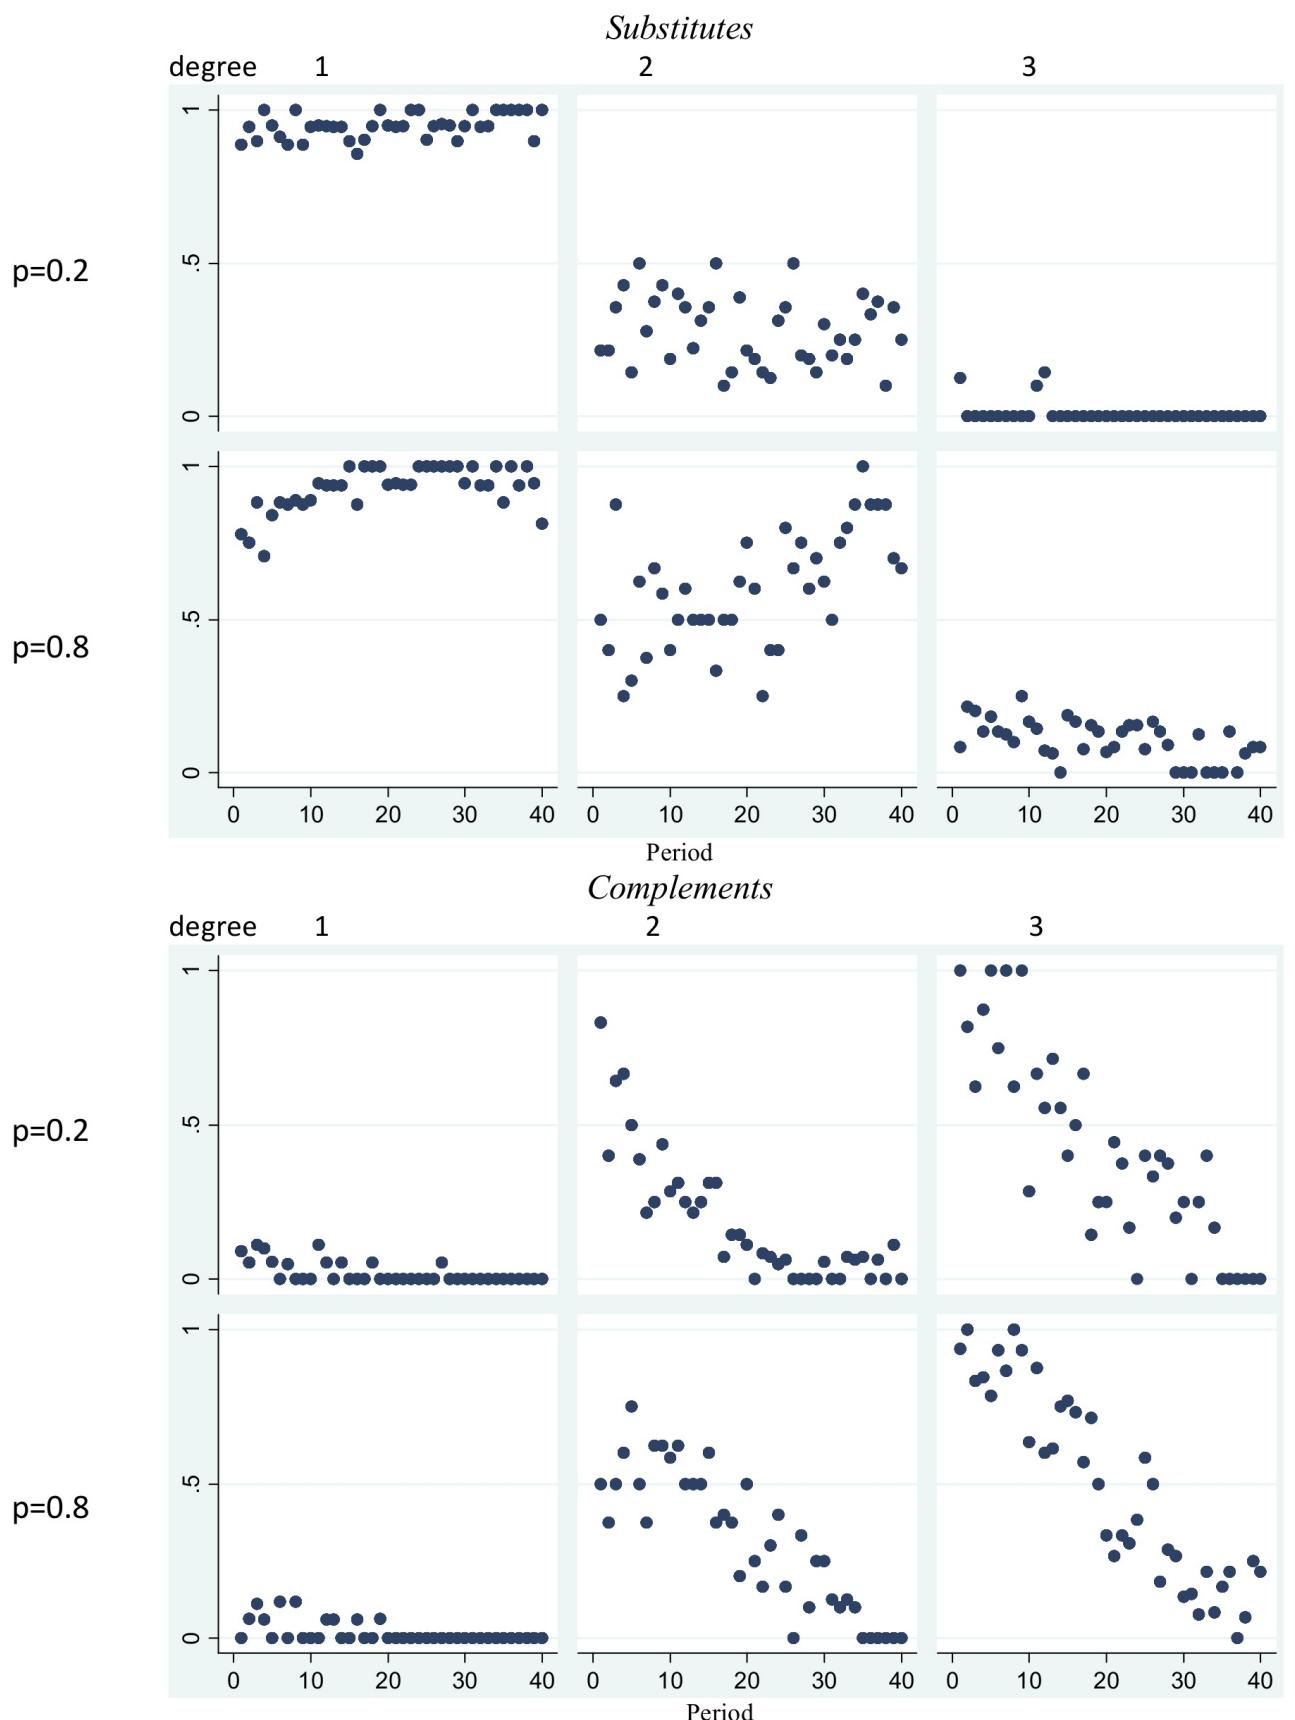

Figure 4.8: Experiment 1 – Relative frequencies of choices by degree. Taken from Charness, Feri, Meléndez-Jiménez, and Sutter [2014]

		Active Degrees	Inactive Degrees
Substitutes	p=0.20	1	2,3
	p=0.80	1, 2	3
Complements	p=0.20	—	1,2,3
	p=0.80	— 2,3	1,2,3 1

Table 4.5: Equilibrium in Games

choose 1 for higher values of  $p$ . However, these attempts are largely unsuccessful over time and subjects converge to the secure and inefficient equilibrium, eventually.

Concerning the effect of the degree, a person with degree 2 is significantly more likely to be active than a person of degree 1; this difference is considerably larger with  $p = 0.8$  as compared to  $p = 0.2$ . This qualitatively supports the theoretical prediction of a lowering of threshold with an increase in connectivity.

To summarize: *in the weakest-link game subjects choose the secure zero activity equilibrium with low connectivity. The probability of activity increases with the degree and with connectivity. Under the high connectivity network, there is eventually convergence to the inefficient (but secure) zero activity equilibrium.*

Let us summarize what we have learnt in our study of binary games on large networks. We took the view that individuals will have knowledge of some aspects of local network (such as their own degree) and general aspects of the network as a whole (such as its degree distribution). In such a setting, individual strategy will be a mapping from degree to action. The theoretical analysis of binary games with limited network knowledge yields a number of sharp and intuitive predictions. Equilibrium strategies exhibit a simple threshold structure: in games of substitutes, individuals below a threshold choose action 1, while those above the threshold choose action 0. In games of complements, individuals above a threshold choose action 1, while those below the threshold choose action 0. An increase in the connectivity of the network has clear cut effects on these cut-off thresholds. We presented the findings of a laboratory experiment that offers support for these theoretical predictions.

## 4.5 Continuous Action Games

In the previous two sections we have studied binary action games. We now enrich the action possibilities open to individuals: we allow them to chose from a continuum of options. We will focus on games that admit a linear best response for individuals. As in the case of

binary games, we will start by considering a setting in which individuals know the entire network. Our analysis will yield a powerful insight: the behaviour of individuals is proportional to their centrality in the network. We will comment on the social welfare of the equilibrium outcomes. The section concludes with remarks on continuous actions games with incomplete network information. The discussion draws on the original papers by Ballester, Calvó-Armengol, and Zenou [2006], Bramoullé and Kranton [2007] and Galeotti, Goyal, Jackson, Vega-Redondo, and Yariv [2010].

To recall, there is a set of players  $N = \{1, \dots, n\}$ , with  $n \geq 2$ . Individuals simultaneously choose an action: individual  $i$  chooses an action,  $s_i \in \mathbb{R}_+$ . Individuals are located in a network  $g$ . The network has a corresponding adjacency matrix given by  $G$ . In the matrix  $G$ , the entry  $g_{ij}$  reflects the strength of the relationship that  $i$  has with  $j$ . For expositional simplicity, we will assume that  $g_{ij} = g_{ji}$ : in other words, the links (and the networks) are ‘symmetric’. It will be assumed that there are no own links,  $g_{ii} = 0$ . The vector of actions is denoted by  $\mathbf{s} \in \mathbb{R}_+^n$ . The payoff to individual  $i$  depends on this vector,  $\mathbf{s}$ , the undirected network (with adjacency matrix)  $G$ , and other parameters, described below:

$$U_i(\mathbf{s}, \mathbf{G}) = \underbrace{s_i \left( b_i + \beta \sum_{j \in N} g_{ij} s_j \right)}_{\text{returns from own action}} - \underbrace{\frac{1}{2} s_i^2}_{\substack{\text{private costs} \\ \text{of own action}}} + \underbrace{P_i(\mathbf{s}_{-i}, \mathbf{G}, \mathbf{b})}_{\text{pure externalities}}. \quad (4.20)$$

The marginal returns from increasing the action  $s_i$  depend on  $i$ 's action,  $s_i$ , and on others' actions. The coefficient  $b_i \in \mathbb{R}$  corresponds to the part of  $i$ 's marginal return that is independent of others' actions, and is called  $i$ 's standalone marginal return. The contribution of others' actions to  $i$ 's marginal return is given by the term  $\beta \sum_{j \in N} g_{ij} s_j$ . Here  $g_{ij} \geq 0$  is a measure of the strength of the interaction between  $i$  and  $j$ ; we assume that for every  $i \in N$ ,  $g_{ii} = 0$  – there are no self-loops in the network  $G$ . The parameter  $\beta$  captures strategic interdependencies. If  $\beta > 0$  then actions are strategic complements; and if  $\beta < 0$  then actions are strategic substitutes. The function  $P_i(\mathbf{s}_{-i}, \mathbf{G}, \mathbf{b})$  captures pure externalities – that is, spillovers that do not affect the best response.

For ease of reference, let us recall a baseline example of a game on networks that satisfies the above properties.

**Example 4.8** (The investment game). Individual  $i$  makes an investment  $s_i$  at a cost  $\frac{1}{2}s_i^2$ . The private marginal return on that investment is  $b_i + \beta \sum_{j \in N} g_{ij} s_j$ , where  $b_i$  is individual  $i$ 's

standalone marginal return and  $\sum_{j \in N} g_{ij}s_j$  is the aggregate local effort. The utility of  $i$  is

$$U_i(\mathbf{s}, \mathbf{G}) = s_i \left( b_i + \beta \sum_{j \in N} g_{ij}s_j \right) - \frac{1}{2}s_i^2.$$

The case with  $\beta > 0$  reflects investment complementarities. Here, an individual's marginal returns are enhanced when his neighbors work harder; this creates both strategic complementarities and positive externalities. The case of  $\beta < 0$  corresponds to strategic substitutes and negative externalities; this can be micro-founded via a model of competition in a market after the investment decisions  $s_i$  have been made.

In making their choices, an individual will seek to equate the marginal returns with the marginal costs of action. This is reflected in the first-order condition for individual  $i$ 's action. Differentiating the payoff with respect to own action and setting it equal to zero and rearranging terms yields us individual  $i$ 's best response:

$$s_i = b_i + \beta \sum_{j \in N} g_{ij}s_j.$$

Thus a player's best response is his stand alone marginal benefit  $b_i$  plus the sum of actions of is neighbours: the direction of movement relative to the autarkic optimum  $b_i$  is determined by whether the  $\beta$  is positive or negative, i.e., whether actions are complements or substitutes, and the connectivity (reflected in the values of  $g_{ij}$ ).

There are three challenges in the study of such games – the equilibrium may not be interior (so that the first order conditions are not appropriate), there may be multiple equilibria, or the spillovers are so large that there is no well defined optimum. A simple way to ensure that the equilibrium is interior and defined by the first order conditions is to require that the spillovers  $\beta$  are suitably small in relation to the network. As we start with an interior autarkic optimum, the best response in the game will then also remain interior. The early literature in this field essentially used this approach and we will present the restrictions needed to ensure this now. Let us work through the mechanics of the derivations to develop a feel for how these restrictions operate and how such games are solved. The study of general network effects, i.e., when  $\beta$  is large, requires more advanced methods that are not covered here. The reader is referred to Bramoullé, Kranton, and D'amours [2014] for an introduction to those methods.

The best responses of the individuals constitute a system of  $n$  linear equations. Recalling that the matrix  $G$  summarizes the cross dependencies, we may write this system in matrix form. In particular, any (interior) Nash equilibrium action profile  $\mathbf{s}^*$  of the game

satisfies

$$[I - \beta G]s^* = b. \quad (4.21)$$

The *spectral radius* of a matrix is the maximum of its eigenvalues' absolute values. Let us denote the eigenvalues of matrix  $G$  by  $\lambda_1(G), \dots, \lambda_n(G)$  and suppose that they are ordered from the highest to the lowest. The key assumption is:

**Assumption 4.1.** *Spectral radius of  $\beta G$  is less than 1, i.e.,  $\lambda_1(G) < 1/\beta$ .*

Under this condition, (4.21) is a necessary and sufficient condition for a solution to the game. This condition also ensures the uniqueness (and stability) of the Nash equilibrium. The interested reader is referred to Ballester, Calvó-Armengol, and Zenou [2006] and Bramoullé, Kranton, and D'amours [2014] for discussions on interpretations of this point.

The eigenvalues provide us a measure of the amplification of spillovers via connections in the network. The assumption places a bound on the magnitude of the spillovers in relation to the parameter  $\beta$ : note in particular that the restriction on the matrix is stricter in inverse proportion to the value of  $\beta$ .

Under Assumption 19.1, the unique Nash equilibrium of the game is given by

$$s^* = [I - \beta G]^{-1}b. \quad (4.22)$$

We now use this characterization to develop a relation between network structure and behaviour.

Suppose that  $\beta$  is a small enough number such that the inverse

$$[I - \beta G]^{-1}$$

is well defined. From Chapter 1, recall that the Bonacich centrality vector is given by:

$$C_b(g, \beta) = [I - \beta G]^{-1}$$

Recall in particular that Bonacich centrality summarizes the sum of weighted walks of different lengths in the network:

$$C_b(i; g, \beta) = \sum_{j=1}^n \sum_k \beta^{k-1} m_{ij}^k(g, \beta). \quad (4.23)$$

where  $m_{ij}^k(g, \beta)$  is the number of weighted walks of length  $k$  between players  $i$  and  $j$ , in network  $g$ .

We summarize our discussion as follows.

**Proposition 4.5.** *Suppose assumption 19.1 is satisfied and payoffs are given by 4.20. There exists a unique equilibrium*

$$\mathbf{s}^* = [\mathbf{I} - \beta \mathbf{G}]^{-1} \mathbf{b}. \quad (4.24)$$

*Equilibrium actions are proportional to Bonacich centralities of individual players.*

It is helpful to work through some examples to appreciate how the content of interaction (complements vs. substitutes) and the structure of the network shapes individual behaviour.

We consider the example given in 4.8. The stand-alone benefit  $b_i$  is set equal to 1, for every  $i \in N$ . In the game of substitutes, the spillover parameter is set equal to  $\beta = -0.05$ , in the games of complements we set  $\beta = 0.05$ . The equilibrium is as in equation 4.22. Figure 4.9 presents equilibrium actions under strategic substitutes in four networks – the star, the cycle, an Erdos-Renyi network (with  $n=20$ ,  $p=0.20$ ) and a scale-free network (with  $n=20$ , Pareto coefficient= 1.33). Figure 4.10 presents behaviour under strategic complements in the same networks.

These figures draw our attention to a number of points. First, we see that in games of complements, as  $\beta > 0$  efforts are positively reinforced as we move along a walk. So individuals who are connected to other well connected individuals have the highest centrality and make the highest efforts. On the other hand, in games of substitutes, as  $\beta < 0$ , the effects alternate: a higher effort by  $i$  lowers incentives of her neighbours, and this in turn pushed up the incentives of  $i$ 's neighbours' neighbours, and so forth. This yield the interesting observation that in such games the hub of the star network chooses the lowest effort. Similar results obtain in the scale-free network, the nodes connected to other highly connected nodes chooses the highest effort under complements, and the lowest effort under substitutes.

The second point to note is that connections raise effort in games of complements as compared to games of substitutes: in the cycle players choose a higher activity level under complements. Finally, observe that for games of complements, the range of effort is greater under the scale-free network as compared to the Erdos-Renyi network with the same average degree (3.5). This is a consequence of the greater dispersion in the centralities in the scale-free network.

The study of continuous action games provides us with a clear prediction on the relation between network location and individual behaviour. We now use this characterization to make some remarks on individual utility and social welfare.

For concreteness, let us focus on example 4.8. Consider the star network presented in

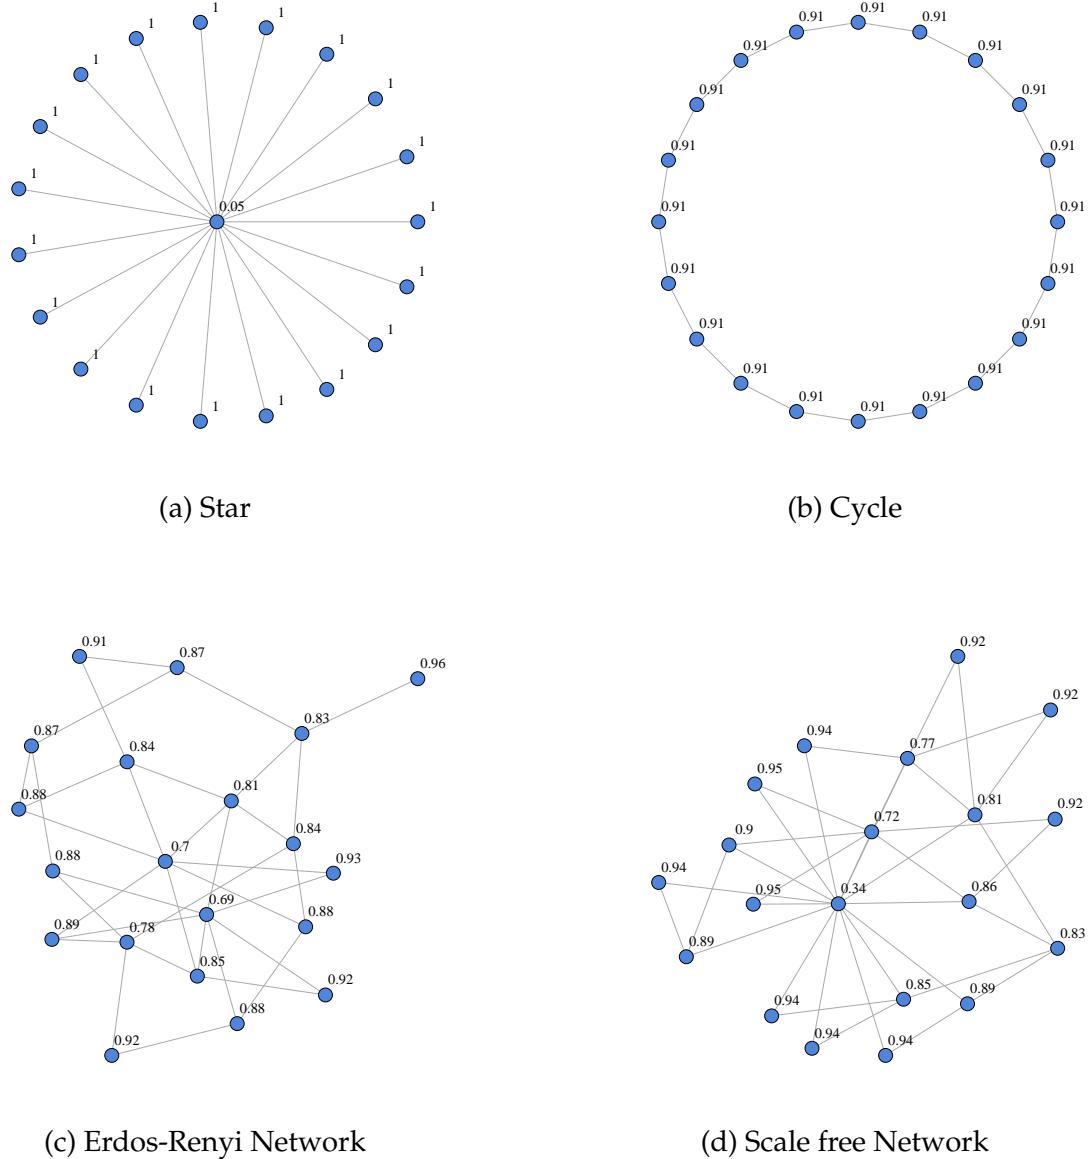

Figure 4.9: Centrality and Effort: Substitutes

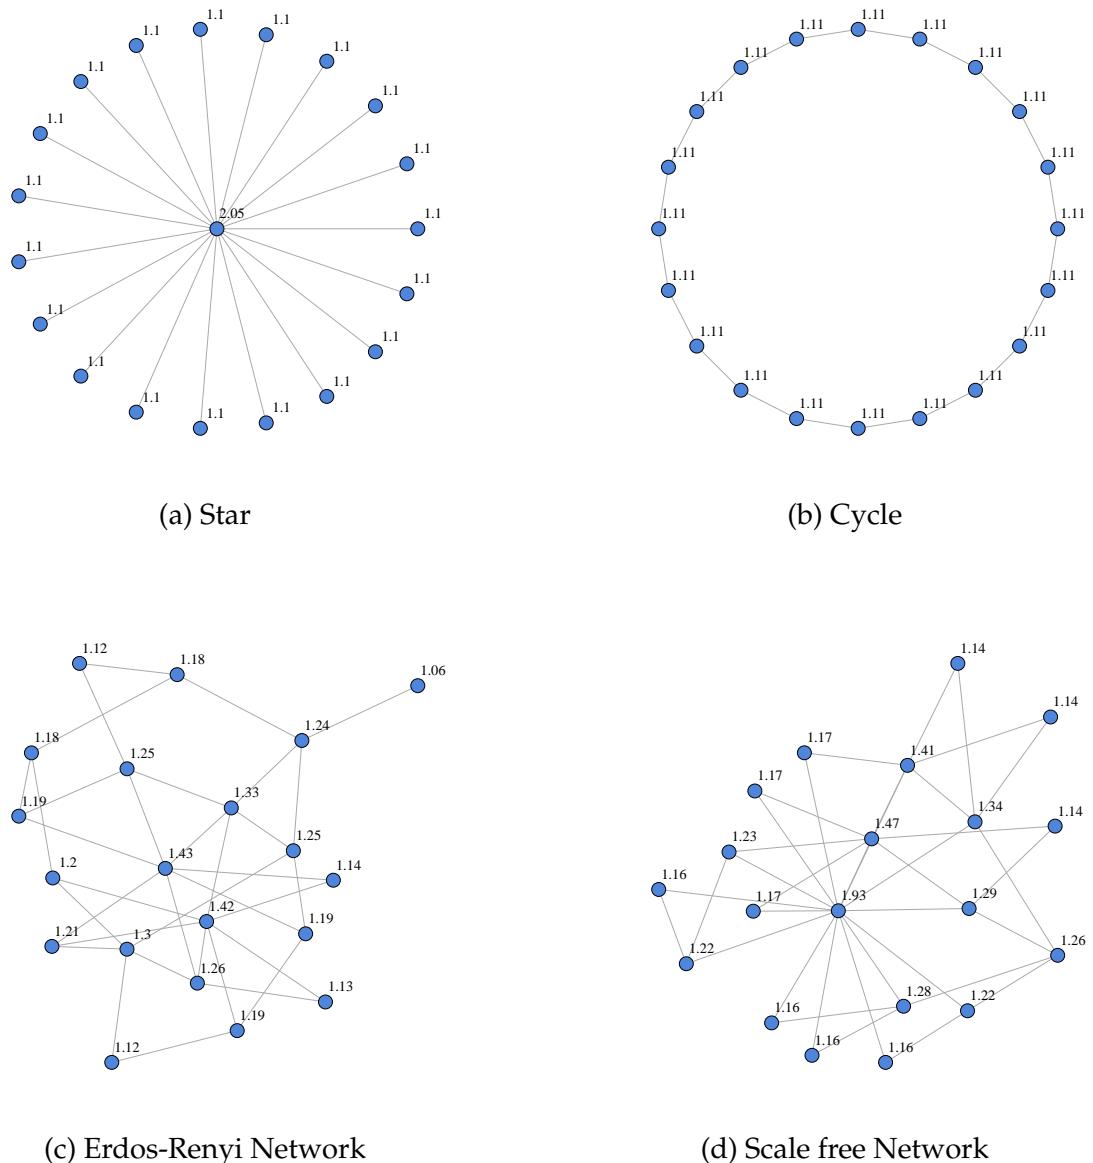

Figure 4.10: Centrality and Effort: Complements

the figures above. Observe that the hub chooses relatively higher effort in the complements game as compared to the strategic substitutes case. The hub also earns a higher payoff in the strategic complements as compared to the strategic substitutes game. Thus in the strategic complements case, centrality yields payoff advantages and these advantages can be quite large as we move toward scale-free networks. Likewise, centrality leads to lower payoffs in the strategic substitutes case. Figure 4.11 presents a snap-shot of payoffs in selected networks with both games of complements and substitutes to bring out this point.

Turning to social welfare, a first remark is that in games with positive externalities, individual efforts are generally too low relative to what is collectively desirable: this holds true in games of complements (the reader should think through why this must also be true in games of substitutes). In the game of strategic substitutes (that we studied above) the externalities are negative and as a result the efforts are too large relative to the social optimum. This wedge between individual optimum/equilibrium and what is collectively desirable suggests that there is space for interventions that can enhance social welfare. We will study optimal interventions in networks in section 4.6 below.

Before we conclude, let us note that we have studied games with linear best responses and assumed that players have complete knowledge of the network. It is possible to study such games in a setting with local network knowledge. Indeed, the arguments developed in section 4.4 can be carried over to a fairly general class of payoffs – that include games with compact and convex strategy sets (with a restriction that individual payoffs remain anonymous and depend only on the sum of neighbours' actions). For full statements and proofs the interested reader should consult Galeotti, Goyal, Jackson, Vega-Redondo, and Yariv [2010].

With these assumptions in place, it is possible to show that there always exists an equilibrium involving monotone (symmetric) strategies in degrees. In games with strategic substitutes equilibrium actions are non-increasing in players' degrees, in games of strategic complements equilibrium actions are non-decreasing in the degree of players. In turn, the monotonicity property of equilibrium actions implies that, with positive externalities, social connections create personal advantages irrespective of whether the game exhibits strategic complements or substitutes: well-connected players earn more than poorly connected players. This implies in particular that, in games of strategic substitutes, higher connected individuals undertake *lower* action and earn *higher* payoffs. The results on changes in networks can similarly be extended: an increase in connectivity is modeled in terms of the notion of first order stochastic dominance of degree distributions. In games of strategic complements this has unambiguous effects – raising action for every degree and also for

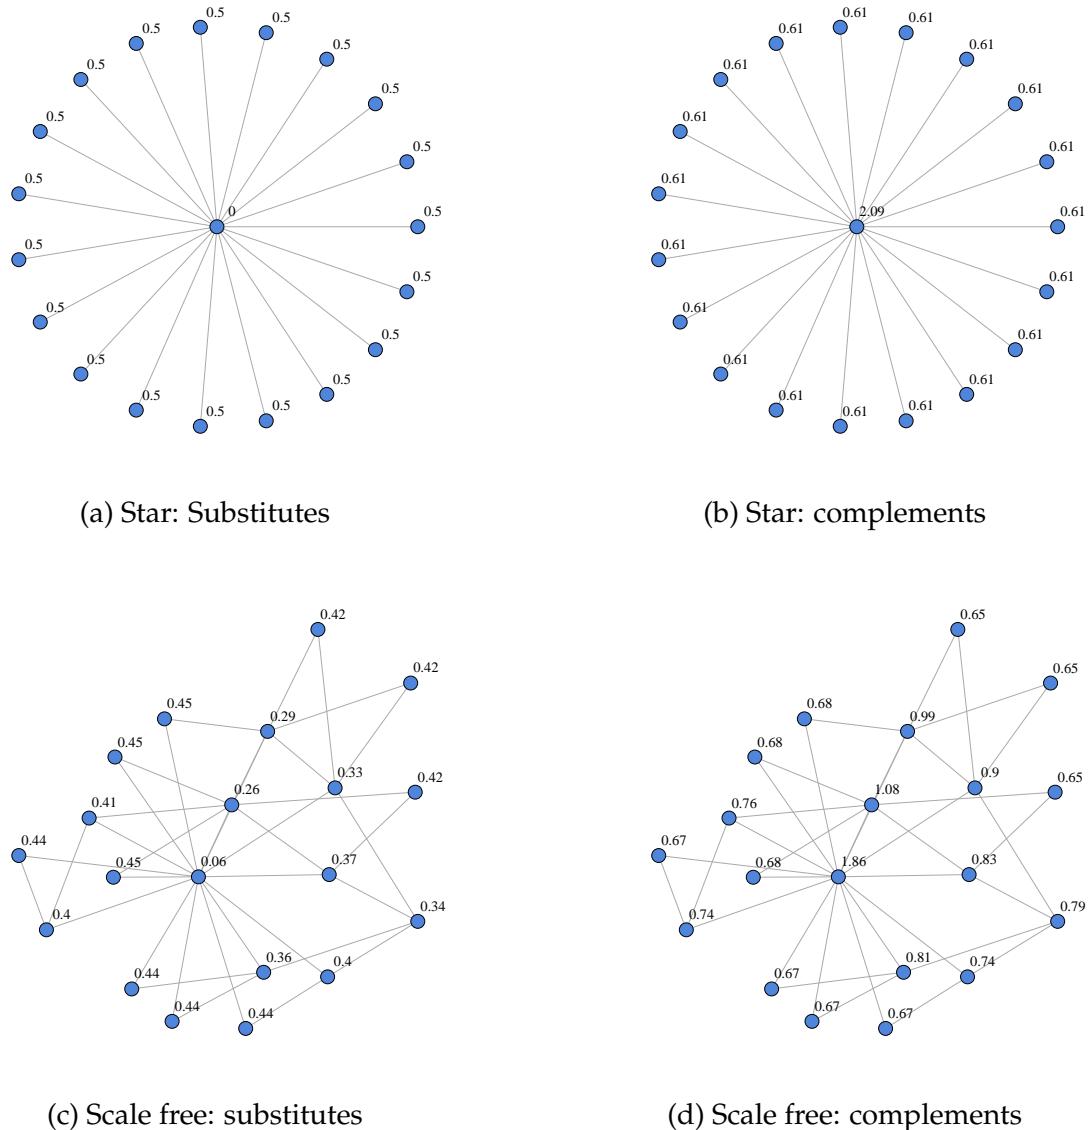

Figure 4.11: Centrality and Payoffs

the average neighbour.

## 4.6 Intervening in a network to influence behaviour

Our study of strategic interaction on networks reveals that equilibrium outcomes are generally socially sub-optimal. This is because individual actions give rise to externalities and individuals do not take these externalities into account in their decision making. One way to address this problem is to adjust the individual marginal returns in such a way that they are brought more in line with the social returns. However, an intervention on one individual has direct and indirect effects on the incentives of others. For example, suppose the planner increases a given individual's stand-alone marginal returns to effort, thereby increasing his effort. If actions are strategic complements, this will push up the incentives of the targeted individual's neighbors. That will increase the efforts of the neighbors of these neighbors, and so forth, creating aligned feedback effects throughout the network. If actions are strategic substitutes, the same intervention will discourage the individual's neighbors from exerting effort. However, the effect on those neighbors' neighbors will be positive – i.e., in the same direction as the effect on the targeted agent. This interplay between spillovers and network structure makes targeting interventions a complex problem. The aim of this section is to develop general principles for how to take into account these direct and indirect effects. Our discussion is based on Galeotti, Golub, and Goyal [2020].

We will consider a simultaneous-move game among individuals as analyzed in section 4.5. We will assume that links are symmetric and that assumption 19.1 holds. Equipped with these assumptions, we know from section 4.5 that the unique Nash equilibrium of the game can be characterized by

$$\mathbf{s}^* = [\mathbf{I} - \beta \mathbf{G}]^{-1} \mathbf{b}. \quad (4.25)$$

Let us now turn to the intervention problem: we will consider the utilitarian social welfare given by the sum of utilities. The external agent, the ‘planner’, whom we shall think of as a utilitarian, seeks to maximize the sum of utilities. Let us define aggregate utility:

$$W(\mathbf{b}, \mathbf{G}) = \sum_{i \in \mathcal{N}} U_i(\mathbf{s}^*, \mathbf{G}).$$

The benevolent planner aims to maximize the utilitarian social welfare at equilibrium by changing a vector of status quo stand-alone marginal returns  $\hat{\mathbf{b}}$  to a vector  $\mathbf{b}$ , subject to a budget constraint.

The timing of this intervention is as follows. The planner moves first and chooses her intervention, and then individuals simultaneously choose actions. The planner’s incentive-

targeting (IT) problem is given by

$$\begin{aligned} & \max_{\mathbf{b}} W(\mathbf{b}, \mathbf{G}) \\ \text{s.t.: } & \mathbf{s}^* = [\mathbf{I} - \beta \mathbf{G}]^{-1} \mathbf{b}, \\ & K(\mathbf{b}, \hat{\mathbf{b}}) = \sum_{i \in \mathcal{N}} (b_i - \hat{b}_i)^2 \leq C, \end{aligned} \tag{IT}$$

where  $C$  is a given budget. The function  $K$  represents an adjustment cost for implementing interventions.

We note that the cost function is separable across individuals and increasing in the magnitude of the change to each individual's incentives. This is a very simple form and it helps us in getting at the basic insights in a straightforward way.

The final assumption we make is the following:

**Property.** *The aggregate equilibrium utility is proportional to the sum of the squares of the equilibrium actions, that is,  $W(\mathbf{b}, \mathbf{G}) = w \cdot (\mathbf{s}^*)^\tau \mathbf{s}^*$  for some  $w \in \mathbb{R}$ , where  $\mathbf{s}^*$  is the Nash equilibrium action profile.*

This property is satisfied by the crime example in section 4.2.1; a question at the end of the chapter works through this point.

We now introduce a basis for the space of stand-alone marginal returns and actions in which, under our assumptions on  $\mathbf{G}$ , strategic effects and the planner's objective both take a simple form.

**Fact.** *If  $\mathbf{G}$  is symmetric then  $\mathbf{G} = \mathbf{U} \Lambda \mathbf{U}^\tau$ , where:*

1.  $\Lambda$  is an  $n \times n$  diagonal matrix whose diagonal entries  $\Lambda_{\ell\ell} = \lambda_\ell$  are the eigenvalues of  $\mathbf{G}$  (which are real numbers), ordered from greatest to least:  $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n$ .
2.  $\mathbf{U}$  is an orthogonal matrix. The  $\ell^{\text{th}}$  column of  $\mathbf{U}$ , which we call  $\mathbf{u}^\ell$ , is a real eigenvector of  $\mathbf{G}$ , namely the eigenvector associated to the eigenvalue  $\lambda_\ell$ , which is normalized so that  $\|\mathbf{u}^\ell\| = 1$  (in the Euclidean norm).

For generic  $\mathbf{G}$ , the decomposition is uniquely determined, except that any column of  $\mathbf{U}$  is determined only up to multiplication by  $-1$ . the  $\ell^{\text{th}}$  eigenvector of  $\mathbf{G}$ , which we denote by  $\mathbf{u}^\ell(\mathbf{G})$ , corresponds to the  $\ell^{\text{th}}$  principal component of  $\mathbf{G}$ .

An important interpretation of this diagonalization is as a decomposition into *principal components*. First, consider the symmetric rank-one matrix that best approximates  $\mathbf{G}$  in the

squared-error sense—equivalently, the vector  $\mathbf{u}$  such that

$$\sum_{i,j \in \mathcal{N}} (g_{ij} - u_i u_j)^2$$

is minimized. The minimizer turns out to be a scaling of the eigenvector  $\mathbf{u}^1$ . Now, if we consider the “residual” matrix  $\mathbf{G}^{(2)} = \mathbf{G} - \mathbf{u}^1(\mathbf{u}^1)^\tau$ , we can perform the same type of decomposition on  $\mathbf{G}^{(2)}$  and obtain the second eigenvector  $\mathbf{u}^2$  as the best rank-one approximation. Proceeding further in this way gives a sequence of vectors that constitute an orthonormal basis. At each step, the next vector generates the rank-one matrix that “best summarizes” the remaining structure in the matrix  $\mathbf{G}$ .

We can think of the columns of  $\mathbf{G}$  as  $n$  data points. The first principal component of  $\mathbf{G}$  is defined as the  $n$ -dimensional vector that minimizes the sum of squares of the distances to the columns of  $\mathbf{G}$ . The first principal component can therefore be thought of as a fictitious column that “best summarizes” the data set of all columns of  $\mathbf{G}$ . To characterize the next principal component, we orthogonally project all columns of  $\mathbf{G}$  off this vector and repeat this procedure for the new columns. We continue in this way, projecting orthogonally off the (subspace generated by) vectors obtained to date, to find the next principal component. A well-known result is that the eigenvectors of  $\mathbf{G}$  that diagonalize the matrix (i.e., the columns of  $\mathbf{U}$ ) are indeed the principal components of  $\mathbf{G}$  in this sense. Moreover, the eigenvalue corresponding to a given principal component quantifies the residual variation explained by that vector.

Figure 4.12 illustrates some eigenvectors/principal components of a circle network with 14 nodes, where links all have equal weight given by 1. For each eigenvector, the color of a node indicates the sign of the entry of that node in that eigenvector (the color red means negative), while the size of a node indicates the absolute value of that entry. we note that the circle network is invariant to rotations (cyclic permutations) of the nodes and so the eigenvectors are determined only up to a rotation. A general feature worth noting is that the entries of the top eigenvectors (with smaller values of  $\ell$ ) are similar among neighboring nodes, while the bottom eigenvectors (with larger values of  $\ell$ ) tend to be negatively correlated among neighboring nodes.

#### 4.6.1 Analysis of the game using principal components

For any vector  $\mathbf{z} \in \mathbb{R}^n$ , let  $\underline{\mathbf{z}} = \mathbf{U}^\tau \mathbf{z}$ . We will refer to  $\underline{z}_\ell$  as the projection of  $\mathbf{z}$  onto the  $\ell^{\text{th}}$  principal component, or the magnitude of  $\mathbf{z}$  in that component. Substituting the expression

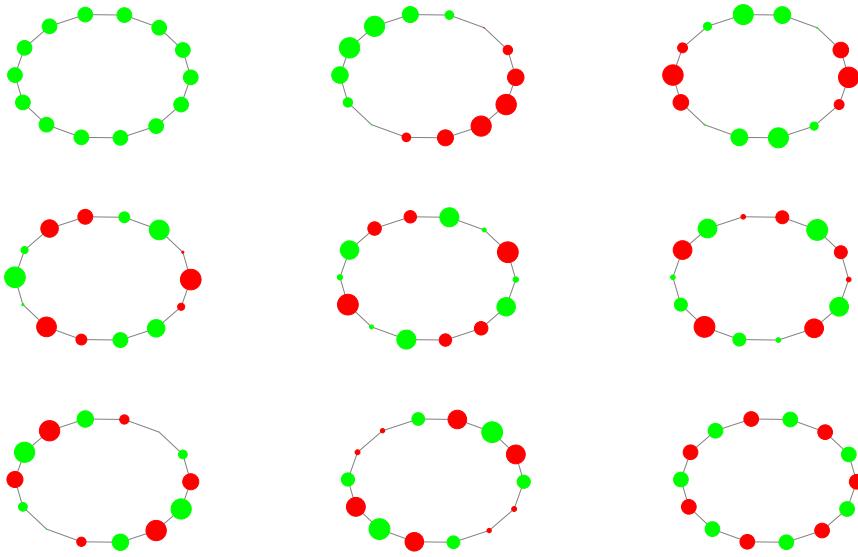

Figure 4.12: (Top) eigenvectors 1, 3, 5. (Middle) eigenvectors 7, 9, 11. (Bottom) eigenvectors 12, 13, 14.

$G = \mathbf{U}\Lambda\mathbf{U}^\tau$  in equation (4.21), we obtain

$$[\mathbf{I} - \beta\mathbf{U}\Lambda\mathbf{U}^\tau]\mathbf{a}^* = \mathbf{b}.$$

Multiplying both sides of this equation by  $\mathbf{U}^\tau$  gives us an analogue of (4.25):

$$[\mathbf{I} - \beta\Lambda]\underline{\mathbf{a}}^* = \underline{\mathbf{b}} \quad \iff \quad \underline{\mathbf{a}}^* = [\mathbf{I} - \beta\Lambda]^{-1}\underline{\mathbf{b}}.$$

This system is diagonal, and the  $\ell^{\text{th}}$  diagonal entry of  $[\mathbf{I} - \beta\Lambda]^{-1}$  is  $\frac{1}{1-\beta\lambda_\ell}$ . Hence, for every  $\ell \in \{1, 2, \dots, n\}$ ,

$$\underline{a}_\ell^* = \frac{1}{1-\beta\lambda_\ell} b_\ell. \tag{4.26}$$

The principal components of  $G$  constitute a basis in which strategic effects are easily described. The equilibrium action  $\underline{a}_\ell^*$  in the  $\ell^{\text{th}}$  principal component of  $G$  is the product of an amplification factor (determined by the strategic parameter  $\beta$  and the eigenvalue  $\lambda_\ell$ ) and  $b_\ell$ , which is simply the projection of  $\mathbf{b}$  onto that principal component. Under Assumption 19.1, for all  $\ell$  we have  $1 - \beta\lambda_\ell > 0$ . This assumption on the spectral radius also implies that  $\beta\Lambda$  has no entries larger than 1. Finally observe that if  $\beta > 0$  ( $\beta < 0$ ), the amplification factor is decreasing (increasing) in  $\ell$ .

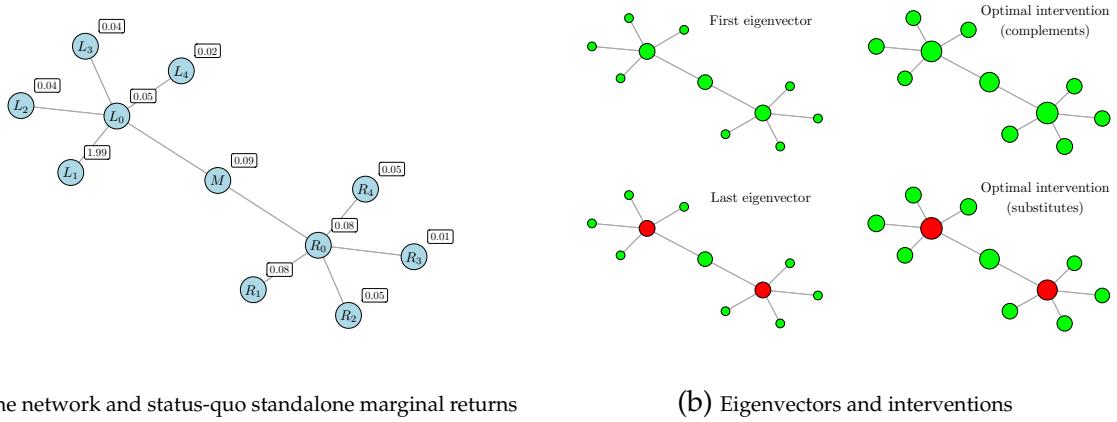

Figure 4.13: An example of optimal interventions with large budgets. Taken from Galeotti, Golub, and Goyal [2020]

We can also use this to give a formula for equilibrium actions in the original coordinates:

$$s_i^* = \sum_{\ell=1}^n \frac{1}{1 - \beta \lambda_\ell} u_i^\ell b_\ell.$$

Figure 4.13 depicts the optimal intervention in an example where the budget is large. We consider an 11-node undirected network with binary links containing two hubs,  $L_0$  and  $R_0$ , that are connected by an intermediate node  $M$ . The network is shown in Figure 2(A). The numbers next to the nodes are the ex-ante stand-alone marginal returns; the budget is set to  $C = 500$  (about 125 times larger than  $\|\hat{b}\|^2$ ). Payoffs are as in Example 4.3. For the case of strategic complements, we set  $\beta = 0.1$ , and for strategic substitutes we set  $\beta = -0.1$ . The top-left of Figure 2(B) illustrates the first eigenvector, and the top-right depicts the optimal intervention in a game with strategic complements. The bottom-left of Figure 2(B) illustrates the last eigenvector, and the bottom-right depicts the optimal intervention when the game has strategic substitutes. The node size represents the size of the intervention,  $|b_i^* - \hat{b}_i|$ ; node shading represents the sign of the intervention, with green signifying a positive intervention and red indicating a negative intervention.

For large budgets,  $C$ , the optimal intervention is guided by the “main” component of the network. Under strategic complements, this is the first (largest-eigenvalue) eigenvector of the network, whose entries are individuals’ eigenvector centralities. By increasing the stand-alone marginal return of each individual in proportion to his eigenvector centrality, the planner targets the individuals in proportion to their global contributions to strategic feedbacks. On the other hand, under strategic substitutes, optimal targeting is determined by the last eigenvector of the network (that corresponding to its smallest eigenvalue). The

last eigenvector contains information about the local structure of the network: it determines a way to partition the set of nodes into two sets so that most of the links are across individuals in different sets. The optimal intervention increases the stand-alone marginal returns of all individuals in one set and decreases those of individuals in the other set. This asymmetric targeting reduces crowding-out effects that occur due to the strategic substitutes property.

Let us summarize what we have learnt in this section: games on networks exhibit positive and negative externalities. The equilibrium of these games will therefore generally be socially sub-optimal. We studied the question of how scarce resources can be used to target specific nodes in a network so as to have maximize social welfare. The key to the approach we studied is a particular way to organize the direct and indirect spillover effects of interventions in terms of the principal components/eigenvectors of the matrix of interactions. In particular, any change in individual marginal returns can be expressed in terms of these principal components. This formulation allows us to describe the magnitude of the effect of the change in marginal rewards as a product of the intervention and a multiplier that is determined by an eigenvalue of the network corresponding to that principal component. As the principal components are orthogonal, the effects along various principal components can be treated separately. This formulation yields a clear cut optimal intervention when the budget is large: target first eigenvector in games of complements and the last eigenvector in case of games of strategic substitutes.

## 4.7 Reading Notes

This chapter studies how human behaviour is shaped by network structure. It is impossible to do justice to the extraordinarily wide ranging literature on this subject within one chapter. Goyal [2007a] and Jackson [2008] provide good reviews of the early literature, while Jackson and Zenou [2015] and Bramoullé and Kranton [2016] provide more recent reviews of the theoretical literature. Jackson et al. [2017] provide a more general overview of how networks affect behaviour.

Games on networks has been an active field of research for close to three decades. In the early 1990's, Blume [1993] and Ellison [1993] introduced the study of binary action coordination problems among players located on simple networks like the cycle and a lattice. The study of coordination problems is taken up in the chapter on social coordination. In order to develop some basic intuitions, we start with two binary games – the best-shot and weakest-link games; these are inspired from a paper by Hirshleifer [1983]. Shachter [1986] and Koller and Milch [2003] introduce the notion of multi-agent influence diagrams

to study social strategic interaction. Kearns [2007] introduced *graphical games* and provided algorithms to solve for Nash equilibrium in binary action local interaction games.

We present a number of examples on how networks affect behaviour. Let us place these examples in a broader context of the literature. Best-shot and weakest-link games should be seen a metaphor for a wide range of situations in which actions exhibit substitutes and complements properties. For an early presentation of these games see Hirshleifer [1983].

Research collaboration among firms from Goyal and Moraga-Gonzalez [2001] is an early example of a continuous action game on a network. There is a rather large literature on research alliances and competition among firms. For an overview of the empirical trends see Hagedoorn [2002] and König et al. [2019]. We will revisit some aspects of this application in chapter 15 (on networked markets).

Bramoullé and Kranton [2007] introduced the study of local public goods in networks: their paper also introduced the concept of *maximally independent sets* as a solution to a game of local public goods in networks. There is a large literature that elaborates on different aspects of this game and applies it to different contexts. We will take up models of strategic substitutes in combination with a game of network formation in chapter 11 (on the law of the few).

The weakest-link we study is a variation on the classical weakest link game proposed by Hirshleifer [1983]. In the original game, payoffs depend on the minimum action and thus they are positive only if a player and his contacts all choose action 1. We take the smoother variant studied in this chapter from Galeotti, Goyal, Jackson, Vega-Redondo, and Yariv [2010]. Gagnon and Goyal [2017] introduced the concept of *q-core* to solve this game when players have complete information on the network. We will use the *q-core* in chapter 16 to study the relation between social networks and markets.

The economic study of criminal activity starts with Becker [1968]. Empirical evidence on the role of social interactions in shaping criminal activity is presented in Glaeser, Sacerdote, and Scheinkman [1996]. For a overview of the recent literature on criminal networks see Lindquist and Zenou [2019].

The study of relative consumption effects may be traced to the early work of Torsten Veblen and James Duesenbury. In recent decades interest in relative consumption effects has been revived by the collection of empirical evidence on these effects (e.g., Luttmer [2005] and Kuhn et al. [2011]). This strand of work is also closely related to the ideas on relative effects in happiness that have been advocated by Richard Layard (see Layard [2011]).

Ballester, Calvó-Armengol, and Zenou [2006] studies continuous action games with strategic complements. They introduced the concept of *Bonacich centrality* as a method to

solve such games. A large strand of subsequent research applies the idea of Bonacich centrality to understand behaviour in networks; for an overview of some of this work and for references to the literature see Jackson and Zenou [2015]. We will use Bonacich centrality in chapter 5 (on production networks) and in chapter 10 (on the Great War of Congo).

The literature on games with linear-best responses proceeds under the assumption that the spillovers are sufficiently small. The best overall condition pertains to the spectral radius stated in the chapter. In an important advance, Bramoullé, Kranton, and D'amours [2014] propose an approach, based on potential functions, that generalizes the study of Nash equilibrium to allow for constrained action sets. The concept of a potential function was proposed by Monderer and Shapley [1996]. The interested reader is urged to consult Bramoullé and Kranton [2016] for a careful discussion of the uses of potential functions and also on the open problems in the analysis of continuous action games on networks.

The models in sections 4.3 and 4.5 assume that individuals know the entire network. A parallel strand of the literature explores behaviour in networks when individuals only have local knowledge of the network. Examples of such games are studied in Sundararajan [2005] and Galeotti and Vega-Redondo [2011]. Galeotti, Goyal, Jackson, Vega-Redondo, and Yariv [2010] present a general framework for the study of games when individuals have limited information on the network. Their framework allows for binary action games as well as continuous action games (and it also allows for non-linear best responses). The predictions of these models were experimentally studied in Charness, Feri, Meléndez-Jiménez, and Sutter [2014]. The exposition in the chapter draws on Goyal [2007a] and on Galeotti, Goyal, Jackson, Vega-Redondo, and Yariv [2010] and Charness, Feri, Meléndez-Jiménez, and Sutter [2014]. The Figures from the experiment on binary games in networks have been kindly provided by Miguel-Angel Melendez.

The problem of intervening by targeting ‘key players’ is well known in the networks literature. For an early discussion of ‘key player’ see e.g., Borgatti [2003]. In the economics literature the problem of key player was introduced in the paper by Ballester, Calvó-Armengol, and Zenou [2006]: they study the issue of which nodes to eliminate in order to minimize sum of criminal activity in the network. In this chapter, we present the intervention problem of a utilitarian planner with a budget constraint who targets individuals that are playing a game on a network. The problem of network interventions will be taken up again in chapter 10 (on attack and defence in networks), in chapter 15 (on optimal seeds for the diffusion of innovations) and in chapter 16 (on optimal advertising and pricing in networked markets). For an overview of the literature on the ‘key player’ problem see Zenou [2016]

I am grateful to Yann Bramoullé, Sam Jindani and Mikhail Safronov for suggestions,

useful comments and for sharing materials.

## 4.8 Questions

1. Show that every network contains a maximal independent set.
2. Show that in any network there exists a unique  $q$ -core and that the algorithm outlined in the chapter identifies this  $q$ -core.
3. Fix  $n=6$ . Consider best-shot game. Fix  $c = 1/2$ . Compute the equilibrium in the circle, complete, star networks. Define social welfare as the sum of individual utilities. Compute social welfare in the different equilibria.
4. Fix  $n=6$ . Consider the weakest-link game. Set  $c = 1/2$ . Compute equilibrium in the circle, complete, star. Also compute social welfare in the active equilibria.
5. Fix  $n=6$ . Consider the following variant of the weakest-link game. Given a network  $g$ , and a strategy profile  $s$ , the payoffs of an individual  $i$  are

$$\Pi_i(s|g) = s_i \prod_{j \in N_i(g)} s_j - cs_i \quad (4.27)$$

- (a) Set  $c = 1/2$ . Compute equilibria in the circle, complete, star. Also compute social welfare in the active equilibria.
- (b) Set  $c = 1.2$ . Compute equilibrium in the circle, complete, star. Also compute social welfare in the active equilibria.
6. Consider the best-shot game. Set  $c = 25/64$ . Suppose that degrees take on values 1, 2 and 3 and that the degrees of neighbours are independent. Therefore there exists a unique symmetric equilibrium which is non-increasing and it is fully characterized by a threshold. This question works through the computation of thresholds.
  - (a) Let us start with initial beliefs  $P$  that assign probability one-half to neighbouring players having degrees 1 and 2. Show that in the unique symmetric equilibrium, degree 1 players choose 1 with probability 1, whereas degree 2 players choose 1 with probability 0.
  - (b) Recall from chapter 1, that a degree distribution  $P$  first order stochastically dominates another degree distribution  $P'$  if for every degree  $k$ , the cumulative distribution  $\sum_0^k P(k) \leq \sum_0^k P'(k)$ . Consider a first order stochastic dominance shift

of degree distributions such that neighbouring players are believed to have degrees 2 and 3 with probability one-half each. Show that the unique equilibrium involves degree 2 players choosing action 1 with probability 3/4, whereas degree 3 players choose 1 with probability 0.

- (c) Show that the threshold degree 2 player has lower expectation of action 1 under  $P'$  as compared to  $P$ .
7. Consider a game in which  $n$  players are located on nodes of an undirected network  $g$ . Players simultaneously choose actions  $x_i \in \mathcal{R}_+$ . Let  $N_i(g)$  be the set of players with whom player  $i$  has a link in network  $g$ . The payoffs of player  $i$  faced with a strategy profile  $x$  are given by
- $$\Pi_i(x) = f(x_i + \sum_{j \in N_i(g)} x_j) - cx_i. \quad (4.28)$$
- where  $f(0) = 0$ ,  $f'(\cdot) > 0$  and  $f''(\cdot) < 0$  and  $c > 0$ . Suppose there exists a number  $\hat{x} > 0$  such that  $f'(\hat{x}) = c$ .
- (a) Show that in every non-empty network there exists an equilibrium with specialization: some players choose  $\hat{x}$  and others choose 0.
  - (b) Show that there are only two equilibria in the star network, one in which only the center contributes and the other in which only the spokes contribute.
  - (c) Define social welfare as the sum of individual utilities. Discuss the merits of different networks from a social welfare point of view.
  - (d) Define the costs of decentralization as the ratio of social welfare from the social optimum choice of effort versus the social welfare from the (lowest welfare) Nash equilibrium. Compute this ratio for the star network with  $n$  players.
8. Consider a simultaneous action game played on an undirected network as in the criminal activity example in section 4.2.1. Suppose the payoffs to player  $i$  faced under strategy profile  $s$ , are given by:

$$\Pi_i(s) = 0.5s_i + \frac{1}{2}s_i^2 + 0.01 \sum_{j \neq i} g_{ij} s_i \cdot s_j \quad (4.29)$$

- (a) Fix  $n = 6$ . Compute the equilibrium efforts in a complete, circle, star, and line network.
- (b) Fix  $n = 6$  Compute the equilibria for complete, circle, star, and line networks

when payoff is

$$\Pi_i(s) = 0.5s_i + \frac{1}{2}s_i^2 + 0.02 \sum_{j \neq i} g_{ij}s_i.s_j \quad (4.30)$$

9. Consider the model of research collaboration among firms presented in section 4.2.1.
  - (a) Consider regular networks of degree  $d$ . Compute equilibrium in research efforts as a function of the degree  $d$ . Show that individual effort is falling, firm costs are initially falling but eventually increasing, while firm profits are initially rising but eventually falling as a function of degree  $d$ .
  - (b) Compute the equilibrium efforts and profits of the hub and spoke firms in the star network.
10. Consider the relative consumption model that was presented in section 4.2.1. Let the price for good  $x$  be a numeraire and set it equal to 1 and let the price of good  $y$  be denoted by  $p_y$ . Suppose all households have the same initial income given by  $\omega$ . Fix some network  $g$ .
  - (a) Define the general equilibrium in this economy.
  - (b) Compute the general equilibrium prices as a function of the network  $g$ .
  - (c) Compute the equilibrium consumption of households as a function of their network position.
11. Consider the networks presented in Figure 4.8. Show that the strategies specified as equilibria in the main text are equilibria when we take into the account the correlations in the degree of neighbours.
12. Show that equilibrium in games of example 4.8 satisfies Property A in section 4.6.
13. Consider a star network with undirected binary links. Derive the eigenvalues and eigenvectors of the adjacency matrix corresponding to this network.
14. Suppose the game being played is as in example 4.8. Fix a star network (with symmetric links) and five players. Compute optimal interventions for  $\beta > 0$  and  $\beta < 0$  when the budget is (suitably) large.
15. (Bourlès, Bramoullé, and Perez-Richet [2017]). There are  $n$  agents. Agent  $i$  has income  $y_i^0 \geq 0$  and makes transfer  $t_{ij} \geq 0$  to agent  $j$ . Income after transfers is equal to

$$y_i = y_i^0 - \sum_j t_{ij} + \sum_k t_{ki}$$

where  $\sum_j t_{ij}$  represents overall transfers made by  $i$  while  $\sum_k t_{ki}$  represents overall transfers made to  $i$ . Agents care about each other. Agent  $i$  has private utility over her own consumption and she is also potentially altruistic towards others:

$$v_i(\mathbf{y}) = u_i(y_i) + \sum_j \alpha_{ij} u_j(y_j)$$

where  $u_i$  reflects utility from private consumption (it is twice differentiable and satisfies  $u'_i > 0$  and  $u''_i < 0$ ). The coefficient  $\alpha_{ij}$ , with  $0 \leq \alpha_{ij} < 1$ , measures the strength of the altruistic link that  $i$  has towards  $j$ . Suppose that all individuals have CARA utility functions:  $\forall i, u_i(y) = -e^{-Ay}$ .

- (a) Consider the two agent economy and fix initial incomes  $y_1^0$  and  $y_2^0$ , and suppose that  $-\ln(\alpha_{ij})/A = -\ln(\alpha_{ji})/A = 1$ . Show that a Nash equilibrium in transfers is such that  $y_1 - y_2 \leq 1, y_2 - y_1 \leq 1, t_{12} > 0 \Rightarrow y_1 - y_2 = 1$  and  $t_{21} > 0 \Rightarrow y_2 - y_1 = 1$ . (i). if  $|y_1^0 - y_2^0| \leq 1 \Leftrightarrow y_1^0 - y_2^0 \leq 1$  and  $y_2^0 - y_1^0 \leq 1$  then no transfers is the unique Nash equilibrium. (ii). If 1 is richer than 2 and  $y_1^0 - y_2^0 > 1$  then  $y_1 - y_2 = 1$  and 1 gives to 2 the amount needed to reach this situation.
- (b) Consider a line network with three agents and with agent 2 at the centre; suppose  $y_1^0 = 5, y_2^0 = 5$  and  $y_3^0 = 1$ . Compute the equilibrium.

## **Part II**

# **Economic Networks**

# Chapter 5: Production and Supply Chains

## 5.1 Introduction

*Layman and professional economist alike, practical planner and the subjects of his regulatory activities, all are equally aware of some kind of interconnection between even the remotest parts of the natural economy.* Leontief [1941]

Following the March 11, 2011 earthquake in Japan, physical infrastructure was destroyed and over 19000 people lost their lives. But the effects of this earthquake were not limited to the local economy; they were felt widely across the entire Japanese economy. As Kim and Reynolds (2011) reported,

Supply chain disruptions in Japan have forced at least one global auto maker to delay the launch of two new models and are forcing other industries to shutter plants ( . . . ) The auto maker is just one of dozens, if not hundreds, of Japanese manufacturers facing disruptions to their supply chains as a result of the quake, the subsequent tsunami and a still-unresolved nuclear threat.

This episode raises a number of questions. How do shocks spread through a production system and what is the role of hubs in this transmission? How can firms mitigate the impact of these shocks? What are the processes that give rise to hubs?

To study these questions, we develop a model of a production economy. There are a number of sectors, each producing a distinct good. These goods are used in households and can also be used as inputs into production of other goods – an example of such a good is a computer. The amount of inputs used by a sector from another sector defines a link between the two sectors. Households supply labour to production firms and they use the income they earn from their work to buy goods and services. In every sector, there is a technology of production; firms choose a mix of different inputs in order to produce an output. Market prices help coordinate input demands and supplies across firms and consumers.

We first take up the issue of what determines the size of a sector. This size will depend on how important it is for other sectors, in other words how much its output is used as an input in other sectors. In addition, there is also the indirect demand: a sector's output may be used as an input by a few sectors, but these sectors may in turn be used as inputs in a great many other sectors. Thus the size of a sector is determined by the sum of direct and indirect demands of its output. These demands are reflected in the 'walks' of different lengths in the production network of the economy. In chapter 1, we showed that the Katz-Bonacich centrality summarizes all the walks in a network. This yields the following insight: the size of a sector will be proportional to its Katz-Bonacich centrality in the production network. Equipped with this result, we examine input-output data from a number of countries. We find that the distribution of the centrality is very unequal: a few sectors dominate their respective economies.

We then study the role of central sectors – the hubs – in amplifying sectoral shocks and in generating large scale fluctuations in economic activity. Individual sectors face a variety of shocks – some positive and others negative. One might expect that as the sectors face shocks emanating from distinct sources, and as the sectors are individually small, the shocks will cancel out and that, in the aggregate, the economy will be relatively unperturbed. The model of a production network allows us to explore the scope of this intuition. The second insight is that sectoral shocks do indeed wash out if the sectors are similar size, but that these shocks are amplified and generate large aggregate fluctuations if the distribution of sectoral centralities is very unequal; more precisely if it exhibits a power law.

This result motivates an examination of the economics of network formation: what are the forces that give rise to a production network with unequal sectors? The study of the formation of production networks is still at a very early stage. We provide a brief overview of the research on network formation and then turn to firm level motivations in creating and supporting supply chains.

Firms are aware of the risks of biological, physical and man-made disruptions in the production process: they enter specific sectors, make investments to enhance their own production reliability, and they seek to secure supply by diversifying across input producers. To examine the incentives of firm we study a simple supply chain with multiple layers where layer A supplies input to layer B, layer B supplies to layer C, and so forth. There is a single firm in every layer. Every firm has a baseline reliability level  $1/2$ . The supply chain is successful (or delivers) if every firm in the chain is operational. A firm can invest in plant and machinery and personnel to raise its reliability. We study the incentives of firms to invest.

We find that returns to a firm are increasing in the investments by firm in other layers: more formally, investments in reliability are strategic complements. This suggests that there may exist multiple equilibria with regard to the reliability of the supply chain, a low equilibrium in which no firm invests in reliability and a high reliability equilibrium in which all firms invest. This suggests that there are returns to coordination across firms. A second insight from the model is that when a firm invests in reliability, it raises the likelihood that the supply chain as whole will deliver, and this therefore raises the earnings of the other firms in the chain. To the extent that a firm cannot completely appropriate these gains, there will emerge a gap between the private and the collective returns to a firm's investments. As a firm is primarily interested in its own profits, firms will under-invest in reliability relative to what is collectively desirable. These results are derived in a setting with one firm per layer of the supply chain. We then take up the question of how many firms will join different layers of the supply chain.

As in the original model, the supply chain is a line starting with a source and ending in a sink. The new element is that multiple firms in a layer are linked to all firms in the adjacent upstream and downstream layers. The study of the entry problem yields a number of insights: one, we show that firm entry decisions are strategic complements across layers and are strategic substitutes within a layer. There are thus multiple equilibria in levels of entry. This points to the role of coordination among firms. Finally, as in the basic single firm supply chain model, firms' incentives to enter will typically be lower than what is collectively desirable. Taking the decisions on reliability and entry into account, we conclude that firms will create supply chains that are less reliable than is socially desirable. This wedge between firms incentives and the collective good provides the *raison d'être* for an active public policy.

As the global supply chain becomes more complex and global in scope, it is increasingly at risk from disruptions including natural hazards, accidents, and malicious incidents. Events like Hurricane Katrina in 2005, the eruption of the *Eyjafjallajokull* volcano in Iceland in 2010, and the Japan earthquake and tsunami of 2011; failing infrastructures such as the I-35 bridge collapse in 2007; terrorist attacks such as 9/11, and more recent plots involving air cargo shipments filled with explosives shipped via Europe and the Middle East to the United States, remind us that even localized disruptions can escalate rapidly and impact U.S. interests and the broader global community. We must collectively address the challenges posed by these threats and strengthen our national and international policies accordingly. *US Supply Chain Policy Fact Sheet 2012*.

## 5.2 Case Study: The 2011 Japanese Earthquake

We commence our study of product networks with a brief case study that is taken from Carvalho, Nirei, Saito, and Tahbaz-Salehi [2021]. On March 11, 2011, a magnitude 9.0 earthquake occurred off the northeast coast of Japan. This was the most powerful earthquake in the history of Japan (a country that is prone to earthquakes) and the fifth most powerful across the world since 1900. The earthquake led to significant material damage in one part of Japan, it gave rise to a tsunami that flooded 561 square kilometers of the north east coastline and it led to the failure of the Fukushima Dai-ichi Nuclear Power Plant. This case study describes the direct impact of the earthquake and then presents evidence on the transmission of the shock and its amplification through the upstream and downstream production linkages emanating from the firms in the physically affected areas and spreading across the Japanese economy.

The direct physical damage was concentrated in the four Pacific coast prefectures of Aomori, Fukushima, Iwate, and Miyagi in the Tohoku region. According to government estimates, the earthquake caused losses of the order of Yen 16.9 trillion in terms of capital loss due to destruction of buildings, plants and buildings and equipment amounting to Yen 10.4 trillion. There were close to 20,000 deaths (and several thousand people are missing). These massive losses had an impact of economic standards in that year but also affected the economic growth of the region and the Japanese economy more generally. We now turn to these direct and indirect economic consequences.

First, we note that the (Gross Domestic Product) growth rate of the four disaster-stricken prefectures in the 2011 fiscal year was  $-1.5\%$ ; the growth rate in the previous year was  $0.7\%$ . This was a large fall in growth rate. The four prefectures only account for  $4.6\%$  of the total Japanese GDP therefore the direct impact of this loss in growth on the national economy should be of the order of all in income growth should be of the order of  $0.046 \times (0.7 - (-1.5)) = 0.1\%$ . However, the actual decline in Japan's growth rate was four times as large as it dropped from  $2.6\%$  in year 2010 to  $2.2\%$  in 2011. This large aggregate national level impact motivates an examination of the channels of transmission of the local shock.

The key step in understanding this transmission is the measurement of shocks on firms that are upstream and downstream from the firms in the prefectures hit by the earthquake. To do this requires us to plot the input-output network of connections between firms. Firms that sell to firms in the affected prefectures are immediate upstream, while those that sell these upstream firms are upstream distance 2 from the affected firms and so forth. Similarly, for downstream distances. The network helps us identify how far up-

stream/downstream firms are from the directly affected firms. With this network in place, it is possible to study the relation between the distance in the network and the magnitude of the shock on sales.

There is evidence for large transmission shocks and they are related to the distance in the supply chain network. Specifically, the earthquake led to a 3.8% decline in the growth rate of firms with disaster-hit suppliers (upstream) and a 3.1% decline in the growth rate of firms with disaster-hit customers (downstream). Furthermore, the disruption caused by the earthquake also had indirect negative shocks as it affected the customers' customers (two layers downstream) and their suppliers' suppliers (two layers upstream) and so forth. For example, disaster-stricken firms' customers' customers experienced a 2.8% point reduction in sales growth, while the suppliers' suppliers experienced a 2.1% decline. These observations motivate a number of questions: How do the technological possibilities shape the decisions of firms on inputs? Are some production structures more resilient to shocks as compared to others? What are the incentives that firms have to create buyer and seller relations and do private decisions give rise to resilient networks? We turn to a theoretical framework that addresses these questions.

### 5.3 The Input-Output Model of Production

We will study an economy with a number of sectors. A sector produces a good. This good can be used as an input in the production of the other goods and every good can also be consumed by a household. A sector consists of firms. Firms are given a set of technologies that specify how different a combination of inputs leads to an output. Faced with these technologies and a set of prices in the market, a firm makes decisions on how much to produce and what inputs to use in their production. The households supply labour to the firms in the different sectors. Faced with prices of goods, they then use their income to purchase different goods. We will be studying the competitive market equilibrium of this economy. Of particular interest is the ways in which the production technologies shapes the market prices and the size of different sectors. We will use a model that is taken from Acemoglu, Carvalho, Ozdaglar, and Tahbaz-Salehi [2012a]; the exposition draws on Carvalho and Tahbaz-Salehi [2019].

There are  $N = \{1, \dots, n\}$  distinct goods. A sector corresponds to a good, so there are  $n$  sectors. Each of the goods can be used as an input in the production of the other  $n - 1$  goods and every good can also be used by a household. The households supply labour to the firms in the different sectors. They use their income to purchase the  $n$  goods.

The output of industry  $i$  is given by

$$y_i = z_i \xi_i \ell_i^{\alpha_i} \prod_{j=1}^n x_{ij}^{a_{ij}} \quad (5.1)$$

where  $z_i$  is sector  $i$  specific productivity,  $\ell_i$  is labour employed,  $x_{ij}$  is input from industry  $j$  used in industry  $i$ ,  $\alpha$  is the share of labour. The parameter

$$\xi_i = \alpha_i^{-\alpha_i} \prod_{j=1}^n a_{ij}^{-a_{ij}} \quad (5.2)$$

is a normalization constant.

The exponents  $a_{ij}$  reflect the role of sector input  $j$  in sector  $i$ : a larger  $a_{ij}$  means that good  $j$  is a more important input for the production of good  $i$ , whereas  $a_{ij} = 0$  means that good  $j$  is not needed for  $i$ 's production. It is worth noting that  $a_{ij} \neq a_{ji}$  in general, as industry  $i$ 's reliance on industry  $j$  as an input-supplier may be different from  $j$ 's dependence on  $i$ . Furthermore, it may also be the case that  $a_{ii} > 0$ , as good  $i$  may itself be used as an intermediate input for production by firms in industry  $i$ . Finally, note that the assumption that all technologies exhibit constant returns to scale implies that  $\alpha_i + \sum_j a_{ij} = 1, \forall i$ . In words, constant returns to scale says that if all factors of production scale by a factor  $f$  then output also scales by the same factor. Moreover, as  $\alpha_i > 0$  for all  $i$ ,  $\sum_j a_{ij} < 1$ , for all  $i \in N$ . All variables except for  $x_{ij}$  are exogenous;  $x_{ij}$  is the choice made by firm in sector  $i$  on how much it will buy from a firm in sector  $j$ .

There is a representative consumer in the economy. The consumer's utility is given by

$$u(c_1, c_2, \dots, c_n) = \sum_{i=1}^n \beta_i \log \left( \frac{c_i}{\bar{c}_i} \right) \quad (5.3)$$

where  $\beta_i$  is the weight placed on the good  $i$  by the consumer. The consumer owns 1 unit of labour that is supplied inelastically.

There are competitive markets for every product. The price of product  $i$  is  $p_i$  and the wage for labour is  $w$ : in other words, firms and the consumer take prices as given.

A (representative) firm in sector  $i$  maximizes profit:

$$\Pi_i = p_i y_i - w \ell_i - \sum_j p_j x_{ij} \quad (5.4)$$

where the first term is the gross revenue, the second term is the wage bill and the third term is the total cost of all other inputs.

The consumer maximizes utility subject to their budget constraint:

$$\max u(c); \text{ s.t. } \sum_{i=1}^n p_i c_i \leq w. \quad (5.5)$$

This completes the description of the economy.

The competitive equilibrium of this economy is defined in the usual way: it consists of a collection of prices and quantities such that (i) the representative household maximizes her utility; (ii) the representative firm in each sector maximizes its profits while taking the prices and the wage as given; and (iii) all markets clear. We shall study the size of different sectors of the economy in a competitive equilibrium and relate it to the structure of input and output relations across the sectors.

**Adjacency Matrices and Katz-Bonacich Centrality:** At this stage it is useful to define some concepts that will be useful in the analysis. The input-output linkages between various industries are summarized by a matrix  $A = [a_{ij}]$ , which we will call the economy's input-output matrix. This matrix taken along with the vector of productivity shocks  $z = (z_1; \dots; z_n)$  describes the production side of the economy. Observe that  $\alpha_i > 0$  for all  $i$  means that  $A$  is a nonnegative matrix with row sums that are strictly less than 1. This in turn means that the spectral radius of  $A$  — defined as the largest absolute value of its eigenvalues — is strictly less than 1 (for a derivation of these properties refer to Berman and Plemmons [1979]). Alternatively, we may interpret  $A$  as a graph with  $n$  nodes, with the weights of the directed edges given by  $a_{ij}$ . While the production network representation of the economy is equivalent to the representation using the input-output matrix, it can provide a conceptually simpler framework for summarizing (and visualizing) input-output linkages.

The matrix  $[1 - A]^{-1}$  is known as the *Leontief inverse*. As  $A$  is nonnegative with a spectral radius that is strictly less than 1, we can deduce that  $[1 - A]$  is a non-singular M-matrix. This in turn implies that the Leontief inverse  $L$  always exists and is element-wise nonnegative. Moreover, since the spectral radius of  $A$  is strictly less than 1, the Leontief inverse can be expressed as the infinite sum of the powers of the input-output matrix  $A$  (Stewart [1998]).

$$L = [I - A]^{-1} = \sum_{k=0}^{\infty} A^k. \quad (5.6)$$

This decomposition tells us that the  $l_{ij}$  value in cell  $(i; j)$  of the Leontief inverse measures the importance of industry  $j$  as a direct and indirect input-supplier to industry  $i$  in the economy. Interpreted in terms of the production network representation of the economy,

$l_{ij}$  is a measure of all possible directed walks (of different lengths) that connect industry  $j$  to industry  $i$  over the network. We define  $v_i = \sum_j l_{ji}$ : this is (a variant on) the *Katz-Bonacich centrality* of sector  $i$  as it provides a measure of walks of different lengths emanating from a sector (for an introduction to Katz-Bonacich centrality, refer to chapter 1).

An important focus of the analysis will be the relative size of different sectors. This is measured by the *Domar weight* of an industry: it is the market value of its output as a ratio of the total output of the economy.

$$\lambda_i = \frac{p_i y_i}{GDP}. \quad (5.7)$$

With these preliminaries out of the way, we are now ready to study production and consumption in this economy and the size of sectors.

### 5.3.1 The size of sectors and the aggregate economy

The first step is to derive a firm's demands for different inputs. As all firms are identical, we may write demand at the industry level. This demand is derived by differentiating the profit of a firm with respect to labour and inputs. Industry  $i$ 's demand for labour

$$\ell_i = \frac{p_i y_i \alpha_i}{w} \quad (5.8)$$

Similarly, industry  $i$ 's demand for input from industry  $j$ :

$$x_{ij} = \frac{p_i y_i a_{ij}}{p_j} \quad (5.9)$$

Substituting these demands in the production function yields:

$$y_i = z_i \xi_i \left( \frac{p_i y_i \alpha_i}{w} \right)^{\alpha_i} \prod_{j=1}^n \left( \frac{p_i y_i a_{ij}}{p_j} \right)^{a_{ij}}. \quad (5.10)$$

Dividing by  $y_i$  and taking logs on both side yields us

$$0 = \log p_i + \log z_i + \log \xi_i + \alpha_i \log \alpha_i - \alpha_i \log w + \sum_j^n a_{ij} (\log a_{ij} - \log p_j) \quad (5.11)$$

Rearranging terms, we may rewrite as follows:

$$\log p_i - \alpha_i \log w = -\log z_i - \log \xi_i - \alpha_i \log \alpha_i - \sum_j^n a_{ij} (\log a_{ij} - \log p_j) \quad (5.12)$$

Define  $\epsilon_i = \log z_i$ , recall the normalization constant, and substitute and rearrange to get

$$\log\left(\frac{p_i}{w}\right) + (1 - \alpha_i)\log w = -\epsilon_i + \sum_{j=1}^n a_{ij}\log p_j. \quad (5.13)$$

Recalling  $\sum_j a_{ij} = 1 - \alpha_i$ , we may rewrite equation 5.13 as

$$\log\left(\frac{p_i}{w}\right) = \sum_{j=1}^n a_{ij}\log\left(\frac{p_j}{w}\right) - \epsilon_i \quad (5.14)$$

It is convenient to define  $\hat{p}_i = \log(p_i/w)$ .

The relationship in (5.14) must hold for all industries: so it yields a system of  $n$  equations. Rewriting this system of equations in matrix form we get

$$\hat{p} = A\hat{p} - \epsilon. \quad (5.15)$$

In matrix form, this is expressed as

$$\hat{p} = -[I - A]^{-1}\epsilon. \quad (5.16)$$

We now turn to the consumer demands. Recall that consumer seeks to maximize utility subject to budget constraint. Differentiating with respect to  $c_i$  and simplifying:

$$c_j = \frac{\beta_j w}{p_j} \quad (5.17)$$

Equipped with the demands from firms and consumers, we may write the market clearing condition for product  $j$  is as follows:

$$y_j = c_j + \sum_{i=1}^n x_{ij} \quad (5.18)$$

Substituting firm and consumer demand from above, this market clearing equation may be written as

$$y_j = \frac{\beta_j w}{p_j} + \sum_{i=1}^n \frac{a_{ij} p_i y_i}{p_j} \quad (5.19)$$

Multiplying by  $p_j$  and dividing by  $w$  on both sides we get

$$\frac{p_j y_j}{w} = \beta_j + \sum_{i=1}^n \frac{a_{ij} p_i y_i}{w} \quad (5.20)$$

Rewriting this equation in terms of Domar weights we get

$$\lambda_j = \beta_j + \sum_{i=1}^n a_{ij} \lambda_i. \quad (5.21)$$

We note that Domar weights are a function of consumer preference  $\beta_j$  and production network  $a_{ij}$  and may be written more compactly as:

$$\lambda_i = \sum_{j=1}^n \beta_j l_{ji}. \quad (5.22)$$

Observe that industry impact occurs downstream only. This is an artifact of the Cobb-Douglas production form we are assuming: with this production function, the price and output effects cancel out for upstream firms: if the quantity of good  $i$  falls (because of the negative shock) the price of good  $i$  increases proportionately, leaving  $p_i x_i$  unchanged. Thus there is no upstream impact as a response to productivity shocks. A question at the end of the chapter examines upstream propagation of shocks.

Rewriting the above equation in matrix form and solving for the vector of Domar weights yields

$$\lambda = [1 - A']^{-1} \beta \quad (5.23)$$

Finally, recall from (5.16) that  $\log(p_i/w) = -\sum_{j=1}^n l_{ij} \epsilon_j$ .

Putting these points together, we are led to the following result on the size of a sector:

**Proposition 5.1.** *The log of industry output  $i$  is given by*

$$\log(y_i) = \sum_{j=1}^n l_{ij} \epsilon_j + \delta_i \quad (5.24)$$

where  $\delta_i = \log(\sum_j \beta_j l_{ji})$  is a constant that is independent of the shocks  $z_i$ .

This result reveals that the output of industry  $i$ , i.e., its size, depends on the productivity of every sector weighted by the entries of Leontief inverse. In other words, a sector's size is proportional to its Katz-Bonacich centrality in the production network.

The intuition underlying the result is as follows: Suppose that industry  $j$  is hit by a negative shock that reduces its production. This will push up its price. Such an increase in price will negatively effect the industries that use  $j$  as an input. This negative impact will then flow downstream through the firms/sectors that use this sector as an input, and so forth. The overall effect of downstream propagation of the initial shock is reflected in the economy's Leontief inverse (and summarized in the Katz-Bonacich centralities).

Let us now consider the relation between the production network and the aggregate output. Recall that

$$\log\left(\frac{p_i}{w}\right) = - \sum_{j=1}^n l_{ij}\epsilon_j \quad (5.25)$$

If we multiply on both sides by  $\beta_i$  and sum across all  $i$  we get

$$\sum_{i=1}^n \beta_i \log p_i - \sum_{i=1}^n \beta_i \log w = - \sum_i \beta_i \sum_{j=1}^n l_{ij}\epsilon_j \quad (5.26)$$

Recalling that GDP is simply the wage earnings of consumers and that labour supply is inelastic at 1 unit, it is given by  $w$ . Substituting for this in the previous equation and rearranging, we get:

$$\log(GDP) = \sum_{i=1}^n \beta_i \log p_i + \sum_i \beta_i \sum_{j=1}^n l_{ij}\epsilon_j \quad (5.27)$$

Define consumption good bundle  $P_c = \prod_{i=1}^n p_i^{\beta_i}$  as numeraire and set its price equal to 1. This implies that  $\sum_i \beta_i \log p_i = 0$ .

We are now ready to state a result on the size of the aggregate economy.

**Proposition 5.2.** *An economy's real value added is given by*

$$\log(GDP) = \sum_{i=1}^n \lambda_i \epsilon_i \quad (5.28)$$

$$\lambda_i = \frac{p_i y_i}{GDP} = \sum_{j=1}^n \beta_j l_{ji} \quad (5.29)$$

and  $l_{ji}$  is the  $(j, i)$  element of the Leontief Inverse,  $L = [1 - A]^{-1}$ .

Thus the (log) aggregate output is a linear combination of industry-level productivity shocks, with coefficients given by the industries' Domar weights. Importantly, the Domar weight of an industry  $i$  depends on the downstream linkages from  $i$  to all other sectors. This relation is known as "Hulten's Theorem" (Hulten [1978], Gabaix [2011]). The result also shows that with constant returns Cobb-Douglas technologies and preferences, the Domar weight depends only on the preference shares and the corresponding column of the economy's Leontief inverse.

To appreciate Propositions 5.1 and 5.2 it is helpful to work through a few simple production networks.

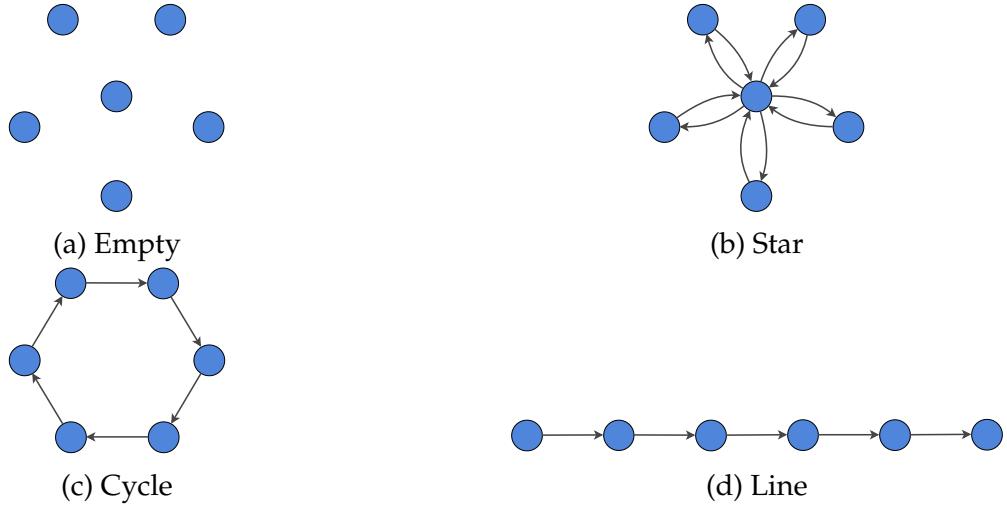

Figure 5.1: Simple Production Networks

### 5.3.2 Computations for simple economies

Consider the production networks represented in Figure 5.1. In these networks there are six sectors:  $n = 6$ . Suppose that the share of labour is the same,  $\alpha_i = 0.2$  for all  $i$ . For simplicity, we will assume that productivity shocks are given by  $z_i = 1$  for every  $i$  and consumer places equal weight all sectors,  $\beta_i = 1/6$ , for all  $i$ . Let us compute the Leontief inverse and the centralities and Domar weights of sectors in the different economies.

For the empty network, the Leontief inverse is simply the identity matrix; the Katz-Bonacich centrality of every node (which is equal to column sum, divided by number of sectors) is therefore given by 1. The Domar weight of each of the sectors is given by 0.17.

Table 5.1 presents the adjacency matrix for cycle network and the corresponding Leontief matrix. We see that as all nodes are symmetric and so the Katz-Bonacich centrality for every sector is the same and given by 5. The Domar weight of each of the sectors is given by 0.83.

### 5.3.3 Remarks on Empirical Production Networks

The theoretical model offers us a useful lens through which to view production economies in the world. Perhaps the most widely used industry-level data is the Input-Output Accounts Data compiled by the Bureau of Economic Analysis (BEA) in the United States. This database provides a detailed breakdown of the U.S. economy into hundreds of industries. We discussed this data in Chapter 1. For easy reference, we briefly recall some important properties of the US network. One, the industry-level network is highly sparsely connected, in the sense that narrowly-defined specialized industries supply inputs on average to only about 11 other industries. Two, the network is dominated by a small number of hubs that are general purpose industries. The weighted out-degree distribution is highly skewed and close to a Pareto distribution. Three, the network exhibits a “small-world”

property: most industry-pairs are indirectly linked by hub-like sectors, thereby the network has short average distances and small diameter. Four, the network exhibits a highly skewed distribution of sectoral Bonacich centralities (that is also well-approximated by a Pareto distribution with diverging second moments).

These properties of production networks are not limited to the United States. To get a sense of the structure of production networks more generally we present statistics from four other large economies – Great Britain, China, India, and Germany (the data is taken from World Input Output Data and is presented at a higher level of aggregation than the BEA data). Let us recall from chapter 1 that weighted out-degree of a sector is defined as follows. Define the weighted out-degree of a sector  $j$  as

$$d_{out}^j = \sum_{i=1}^n w_{ij} \quad (5.30)$$

where  $w_{ij}$  is the input weight from  $j$  to  $i$ . This measure ranges from 0 (if a sector does not supply inputs to any other sector) to  $n$  (if a single sector is the sole input supplier of every sector). Figure 5.2 presents the production networks from these four countries.

Next, recall from our chapter on random origins that, under the Pareto distribution the probability of degree  $k$  is  $P(k) = a/k^c$ , for some positive constants  $a$  and  $c$ . If we take logs on both sides, we get the following equation:

$$\log P(k) = \log a - c \log k. \quad (5.31)$$

Expressed this way, we see that the (log of) probability is a linear function of the (log of) degree. Given any empirical distribution, it is then possible to ask what is the value of  $a$  and  $c$  that offers the best fit. Fitting the Pareto distribution to the weighted out-degree distribution of the four countries, we get the coefficients 2.28 for China, 2.25 for India, 1.74 for Great Britain, and 1.84 for Germany.

The top 5 sectors in terms of size are presented in Table 5.4. An interesting aspect of the networks across countries is that, depending on the level of economic development, the networks cluster around different central industries. Table 5.4 below illustrates this by comparing the top 5 sectors in great Britain, China, India and Germany. We see that Great Britain and Germany share two sectors out of their top five – Administrative/support services and legal and accounting services (it is worth comparing these sectors with the largest sectors in the United States mentioned in chapter 1). Similarly, China and India, also have 2 sectors in common – Manufacturing: chemicals and chemical products and financial services. We also note the prominent role of general purpose sectors like financial services, legal and accounting, and administrative services in these economies, (313) Wholesale Trade

Table 5.4: Comparing Top Sectors Across 4 Leading Economies

To appreciate the inequality in sectoral size, it is instructive to look at the shares of the top 5 sectors. Table 5.5 presents the shares of these top 5 sectors from the four economies. We see that the top 5 sectors make up over 35% of the national economy in India, over 30% in Great Britain and Germany and over 25% in China.

GREAT BRITAIN	CHINA	INDIA	GERMANY
8.68%	5.85%	11.26%	9.60%
6.27%	5.79%	7.51%	6.47%
5.90%	5.68%	6.33%	6.27%
5.70%	5.23%	5.91%	5.58%
5.38%	5.16%	5.71%	5.53%

Table 5.5: Comparing Top Sectors Across 4 Leading Economies

### 5.3.4 Network Structure and Aggregate Volatility

We turn next to the relation between network structure and shock propagation in the economy. The traditional view is that independent sector level shocks will not have a large impact on the aggregate economy, see e.g., Lucas [1977]. The intuition is that shocks on the different sectors have distinct origins and therefore some of them will be positive and other negative. They will therefore cancel out and therefore not have a large aggregate impact. In what follows, we will examine the scope of this argument and demonstrate that it hinges crucially on the network structure of the production economy.

To bring out the role of the network structure in the simplest way, we will simplify some aspects of the production process. First suppose that the productivity shocks are identical and independent across sectors: so,  $\epsilon_i = \epsilon$ , for every sector  $i$ . Moreover, suppose that the mean or average shock is of size 0 and that its standard deviation is  $\sigma$ . Also assume for simplicity that all sectors use labour in the same way, i.e.,  $\alpha_i = \alpha > 0$ , for all  $i \in N$ .

Recall that

$$\log(GDP) = \sum_{i=1}^n \lambda_i \epsilon_i. \quad (5.32)$$

The volatility of the economy may be measured by the standard deviation of the aggregate output

$$\begin{aligned} \sigma_{agg} &= \sqrt{E(\log w)^2} = \sqrt{E\left(\sum_{i=1}^n \lambda_i \epsilon_i\right)^2} \\ &= \sqrt{\sum_{i=1}^n \lambda_i^2 E(\epsilon_i^2)} = \sqrt{\sum_{i=1}^n \lambda_i^2 ((E\epsilon)^2 + \sigma^2)} \end{aligned} \quad (5.33)$$

where we have used the formula for a random variable  $x$ ,  $\sigma_x^2 = Ex^2 - (Ex)^2$ . Noting that  $E\epsilon = 0$  and  $\|\lambda\| = \sqrt{\sum_{i=1}^n \lambda_i^2}$ , we obtain the following compact expression:

$$\sigma_{agg} = \sigma \|\lambda\|$$

To appreciate the magnitude of aggregate volatility in an economy, we next turn to the mean and variance of the distribution of its Domar weights. Recall from the discussion in the previous section that the Domar weight

$$\lambda_i = \sum_{j=1}^n \beta_j l_{ji} \quad (5.34)$$

Therefore the sum of Domar weights

$$\sum_{i=1}^n \lambda_i = \sum_{i=1}^n \sum_{j=1}^n \beta_j l_{ji} = \frac{1}{\alpha}. \quad (5.35)$$

We can therefore write the mean value of  $\lambda_i$ ,  $E(\lambda) = 1/(n\alpha)$ . Turning to the variance, note that

$$\begin{aligned} \sum_i \lambda_i^2 &= n \frac{\sum_i \lambda_i^2}{n} = n E(\lambda^2) \\ &= n(E(\lambda)^2 + \sigma^2(\lambda)) = nE(\lambda)^2 \left[ 1 + \frac{\sigma(\lambda)}{E(\lambda)^2} \right] \end{aligned} \quad (5.36)$$

where we have again used the formula for a random variable  $x$ ,  $\sigma_x^2 = Ex^2 - (Ex)^2$ . Substituting for  $\sum_i \lambda_i^2$  in equation (5.34) we arrive at

$$\sigma_{agg} = \frac{\sigma/\alpha}{\sqrt{n}} \sqrt{1 + n^2\alpha^2 var(\lambda_1, \lambda_2, \dots, \lambda_n)} \quad (5.37)$$

Sectoral size is central for an understanding of aggregate volatility. To see this, note that if the Domar weights are equal then  $var(\lambda_1, \dots, \lambda_n) = 0$ . Substituting in equation (5.37) yields us the expression:

$$\sigma_{agg} = \frac{\sigma/\alpha}{\sqrt{n}} \quad (5.38)$$

As  $\sigma$  and  $\alpha$  are constants, this means that the fluctuation in aggregate output is proportional to  $1/\sqrt{n}$ . We have therefore arrived at the conventional wisdom: aggregate volatility becomes negligible as the number of sectors  $n$  grows.

From Proposition 5.1 we know that the Domar weights of a sector are an equilibrium outcome and that reflect the production network and the consumer demands. In order to focus on the network, let us further assume that consumer assigns equal weight to all goods:  $\beta_i = 1/n, \forall i \in N$ . Recall that the Domar weight  $\lambda_i = v_i/n$ , where

$$v_i = \sum_{j=1}^n l_{ji}. \quad (5.39)$$

is the column sum of Leontief inverse matrix and indicates the importance of industry  $i$  as supplier to economy. Substitute for  $\lambda_i$  in (5.37) and noting that  $\sigma^2(\lambda) = \sigma^2(v)/n^2$  we get that

$$\sigma_{agg} = \frac{\sigma}{\sqrt{n}} \sqrt{\alpha^{-2} + var(v_1, \dots, v_n)} \quad (5.40)$$

where we have used the same definition of variance as before.

Equation 5.40 brings out an important insight: heterogeneity across the industries can lead to significant levels of aggregate volatility. For example, if the  $v_i$ 's have a Pareto distribution with exponent  $\gamma \in (1, 2)$  then it can be shown that  $\sigma_{agg}$  will be proportional to  $n^{1/\gamma-1}$ , and therefore it will be unbounded (the relation between the coefficient and the variance is discussed in the chapter on random origins. The interested reader may also wish to refer to Gabaix [2011] and Acemoglu, Carvalh, Ozdaglar, and Tahbaz-Salehi [2012a] for further analysis of this property).

The intuition underlying this result comes from the propagation mechanism that we developed in Propositions 5.1 and 5.2. Sector level shocks cancel out at the aggregate level

if the sectors are roughly of the same size. But when the sectors are very unequal in their roles as input-suppliers, shocks to sectors that are more important suppliers propagate more widely and dominate the shocks to less prominent sectors. These observations are at the heart of the granularity hypothesis: in the presence of significant heterogeneity at the micro level, sector level shocks can be amplified by the network structure of production.

To appreciate the role of unequal Domar weights, suppose next that they are Pareto distributed. Given  $\gamma \in (1, 2)$ , the tail distribution for  $\lambda$  is  $\lambda^{-\gamma}$ . In this context, a smaller  $\gamma$  reflects greater heterogeneity. The aggregate fluctuation is proportional to  $n^{1/\gamma-1}$  (for large  $n$ ). It may be checked that this is unbounded. Thus the impact of sectoral shocks on aggregate economy depend on the nature of Domar weights. If the Domar weights are roughly equal then the aggregate impact of sectoral shocks is modest. By contrast, if the Domar weights follow a power law, the probability of  $\lambda$  is  $\lambda^{-\gamma}$ , for  $\gamma \in (2, 3)$  and the variance grows without bound (this result was derived in chapter 2). This in turn means that the fluctuation in aggregate output too is unbounded.

### Shock propagation: applications

Figure 5.1 takes up four networks to illustrate how this analysis on aggregate volatility can be applied. Consider first an empty network in which every sector only uses labour as an input. In this economy, shocks to any given sector will not affect production in any other sector: there is no amplification of micro-level volatility.

Next consider the cycle network, in which every sector acts as an input into one other sector. In this setting, shocks do percolate, but the effects have a similar magnitude, as every sector is symmetrically located in the network. More generally, if shocks respect the assumptions of zero mean and equal variance, then they will indeed tend to cancel out: the standard deviation will decline as the number of nodes grows (in line with the expression  $1/\sqrt{n}$ ).

A supply chain suggests a situation in which inputs flow unidirectionally from a well-defined upstream sector - for example, rare earth minerals. Its output is successively transformed into magnets that are used in speakers, which are ultimately incorporated in the final downstream sector, the smart phone. This is a simple line network (the upstream node, with no incoming links), with a single sink (the downstream node, with no outgoing links). The effects of a shock will depend on the location in the chain: for example, a shock at the most upstream source (sector 1) now have a first-round effect on its immediate downstream customer sector 2; a smaller, second-round effect on sector 3; and an even smaller, third round, effect on sector 4. The remaining three sectors contribute in a similar manner except for the fact that they are closer to the sink node and hence do not

contribute to aggregate volatility with as many higher order indirect effects. This source-sink arrangement of the production network draws attention to the disproportionate role of central technologies. The next example brings this out more powerfully.

Finally, consider a setting in which a single general purpose technology serves as the only input (in addition to labour) in all other sectors. Moreover, each of the other sectors is an input for the general purpose technology. Figure 5.1 illustrates this configuration as the star economy. This is a very stylized way to represent the role of sectors such as real estate and construction and information technology. This network yields the highest volatility across the four networks considered. The reason for this is the large effect of the central hub sector: a shock to this sector has large first order effects on all sectors, while a shock to any other sector has a direct effect on one other sector and an indirect effect on every other sector.

These theoretical considerations are of substantive interest as production networks in important economies exhibit great inequality. Recall that the size of a sector is related to its centrality in the production network. With this in mind, Figure 5.3 plots the centrality distribution in Great Britain, China, India, and Germany. The Pareto coefficients of the fitted curves are 1.96, 1.67, 1.65, and 1.82, respectively (we fit the coefficient,  $b$ , in the function  $y = e^a x^b$ ).

Decisions on investments and on securing supply chains are ultimately made by firms. To understand whether they will act appropriately – whether they will invest adequately to make their production reliable, who they will use as input suppliers, and which sectors they will enter – it is important to understand the connections at the firm level. The approach of mapping relations at the sectoral level can be adapted to study inter-firm relations: the nodes are now firms and the links reflect the input relations between firms. The inter-firm supply chain networks have been studied for a few countries such as Belgium and Japan. As in the case of sector level networks, inter-firm networks exhibit extensive heterogeneity that is consistent with power law distributions. In contrast to the sectoral network, the in-degree distribution is also highly skewed. Finally, the size of a firm is positively correlated with both its number of upstream supplier firms and its downstream customer firms.

The discussion has brought out the role of production connections between firms/sectors in transmitting shocks and it has illustrated the role of hub nodes in amplifying shocks. This motivates a closer study of the economic processes that give rise to hubs.

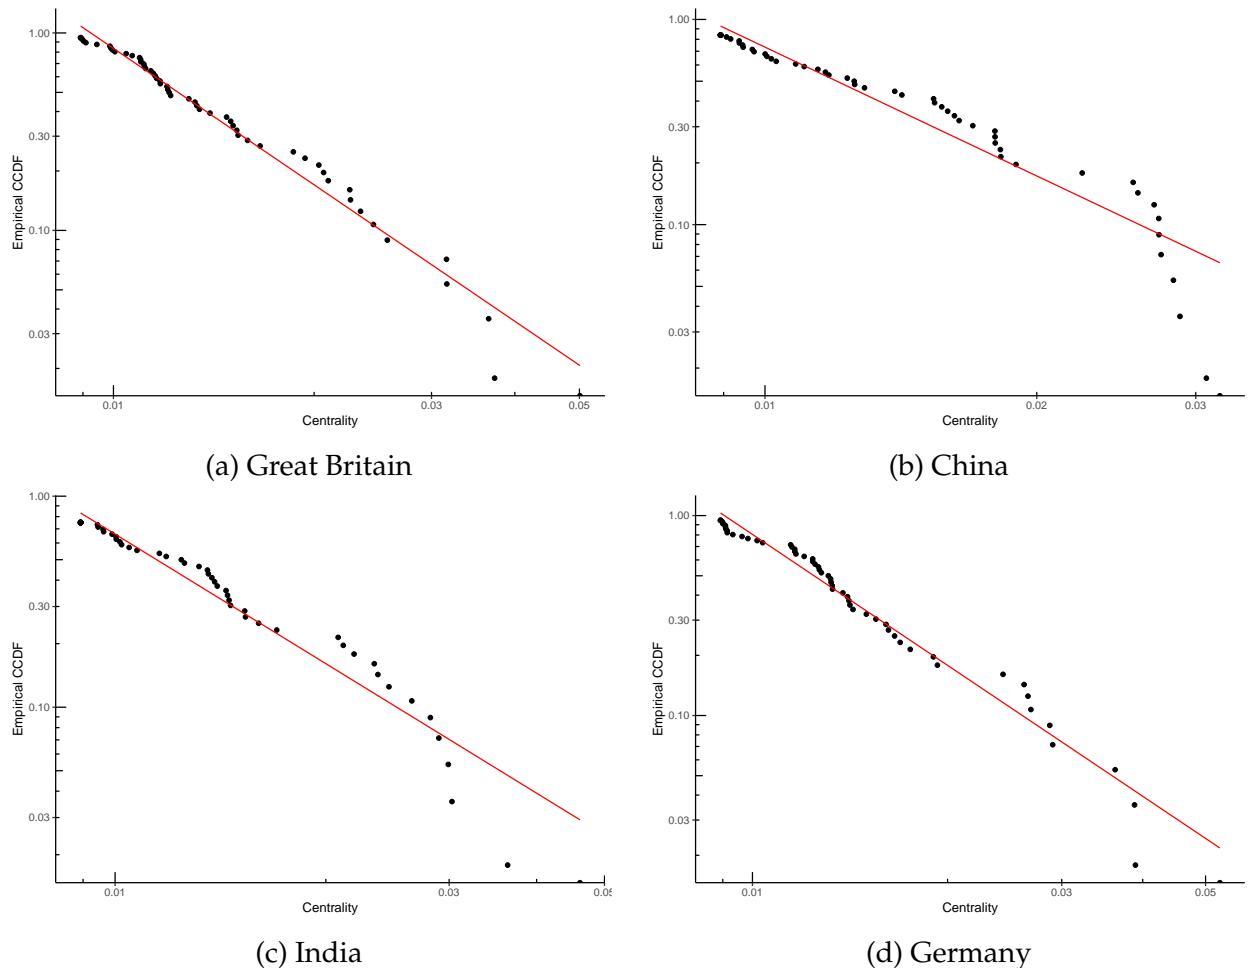

Figure 5.3: Tail Distribution of Centralities, 2014. Data from World Input-Output Database ([www.wiod.org](http://www.wiod.org)).

### 5.3.5 Endogenous Networks

We expect that firms will respond to changes in economic conditions and this response may entail a change in their technology and their suppliers and trading partners. For instance, they may source new inputs to take advantage of technological innovations or may enter into relationships with new customers in response to a customer's exit. These changes will give rise to changes in the production network and this may significantly alter the economy's response to exogenous shocks.

To accommodate these considerations, a small but growing literature develops a theory of production and endogenous network formation. The economic forces involved are complex and include the direct and indirect network effects as well as the combinatorial nature of graphs. A formal presentation of this work is outside the scope of the present chapter and we limit ourselves to mentioning some papers only.

In an early strand of work, this challenge was addressed through statistical models of network formation. Atalay, Hortacsu, Roberts, and Syverson [2011] develop a model in which links between firms are created through a variant of the preferential attachment model (that was proposed in Chapter 2). Carvalho and Voigtlander [2015] propose an industry-level network formation model that builds on the network formation model of Jackson and Rogers [2007] (presented in chapter 3 above). In that model, existing input-output linkages are used to search for new inputs for production. Recall that the model generates a scale free degree distribution and also high clustering. Using industry level data, and consistent with the model's central mechanism, Carvalho and Voigtlander [2015] find that producers are more likely to adopt inputs that are already in use by their current (direct or indirect) upstream suppliers. These statistical models are able to match some of the key attributes of real-world production networks, but they abstract from incentives that depend on the specific inputs and production technologies. Their use for normative and policy purposes is therefore limited.

Oberfield [2018] proposes a model in which firm level incentives are incorporated. In his model, firms optimally choose one input from a randomly evolving set of suppliers. He finds that such endogenous choice results in the emergence of star suppliers that sell their goods to many other firms for intermediate use. In a recent paper, Acemoglu and Azar [2020] consider a model in which firms decide which subset of the other industries to use as input-suppliers, with each input combination leading to a different constant returns to scale production technology. The key assumption in the model is that markets are "contestable" (a large number of firms have access to the same menu of technologies). This assumption ensures that, while making its input combination decisions, each firm can take

the production network and all prices as given.

## 5.4 Supply Chains: Fragility and Resilience

In a modern economy almost any product – be it a cup of coffee or a smart phone – arises out of a supply chain with multiple layers, the output of one layer forming an essential input in the production of the next layer. Firms are aware of the shocks and the uncertainties associated with these multi-layer chains and they take steps to mitigate them – they invest in their own reliability, choose which layer of the supply chains to enter opportunistically, and seek to secure their input supply and downstream demand by creating links with multiple suppliers and buyers. As supply chains are complex, these decisions involve complicated interactions with other firms. We present a simple model of a supply chain to explore incentives of firms and the performance of supply chains they create.

The simplest example of a supply chain is a line with a unique source and unique sink: layer A supplies inputs to layer B, layer B supplies inputs to layer C, and so forth. Let us assume that there is a single firm in each layer. For ease of computations, assume that there is a baseline reliability level  $1/2$  for every firm, i.e., this is the probability that a level produces a viable product using inputs from previous level. There is then a probability  $1/2$  that the supply chain with a single layer delivers, a probability  $1/4$  that a chain with two layers delivers, and so forth. A supply chain with  $n$  layers successfully therefore delivers with probability  $1/2^n$ .

Firms embedded in this supply chain can take steps to improve their performance. Suppose that a firm earns 1 if the supply chain is successful and that it earns 0 if the chain fails to deliver. Let us say that with an investment  $C$  the firm can raise the reliability to 1. In a supply chain with a single firm, a firm compares an expected return of  $1/2$  with the expected return of 1. The returns to investment are  $1/2$ . So the firm will undertake the investment if  $C < 1/2$ .

Next consider a supply chain with two layers, an upstream layer and a downstream layer. As before, suppose that a firm earns 1 in case the supply chain delivers successfully. It is instructive to start with a situation with zero investments in reliability. The supply chain delivers with probability  $1/4$  and both firms expect to earn  $1/4$ . If the upstream firm alone makes an investment then it earns 1 in case of success (this happens now with probability  $1/2$ ) and 0 in case of failure (this happens with probability  $1/2$ ). The firm thus expects to earn  $1/2$  if it invests. So a firm will make the investment if the return  $C < 1/4$ .

To appreciate the strategic relation between investments by firms, suppose next that downstream firm makes the investment  $C$ . This means that the expected returns to up-

stream firm without any investment is  $1/2$ . In this situation, if the upstream firm makes the investment then the supply chain delivers with certainty and the upstream firm expects to earn 1. So the return to investment is  $1/2$ . We have thus established that the returns to upstream firm are larger when the downstream firm invests in reliability. This reveals that the investments in reliability by different firms are strategic complements.

We may summarize our computations as follows: a firm will invest in reliability irrespective of what the other firm does if  $C < 1/4$ , it invests only if the other firm invests in case  $1/4 < C < 1/2$ , and it never invests in reliability if  $C > 1/2$ .

More generally, we may infer that in a supply chain with  $k$  layers (and  $k$  firms), a firm always invests if  $C < 1/2^k$ , it invests so long as all other firms invest if  $1/2^k < C < 1/2$ , and it never invests if  $C > 1/2$ . As the chain grows in length,  $1/2^k$  becomes progressively smaller. The need for firms to coordinate their investment therefore becomes more pressing but at the same time growing supply chain also makes coordination more difficult.

Observe next that even if firms can coordinate on their investment decisions they will never invest if  $C > 1/2$ . So we know that if  $C > 1/2$  then the supply chain will deliver with probability  $1/2^k$ . Thus the likelihood of delivery is small and falling as  $k$  grows. Is this a desirable state of affairs? Is this the best the firms can hope to do?

Consider the collective problem of the firms. If the supply chain is successful their joint earnings are  $k$ . The complementarity in investments tells us that we only need to compare the two polar cases: all firms invest versus no firm invests. If all firms invest, the supply chain delivers with certainty. The aggregate net earnings are

$$k - kC = k(1 - C) \quad (5.41)$$

By contrast, if no firm invests then the joint earnings are  $k/2^k$ . A comparison of the two expressions tells us that firms should invest if

$$1 - C > 1/2^k \quad (5.42)$$

As the number of layers grows, the term  $1/2^k$  becomes progressively smaller, and converges to 0. In other words, all firms should invest so long as  $C < 1$ . These simple computations reveal a key tension in the supply chain: at an individual level, firms have an incentive to invest only if  $C < 1/2$ , but it is in their collective interest to invest so long as  $C < 1$ . Thus in the range  $1/2 < C < 1$ , no firm will invest even though it is in the interest of all firms to invest. These observations are summarized as follows.

**Proposition 5.3.** *Consider a line supply chain with  $k$  layers and with one firm in each layer. The investments of firms across different layers are strategic complements. This gives rise to the possibil-*

*ity of multiple equilibria and for a need for firms to coordinate to achieve a high reliability outcome. There is a wedge between the private benefits to investment in reliability and the collective gains from doing so: as a result, firms will under-invest in reliability. This under-investment grows with the length of the supply chain.*

### 5.4.1 The case of multiple firms in a layer

There is one important aspect of actual supply chains that is missing in the model above – the presence of multiple firms producing the same output. We extend the model in the following way: we suppose as before that there is a single line starting with A that supplies to B, which supplies to C, and so forth; but now we allow firms to decide whether they wish to enter a layer of the supply chain. For simplicity suppose there are many firms that are all interchangeable and that can enter one and only one layer.

To develop our arguments, it is instructive to consider the 2-layer network presented in Figure 5.4. There are two layers, an upstream layer, U, and a downstream layer, D. The supply chain can potentially contain several firms in every layer and there are links between every firm and firms in the adjacent layers. In this network, every firm in layer D can source inputs from every firm in layer U. In the graph on the right, this structure is presented with multiple layers. In other words, the network is a complete multi-partite network. As in our original line supply chain, here too, each firm has a baseline probability 1/2 of being functional. To keep the computations simple, suppose that the firms face equal and independent shocks (thus the likelihood of a firm being operational is unrelated to the status of any other firm).

Let us consider the decision of a firm to enter the two-layer supply chain. Entering a production layer entails investments in plant and equipment and personnel, that are summarized by a fixed cost  $F > 0$ . The supply chain delivers an output if there is at least one operational firm in each layer. In the simple case with only one firm per layer the payoffs are simple: if the supply chain delivers then every operational firm earns 1. A non-operational firms earn 0 (less the costs of entry  $F$ ), irrespective of whether the supply chain delivers or not.

The returns to entering a layer depend on the number of firms present in different layers of the supply chain. Consider the 2-layer network and suppose there is no firm active in any layer of the supply chain. A firm is considering entering (say) the upstream layer. The expected returns are 0: this is because there no firm in the downstream layer. So the supply chain cannot deliver the output, irrespective of what this firm decides. On the other hand, if there is already a firm in the downstream layer then there is a positive value to entering upstream. The supply chain delivers only if firms in either layer are operational, so the

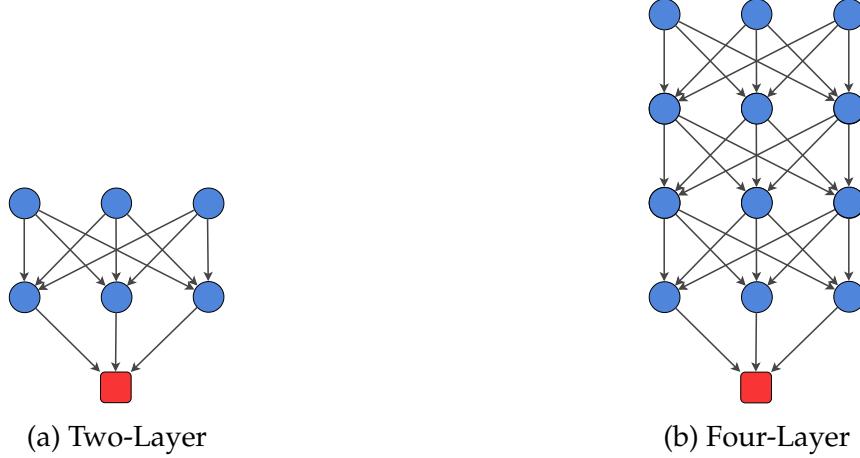

Figure 5.4: Supply Chains

probability of successful delivery is  $1/2 \times 1/2 = 1/4$ . Then, upon entry, the firm expects to earn  $1/4$ . The firm will enter so long as  $F < 1/4$ .

Let us now consider the entry decision with multiple firms in different layers of the supply chain. Suppose that there is one firm in each of the two layers: what are the returns to a firm from entering the downstream layer? Observe that the supply chain can only deliver if the firm in layer U is operational: this happens with probability  $1/2$ . Given that layer U is functional, the firm in question will earn profits if it is itself operational: this again happens with probability  $1/2$ . There is however a further complication – the returns to this firm will depend on whether the other firm in layer D is functional or not and the form of competition with that firm. To keep matters simple suppose that all firms in a layer produce a perfectly substitutable output. This suggests that a firm A in layer X earns a positive payoff if and only if it is itself operational, all other firms in its layer are *not* operational, and all other layers are operational. Returning to our example with two layers, with one firm in each layer, we can write the expected profits of the firm that enters the downstream layer as:

$$\frac{1}{2} \frac{1}{2} \frac{1}{2} - F. \quad (5.43)$$

Thus the firm will enter if  $F < 1/8$ .

Suppose that the firm enters the downstream layer: so there are now 2 firms in layer D and 1 firm in layer U. What are the returns to a firm from entering layer U? As before, we need to keep track of the likelihood of layer D being operational and the likelihood of the other firm in layer U failing. Keeping these factors in mind, the profits of the firm that enters layer U are:

$$\frac{3}{4} \frac{1}{2} \frac{1}{2} - F. \quad (5.44)$$

Thus the firm will enter the upstream layer if  $F < 3/16$ .

These computations tell us that a firm's incentive to enter a layer

- increase with the number of firms in other layers.
- decrease with the number of firms in that layer.

The first effect says that entry in different layers is complementary: as firms enter in different layers, a firm has enhanced incentives to enter its chosen layer. The second effect goes in the opposite direction: entering decisions in the same layer are strategic substitutes: this is due to the 'competition' between firms in the same layer.

Let us now define a supply chain more generally. A supply chain  $\ell = \{\ell_1, \dots, \ell_k\}$ , consists of  $\ell_i$  firms in layer  $i$  where  $i = 1, \dots, k$  denotes the layers. We shall say that a supply chain  $\ell$  is *stable* if no firm that is outside wishes to enter and no firm in the supply chain wishes to exit or switch to another layer

Suppose that a firm wishes to enter a supply chain with  $m$  firms in every layer. The entry of the firm gives rise to a supply chain in which one layer contains  $m + 1$  firms, and all other layers contain exactly  $m$  firms. The complementarity property tells us that new firm's will have an even greater incentive to enter one of the remaining layers with  $m$  firms. Reasoning through this complementarity, one layer at a time, we can conclude that in a stable supply chain, every layer must contain an equal number of firms.

Consider the stability of a 2-layer supply chain with 1 firm in each layer. A firm prefers to stay if expected returns,  $1/4$ , are larger than the cost  $F$ . On the other hand, no new firm wishes to enter if  $F > 1/8$ . So a single firm 2-layer supply chain is stable if

$$\frac{1}{8} < F < \frac{1}{4} \quad (5.45)$$

Similarly, we can verify that a chain with two firms in each layer is stable if

$$\frac{3}{32} < F < \frac{3}{16} \quad (5.46)$$

These computations reveal an interesting fact about the strategic structure of the entry problem: there is a range of costs,  $2/16 < F < 3/16$ , in which a 1 firm per layer supply chain and a 2 firm per layer supply chain are both stable.

This multiplicity of stable supply chains motivates the question: which of the two supply chains is better and more generally what is an optimal supply chain?

In a single firm 2-layer supply chain the collective or joint earnings of the two firms are

$$\frac{1}{2} - 2F \quad (5.47)$$

From the computations above, in a 2 firm 2-layer supply chain the payoff of a firm is equal to  $3/16 - F$ . This tells us that the profits of an individual firm are larger in the 1 firm 2-layer supply chain as compared to the two firm 2-layer supply chain. Let us next consider the joint profits of the active firms. As all firms are symmetric, the joint earnings of the four firms in the 2 firm 2-layer supply chain are

$$\frac{12}{16} - 4F \quad (5.48)$$

It follows that the aggregate profits in the 2 firm 2-layer supply chain are higher than the aggregate profits in the 1 firm 2-layer supply chain if

$$F < \frac{1}{8} \quad (5.49)$$

This means that in the range of costs  $2/16 < F < 3/16$ , the 1 firm 2-layer chain is better for the firms in the chain as compared to the 2 firm 2-layer supply chain. Thus in the range of costs when both one firm and two firm per layer supply chains are stable, the 1 firm 2-layer supply chain is better for the firms.

At a higher level, we may say that the purpose of a supply chain is to deliver the good. With this in mind, let us consider the total surplus net of costs of entry. Implicit in the definition of earnings is the idea that in a successful two layer supply chain the value of the good delivered is 2. The likelihood that such a chain will deliver is simply the probability that both layers are operational. This probability is  $9/16$ . So the social value of such a chain is

$$2 \times \frac{9}{16} - 4F \quad (5.50)$$

A comparison of (5.50) with the expression for joint profits of firms in (5.48) reveals that there is a wedge between the joint profits of the firms and the social value of a 2 firm 2-layer supply chain. This reflects the competition effect of multiple operational firms in the same layer.

To summarize, the analysis on firms choices in supply chains brings out a rich set of interactions – a firm's returns to investment depend the investments in reliability by other firms. In particular, we showed that the investments are strategic complements. This gives rise to the possibility of multiple equilibrium. There also exists a wedge between private

and collective returns to investment suggesting that firms will generally under invest relative to what is in their collective interest. The discussion on entry in supply chains reveals rich strategic relations: entry decisions are strategic complements across layers but strategic substitutes within the same layer. A general message is that there is need for a policy intervention as firms acting in private interest will create supply chains that are insufficiently reliable.

## 5.5 Reading Notes

The study of an economy in terms of its input-output relations between its different sectors has a long tradition. For an early introduction to the literature see Leontief [1941] and Leontief [1951]. Following the early work of Wassily Leontief and his collaborators, a large strand of research explored aspects of economic planning and development using input-output models. This work was accompanied with the collection of very detailed data on input-output relations of different economies across the world. The more recent interest in input-output relations may be traced to Black [2009], and Long and Plosser [1983]. Acemoglu, Carvalh, Ozdaglar, and Tahbaz-Salehi [2012a] build on this tradition and combine it with ideas from the economics of networks and the work of Gabaix [2011] on the ‘granularity hypothesis’. For an early empirical study of production networks see Blöchl, Theis, Vega-Redondo, and Fisher [2011]. An important strand of research has emerged following the work of Acemoglu, Carvalh, Ozdaglar, and Tahbaz-Salehi [2012a]. This work includes Acemoglu, Akcigit, and Kerr [2016a] and Baqaee and Farhi [2019] among others. Carvalho [2014] and Carvalho and Tahbaz-Salehi [2019] provide excellent surveys of this work. Our exposition draws heavily on Carvalho and Tahbaz-Salehi [2019].

The data on input-output tables is taken from the website: [www.wiod.org](http://www.wiod.org)

Supply chains are a major object of study in many disciplines including economics, operations research, management science, organization theory and economic sociology. The emergence of a liberal trading regime has been complemented with advances in information technology to give rise to global supply chains. This in turn has been studies extensively by different strands of research. It is not possible to do justice to this large and fascinating body of work here. For important contributions from an economics perspective see Antras and Chor [2013] and Antras and Helpman [2004]. For an influential contribution on the role of complementarities in the reliability of production see Kremer [1993]. Our aim was to develop some basic economics of firm level decisions in relation to reliability and participation in supply chains. We developed a model that builds on ideas taken from Elliott, Golub, and Leduc [2020b] and Bimpikis, Candogan, and Ehsani [2019].

I am grateful to Ozan Candogan, Vasco Carvalho, Ben Golub, and Joerg Kalbfuss for helpful discussions on issues relating to this chapter.

## 5.6 Questions

1. Consider a production economy. Set  $n = 4$ . Firms use a Cobb-Douglas constant returns to scale technology; every industry uses labour in the same proportion,  $\alpha_i = 1/5 \in (0,1)$ . Industry  $i$  faces a productivity shock  $z_i$ . Consumer has a log utility that assigns equal weight to all four products, so  $\beta_i = \beta = 1/4$ . The consumer has endowment of 1 unit of labour that she supplies inelastically.
  - (a) Write down the definition of competitive equilibrium.
  - (b) Fix the production network to be an undirected complete network in which every industry uses itself and the other three industries in equal measure (so for all  $i, j$ ,  $a_{ij} = 1/5$ ). Derive the Leontief matrix and the Domar weights for this economy. Compute the equilibrium output and prices. (Please use computer software as needed.)
  - (c) Fix the production network to be a star network. The hub industry uses itself and the other three industries in equal measure,  $1/5$ , while the other three industries each uses itself and the hub with coefficient  $2/5$  each. Derive the Leontief matrix and the Domar weights for this economy. Compute the equilibrium output and prices.
  - (d) Comment on the potential for propagation of industry level shocks in these two economies.
2. Consider a production economy with four sectors,  $n = 4$ . Firms use a Cobb-Douglas constant returns to scale technology. Every industry uses labour in the same proportion,  $\alpha_i = 1/5$ . Industry  $i$  faces a productivity shock  $z_i = 1$  for all sectors. Consumer has a log utility that assigns equal weight to all four products, so  $\beta_i = \beta = 1/4$ . The consumer has endowment of 1 unit of labour that she supplies inelastically.
  - (a) Consider the network as in left panel of Figure 5.5. Write out the adjacency matrix and then derive the Leontief matrix and the Domar weights for this economy. Assuming  $z_i = 1$ , for all  $i$ , compute the equilibrium output of different sectors (use computer software as appropriate.)
  - (b) Consider the network as in right panel of Figure 5.5. Write out the adjacency matrix and derive the Leontief matrix and the Domar weights for this economy.

Figure 5.5: Supply Chains

Assuming  $z_i = 1$ , for all  $i$ , compute the equilibrium output of the different sectors (use computer software as appropriate.)

3. Consider the model of production from the lecture but now suppose the government purchases an exogenously given quantity  $q_i$  of good  $i$ . These demands are financed by lump sum taxes imposed on consumers. Reason carefully on how such government demands will propagate upstream from the affected markets with high demands to their suppliers and further upstream along the production network.
4. Discuss possible reasons for the unequal size and centrality of sectors in modern economies.
5. Consider the two layer supply chain problem discussed in Chapter 4. There is one firm in each layer. Suppose the probability of successful operation for a firm is  $p \in (0, 1)$  and that it is identical and independent across firms. A firm can raise its reliability level from  $p$  to 1 by investing  $C > 0$ . Derive the equilibrium reliability investments as a function of  $C$  and  $p$ .
6. Consider the two layer supply chain problem with firm entry discussed in Chapter 4. Firms can enter one layer. Suppose the probability of successful operation for a firm is  $p \in (0, 1)$  and that it costs  $F$  to enter into a layer. Derive the entry equilibrium as a function of  $F$  and  $p$ .

# Chapter 6: Infrastructure

## 6.1 Introduction

Surviving works of infrastructure from antiquity, such as the urban grids of Mohenjo-daro in the Indus Valley, the Roman Roads and aqueducts, and the Great Wall of China continue to impress us but there is no historical parallel to the extraordinary range of transport and infrastructure networks that we see in the modern world. Examples include airlines, roads and trains, shipping, electricity, pipelines, and the internet. It is difficult to do justice to this range of networks in the space of a single chapter. We will consider three transport networks – airline, roads, and trains – to illustrate this diversity. The chapter will then present theoretical models with a view to developing economic principles that can help us understand their structure and impact of these networks on economic activity.

We start with airlines. Air travel has grown enormously over the past few decades. Our point of departure is an empirical observation from our discussions in the introductory chapters: most airlines operate a hub-spoke structure and some recent low cost airlines operate point-to-point networks. What are the determinants of network structure? We develop a theoretical model with two ingredients – one, fixed costs in creating links and two, benefits of flying that are falling in the number of flight transfers one makes. The model predicts that airlines will either choose a *point-to-point* network or a *hub-spoke* network depending on the cost of creating flight links relative to the benefits of direct versus indirect flights. We use the theory to understand the routing networks of different airlines.

We then turn to road and train networks. The discussion begins with case studies on the Roman Road network, the Indian Railways and the American Railroads. These case studies help to bring out the scale of networks and to indicate the enormous resources that are devoted to their creation. They also draw attention to the topological features of these networks. A distinctive feature of these transport networks, as compared to airline networks, is that physical geography has an important influence on costs of linking. We draw upon the classical work of Robert Fogel and the significant advances made by recent research to develop a theoretical framework to study the relation between transport net-

works and economic activity. In this approach, the key idea is that transport networks help reduce the costs of shipping goods between locations; thus transport networks determine market access. The integration of markets in turn facilitates better allocation of resources and thereby raises incomes. Thus, on the one hand, transport networks seek to connect locations that are more productive and, on the other hand, the connections themselves shape the flow of goods and labour and that shapes the scale of activity and the performance of different locations. Thus network design may play a decisive role in determining the fate of locations.

We conclude with a discussion of the Belt and Road Initiative (BRI) launched by China in 2013. The BRI covers a wide range of infrastructure and involves a large number of countries. The discussion draws attention to the main elements of the initiative and connects them to the theoretical considerations developed in the chapter.

## 6.2 Airlines

The idea of flying goes as far back as back as the myth of Daedalus and Icarus, Leonardo da Vinci's designs of the 15th century brought it closer to reality, but air travel as we know it really began in the early twentieth century, as entrepreneurs and engineers and governments built on what the Wright Brothers had started not so long before. In this section, attention will focus on passenger air travel and the airlines that operate the planes. We begin with a brief discussion of the empirical background.

### 6.2.1 Empirical Background

Historically, airlines services have been either state owned or heavily regulated. This meant that both the routing as well as the pricing of services were controlled. In the United States, private firms were allowed to function but were strictly regulated. In most other parts of the world air services were provided by a natural monopoly (and this remains the case in many countries). Over the past three decades there have been a number of major developments. One, passenger traffic has grown greatly: over the past two decades international passenger numbers have grown by over 5% annually in most years. Two, in some large countries like India and China growth has been double digit for most of the past decade (2010-2020) and countries in Africa and Latin America are expected to have high growth rates in the coming decade. Three, many countries have liberalized the airline sector – public sector airlines have been privatized and a number of new companies have entered. Economy airlines like EasyJet, Southwest, and Ryanair have become dominant in Europe

and the United States.

Airlines use a variety of strategies to compete in the market that include the flights they operate and the prices they charge on these flights. In addition, airlines also form alliances with other airlines to share capacity and facilities and provide a broader market coverage. We focus on the network of flight connections chosen by airlines.

In our earlier discussion in chapters 1 and 2, we noted that large international airlines such as British Airways and Singapore Airlines operate a hub-spoke network, while low cost airlines such as Southwest Airlines and Ryanair have a dense network that is closer to a point-to-point network. We present data on a few airlines to develop a sense of their size and their network structures. These numbers draw attention to the networks of some of the world's biggest airlines (and correspondingly largest air travel markets). They also highlight marked differences in the density of direct flights across airlines: British Airways, Egypt Air, and Singapore Airlines operate something close to a hub-spoke structure, while some of the other airlines operate dense flight networks (with close to 50% of flights being direct). The data also highlight the growth of new airlines (such as Ryanair and EasyJet (in Europe), Indigo and Spicejet (in India) and China Eastern and Southern (in China)). This reflects two aspects of the dynamics of the airlines industry over the last two decades: deregulation and open sky policies in Europe and economic growth in China and India both leading to a massive expansion in air travel.

Airlines	Destinations	Flights
British Airways	226	348
Singapore Airlines	68	103
Ryanair	221	1741
EasyJet	127	420
Indigo	75	508
SpiceJet	68	267
Southwest	109	2641
China Southern	235	960
China Eastern	210	947
American Airlines	352	1256
United Airlines	384	1112
EgyptAir	87	118

Table 6.1: Some leading airlines. Data Source: <https://www.ch-aviation.com/portal/>

For concreteness, we present the networks of some leading airlines from different parts of the world: Singapore Airlines and Ryanair in Figure 6.1 and China Southern and Indigo Airlines in Figure 6.2. Why do these airlines have such different routing networks? We

now examine the economic considerations that go into the design of an airline network.

In these networks there are two types of trips: direct trips (without stops) and indirect trips. We will assume that passengers prefer direct flights to indirect flights. Airlines incur costs in operating a flight: these costs include depreciation of aircrafts, personnel salaries, landing slot charges at airports, and costs of selling tickets and checking-in passengers.

To develop a feel for key trade-offs suppose that there is passenger demand 20 from every city to every other city. Consider the network in figure 6.3a. If a plane has capacity 60, then a direct flight between a pair of cities entails excess capacity of 40.

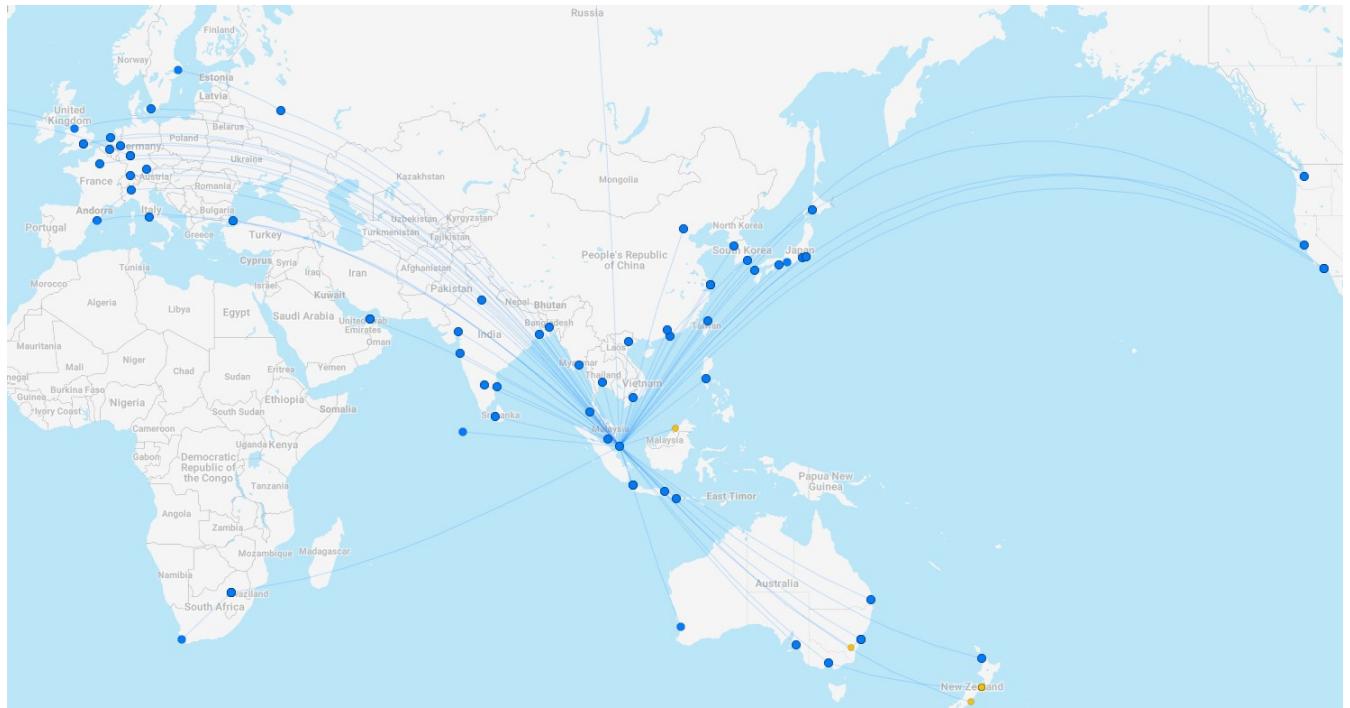

Figure 6.3 presents a hub-spoke network. In this network, every flight carries 60 passengers: thus every flight operates on full capacity. This is referred to as *economies of density*. The trade-off is that in a hub-spoke network there are more indirect flights and as passenger dislike making flight changes, this may push the airline to charge lower prices. A question at the end of the chapter examines pricing in airlines networks. With these remarks as background we present a theoretical framework to study the economics of airline routing.

### 6.2.2 A simple model of airline routing

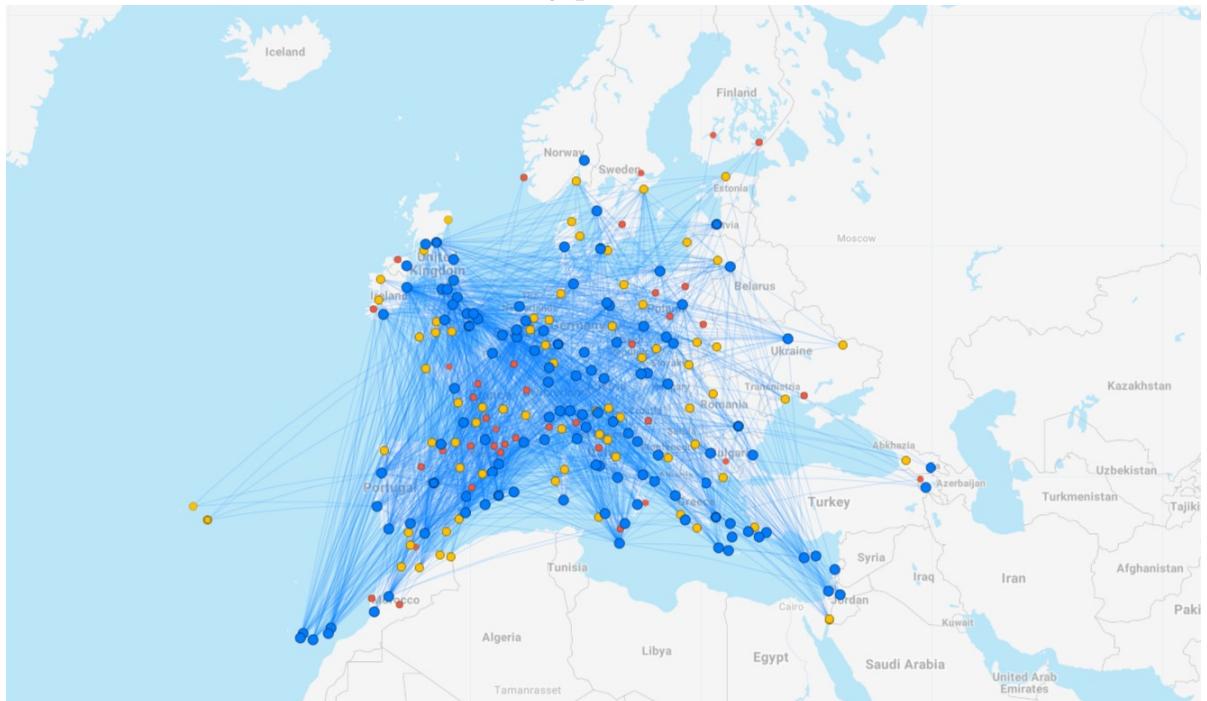

Our discussion in this section is based on a model taken from Hendricks, Piccione, and Tan [1995]. There are  $N$  cities in all; people living in each city wish to travel to other cities. Let  $A, B$  denote a pair of cities. A *direct connection* is a non-stop flight from  $A$  to  $B$ . A flight routing network is a graph  $g$ ; a typical link in this network is denoted by  $g_{AB}$ , for simplicity suppose that all flights are return flights: so  $g_{A,B} = g_{B,A}$  and we can talk of links from now as signifying a return flight. The number of links operated in a network  $g$  is given by  $m(g)$ . A sequence of cities  $A_1, A_2, \dots, A_{z+1}$  is called a *path* if there is a direct link between two consecutive cities and the length of the path is  $z$ : this is the number of direct flights in the path. Two cities are *connected* if there exists a path between them. A *network* is said to be *connected* if it connects every pair of cities. A network  $G$  is a hub-spoke network of size  $m$  if there exists a city  $A$ , the hub city, that is linked to  $m$  other cities.

Let us next consider the costs of operating this network. For every link between two cities  $A$  and  $B$ , let  $f > 0$  be the cost of operating a direct flight. Then the cost of a network with  $k$  links is  $fk$ .

An airline carrier's *operating profits* are the revenue minus the variable costs. They can therefore be written as the sum of profits across city-market pairs. In each city pair they depend on the length of the path a traveler has to traverse: let  $\pi(z)$  denote the gross returns for a city pair that is distance  $z$  apart in the network. We make the assumption that

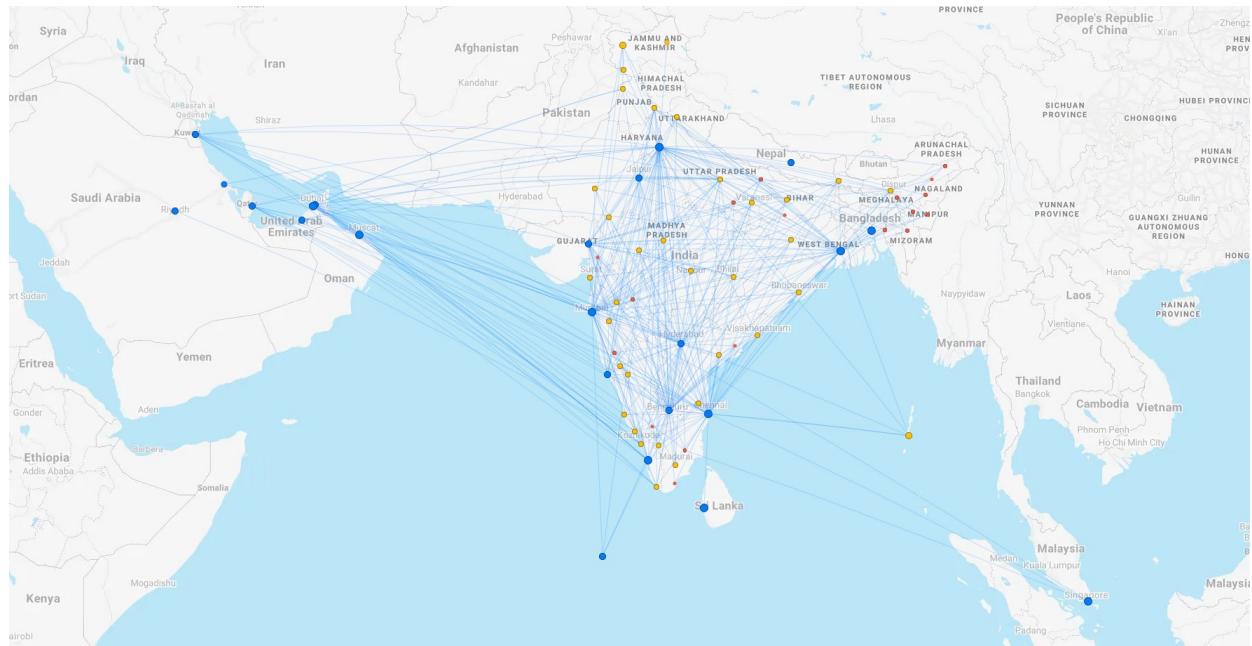

(a) Singapore Airlines

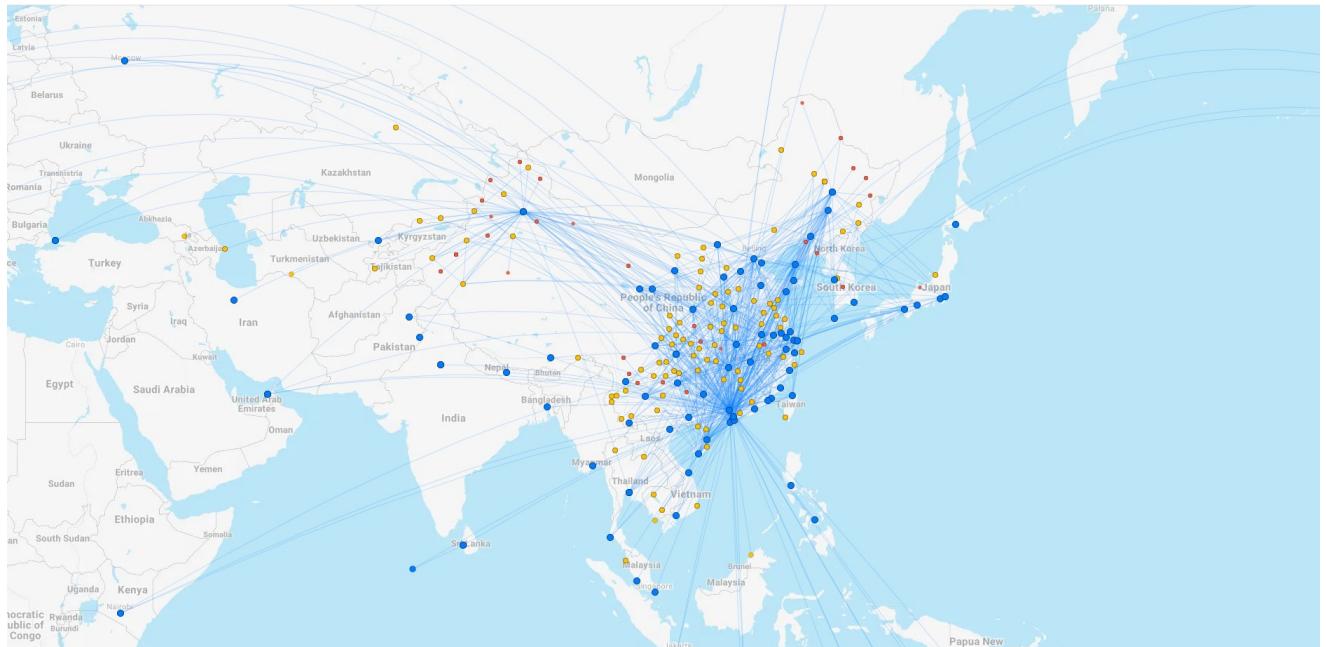

(b) Ryanair

Figure 6.1: Airline Networks: examples

(a) Indigo Airlines

(b) China Southern

Figure 6.2: Airline Networks: examples

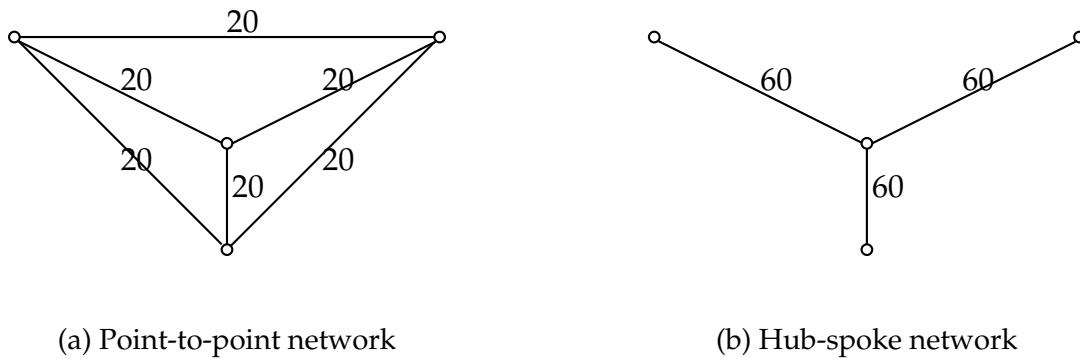

Figure 6.3: Capacity Use in Networks

passengers prefer fewer flight stops and changes. Thus gross profits are larger for city pairs that are closer in the network.

$$\pi(z) \geq \pi(z+1) \geq 0 \forall z \quad (6.1)$$

The profits of an airline will therefore depend on the number of flights it operates and the length of the lights passengers have to traverse. Let  $d(A, B; g)$  be the length of the shortest path in the network  $g$  between two cities  $A$  and  $B$ . The profits of the airline can be written as:

$$\Pi(g) = \sum_{i,j:i < j} \pi(d(i,j;g)) - fm(g). \quad (6.2)$$

Clearly, there would be no flights created if the costs are too large. To rule out empty networks, we assume:

$$(n-1)\pi_m(1) + \frac{(n-1)(n-2)}{2}\pi_m(2) > (n-1)f. \quad (6.3)$$

The first term on the left hand side of the inequality reflect the returns from  $n - 1$  direct flights between the spokes and the hub, and the second term reflects the returns from all the one-stop indirect flight between the spokes that goes through the hub. This assumption therefore says that the benefits of a hub-spoke network outweigh the costs of operating the  $n - 1$  routes.

The following result provides us a complete description of optimal routing networks.

**Proposition 6.1.** Suppose (6.1) and (6.3) hold. Then there exists some  $f^*$  such that

- (a) for  $f < f^*$  the optimal network is the point-to-point network.
  - (b) for  $f > f^*$  the optimal network is the hub-spoke network.

Let us develop the arguments underlying this result. First, we will show that creating less than  $n - 1$  links is never optimal. As  $m$  is less than  $n - 1$ , we know that the airline cannot connect all cities. What is the best it can hope to do? Well, it provides direct flights between  $m$  city pairs and provides a one stop flight for the remaining pairs of connected cities. This is possible with a hub-spoke network with  $m$  spokes. The airline earns a profit of

$$m\pi(1) + \frac{m(m-1)}{2}\pi(2) - fm \quad (6.4)$$

using this network. Could such a network ever be optimal for the airline? No. To see why, observe that the last link – the  $m^{th}$  link – helps connect a city to the hub-spoke network with  $m - 1$  spoke cities. So the marginal cost of the last flight is  $f$ , while the marginal return is the difference in the operating profits of the  $m - 1$  hub-spoke network as compared to the  $m$  hub-spoke network. This is given by  $\pi(1) + (m - 1)\pi(2)$ . Reasoning similarly, the marginal value of increasing number of direct flights from  $m$  to  $m + 1$  is  $\pi(1) + m\pi(2)$ . Thus if link  $m$  is profitable, so is link  $m + 1$ . This means that if the airline found it profitable to add flight  $m$ , it would be even more profitable to add flight  $m + 1$ . This tells us that a network with  $0 < m < n - 1$  is never optimal. This is an example of agglomeration: once a hub-spoke network begins to form, the marginal returns to connecting grow with the size of the network.

Next, consider a network with exactly  $n - 1$  direct flights: such a network provides a direct flight between  $(n - 1)$  city pairs. The shortest path length for all the other  $(n(n - 1)/2 - (n - 1))$  city pairs is 2. The hub-spoke network with  $n - 1$  links attains this best case scenario. The profits of the airline in this hub-spoke network are

$$(n - 1)\pi(1) + \frac{(n - 1)(n - 2)}{2}\pi(2) - (n - 1)f \quad (6.5)$$

What are the marginal returns to adding a link to this hub-spoke network? The new flight would connect two spoke cities: thus the marginal returns are given by the difference in profit between a direct flight and a single stop flight:  $(\pi(1) - \pi(2))$ . It therefore follows that if  $f < (\pi(1) - \pi(2))$ , then it is profitable for the airline to add a link. Observe that the marginal returns to adding links between any pair of spokes remains unchanged as we connect spokes. Thus if it is profitable to connect one pair then it is profitable to connect all pairs, i.e., to create a point-to-point network. We have thus shown that an optimal network is either the hub-spoke network or the point-to-point network.

These arguments provide a very general basis for understanding the optimal networks not only for airlines but also in other settings, so it is instructive to present the details.

**Proof:** We show that a network with  $n - 1 < m < n(n - 1)/2$  links cannot be optimal. Note that with  $m$  links there are  $2m$  direct connections and at most  $(n(n - 1) - 2m)$  connections with 1 stop. Thus gross profits are bounded above by the expression

$$m\pi(1) + \left( \frac{n(n-1)}{2} - m \right) \pi(2)$$

This payoff is attained by a hub-spoke network of the following type: a hub-spoke network with  $(n - 1)$  links plus  $(m - (n - 1))$  direct links between remaining spoke cities.

Note that the gain from adding a direct connection  $(m + 1)$ , is given by  $(\pi(1) - \pi(2))$ . Thus if  $f < (\pi(1) - \pi(2))$ , then it is profitable to create an additional link. Otherwise the  $(n - 1)$  hub-spoke network generates a higher gross profit as compared to any larger network.

The second step shows that a network with  $m < n - 1$  links is never optimal. Suppose  $X$  is an optimal network with  $m < n - 1$  links. Then the maximum pay-off from such a network is given by

$$m\pi(1) + \left( \frac{m(m+1)}{2} - m \right) \pi(2) - mf \quad (6.6)$$

Since  $m$  links is preferred to  $(m - 1)$  links, it must be that the payoff with  $m - 1$  links is lower,

$$(m-1)\pi(1) + \left( \frac{(m-1)m}{2} - (m-1) \right) \pi(2) - (m-1)f \quad (6.7)$$

As (6.6) is greater than (6.7), we get

$$\begin{aligned} & \pi(1)(m - (m - 1)) + \pi(2) \left( \frac{m(m-1)}{2} - \frac{(m-1)(m-2)}{2} \right) - f > 0 \\ \Rightarrow & \pi(1) + \pi(2)(m - 1) - f > 0 \end{aligned} \quad (6.8)$$

The pay-off from adding link  $m + 1$  is given by

$$(m+1)\pi(1) + \left( \frac{(m+1)(m+2)}{2} - (m+1) \right) \pi(2) - (m+1)f \quad (6.9)$$

Subtracting (6.6) from (6.9) we get that the benefit to adding an additional link is

$$\pi(1)((m+1) - m) + \pi(2) \left( \frac{m(m+1)}{2} - \frac{m(m-1)}{2} \right) - f$$

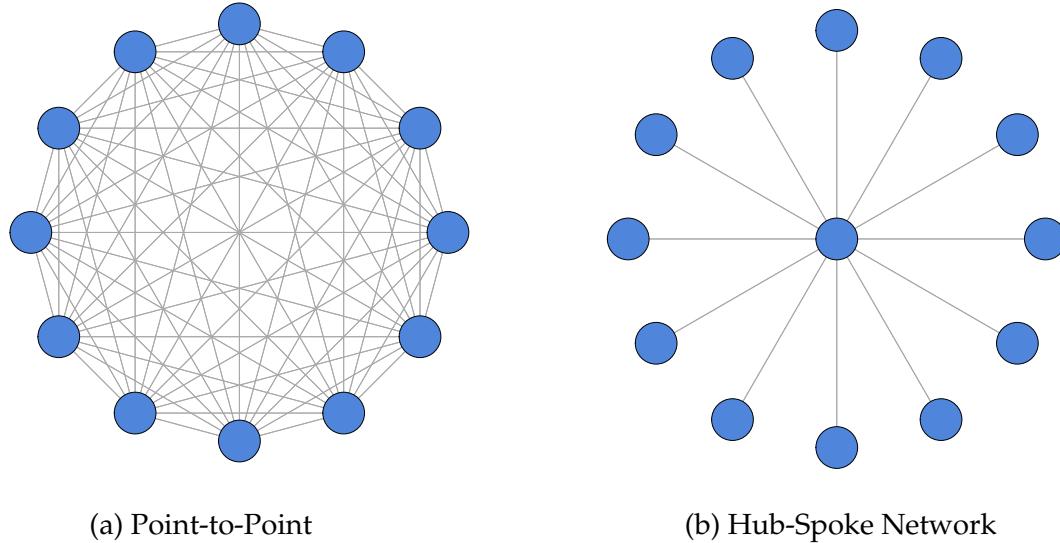

Figure 6.4: Optimal Airline Networks

## Simplifying

$$\pi(1) + \pi(2)m - f \quad (6.10)$$

Clearly (6.10) is positive given that (6.8) holds. Hence  $0 < m < n - 1$  cannot be profitable. Assumption (6.3) rules out the empty network (with  $m = 0$ ). The proof is complete.

Figure 6.4 presents the optimal networks. We next use the theory as a lens through which to see the structure of airline networks in different parts of the world.

### 6.2.3 Mapping Theory to Empirical Routing Networks

Let us use the model as a lens to view different airline routing networks. There are a number of forces at work but as a first step it is instructive to use the theory to reason about this question. Ryanair operates the Boeing 737-800 plane with a capacity of 189 exclusively; British Airways uses a range of planes but for its long-haul flights British Airways uses the Boeing 777-200 plane, with a capacity ranging from 314 to 451. These differences in capacity can be related to our discussion on capacity of planes and shape of network in Figure 6.3: larger capacity planes are consistent with hub-spoke networks, while smaller capacity planes are consistent with point-to-point networks. A second point concerns the airports that the two airlines use. British Airways uses principal airports at major cities that have high landing fees; by contrast, Ryanair is well known for operating its flights from smaller

airports that charge lower landing fees. Both these features lowers the fixed cost of operating direct flights for Ryanair. The theory therefore helps us understand why Ryanair operates a dense network (with point-to-point tickets only), whereas British Airways operates a hub-spoke network. Similar considerations arise when we consider the networks of the other airlines mentioned in Table 6.1.

There are a number of other considerations that are important and that can be accommodated within the theoretical framework. We have assumed that the demand for travel is equal across city pairs. Clearly larger city pairs will have different demand as compared to small cities. This will shape the routing network in an intuitive way: the airline will operate a hub-spoke network in which the larger cities will also have a direct link. This problem is examined in a question at the end of the chapter. We have considered the problem of optimal network design by a monopoly airline. In principle, it is possible that airlines may choose richer and more complicated routing networks when facing competition from other airlines. A question at the end of the chapter examines competition among airlines and develops conditions under which competing airlines will create hub-spoke networks.

Let us summarize what we have learnt in this section. Air travel has grown enormously since the 1950's and this growth has been especially large in the last two decades. This growth has been accompanied with a progressive deregulation of the market for flying. The result has been an expansion of older airlines and the emergence of a number of new airline companies. These airlines compete with each other to serve consumers. Their strategies include pricing and the routing of flights. We have focused on the design of routing networks. Airlines operate a variety of routing networks ranging from the hub-spoke network to dense point-to-point networks. We explored a simple model of airline network design: in this model there are two key ingredients – costs of setting up direct routes and the higher benefits of direct routes. This model yields the following insight – when all city pairs have similar demand for air travel the optimal network is either a hub-spoke or a point-to-point network, i.e., all other networks are sub-optimal. We commented on the ways in which this insight can be extended and how it helps us understand features of real world airline networks.

### 6.3 Roads and Trains

To set the stage, we start with a brief discussion of an ancient transport network – Roman Roads. This is followed by a discussion of two large modern transport networks – American Railroads and Railways in Colonial India. The aim of these short case studies is to bring out the extraordinary scale of these networks, to discuss the goals of the network

builders, and to draw attention to the spatial dimension of these networks (that sets them apart from airline networks).

### ROMAN ROADS

At its peak, in the first half of the second century AD, the Roman Empire ranged from Hadrian's Wall (in Scotland) and the banks of the Rhine river in the North to Morocco and Egypt in the South and it ranged from Spain in the West all the way to the Euphrates River (in Mesopotamia) in the East. The first roads were started between Rome and the south east of Italy in 312 BC and formed the basis of the Via Appia. At the peak of the empire the Romans had built over 80,000 kilometers of hard-surfaced roads connecting their capital with the frontiers of their far-flung empire. Our discussion draws on the Britannica [2000].

Wars were frequent and roads were the principal mode of transport for the army and for the consolidation of captured territory into the empire. At the start, highways connected the capital, Rome, with near by provinces and towns that had recently been taken over by the Romans. The first of the great Roman roads, the Via Appia, started in 312 BCE, originally ran southeast from Rome to Tarentum (modern Taranto) and was later extended to Brundisium (modern Brindisi) on the Adriatic coast. By the beginning of the 2nd century BC, four other great roads radiated from Rome: the Via Aurelia, extending northwest to Genua (modern Genoa), the Via Flaminia, running north to the Adriatic, where it joined the Via Aemilia, crossed the Rubicon, and led northwest; the Via Valeria, east across the peninsula by way of Lake Fucinus (Conca del Fucino); and the Via Latina, running southeast and joining the Via Appia near Capua. These major roads were supplemented by numerous feeder roads extending far into the Roman provinces, thereby creating a network with a hub at Rome, giving rise to the expression, "*all roads lead to Rome*".

In 145 BC, the Romans started constructing the Via Egnatia, an extension of the Via Appia beyond the Adriatic into Greece and Asia Minor, where it joined the ancient Persian Royal Road. In northern Africa the Romans followed up their conquest of Carthage by building a road system that spanned the south shore of the Mediterranean. In Gaul, they developed a system centred near Lyon, from where the main roads extended to the Rhine, Bordeaux, and the English Channel. In Britain, a network was created with roads stretching out from London. In France and England the principal roads were laid out in a hub-spoke structure, while in Spain the geography dictated a system of main roads around the periphery of the peninsula (with secondary roads leading into the central plateau). Figure 6.5 presents a map of the principal Roman highway network at the time of Emperor Hadrian, in 125 AD. In summary, the network combined key elements of the hub-spoke structure, reached out toward the boundaries of the empire, and respected the physical constraints of geography.

Once in place, the roads, came to be used for to transport agricultural produce of different kinds (oil, olives, wheat, and wine) and by the imperial courier system. The Roman Road system continued to serve Europe throughout the Middle Ages; many major modern roads have been built on old Roman routes, but fragments of the old system survive and remain in use in many parts of Europe even today. For a detailed and fascinating study of Roman infrastructure visit the web site: <https://classics.stanford.edu/>

### RAILROADS IN COLONIAL INDIA

We next turn to another of history's great transportation projects – the vast network of train tracks built in colonial India (an area covering modern India, Pakistan, and Bangladesh). The first railway line in India, Red Hill Rail Road, was built to bring granite for road building work in Madras in 1836. However, the start of the construction of a national railway network is generally traced back to a railway line that ran from Bombay to Thane and started operation in April 1853. The train network was built over the period 1852-1930, and in the end stretched over 67,000 kilometers. The material in this case study draws on Donaldson [2018].

Prior to the creation of train network, goods transport within India took place on roads, rivers, and coastal shipping routes. The bulk of inland travel was carried by bullocks, along the road network. On the best road surfaces and during optimal weather conditions, bullock-carts could cover 20–30 km per day. Trade was also carried by "pack" bullocks (that carried goods strapped to their backs and generally traveled directly over pasture land), that were considerably slower and riskier than cart bullocks. Water transport was superior to road transport, but it functioned only on the Brahmaputra, Ganges, and Indus river systems. Coastal shipping was available along India's long coastline; steamships were fast and could cover over 100 km per day but only served major sea ports. Against this backdrop of costly and slow internal transportation, the potential for economic effects appears to be very large when we note that in comparison to traditional modes of transport, railroads could ship commodities at over 600 km in a day, and at much lower per unit distance freight rates. It is not surprising that the construction of a train network was discussed as early as 1832.

The decisions on where to lay the train tracks were made by the Government of India. The Government had three motives for building railroads – military, commercial, and humanitarian. Since its inception, military motives were prominent and appeared at every stage of the development of the network. The military consideration was reinforced after the Mutiny of 1857.

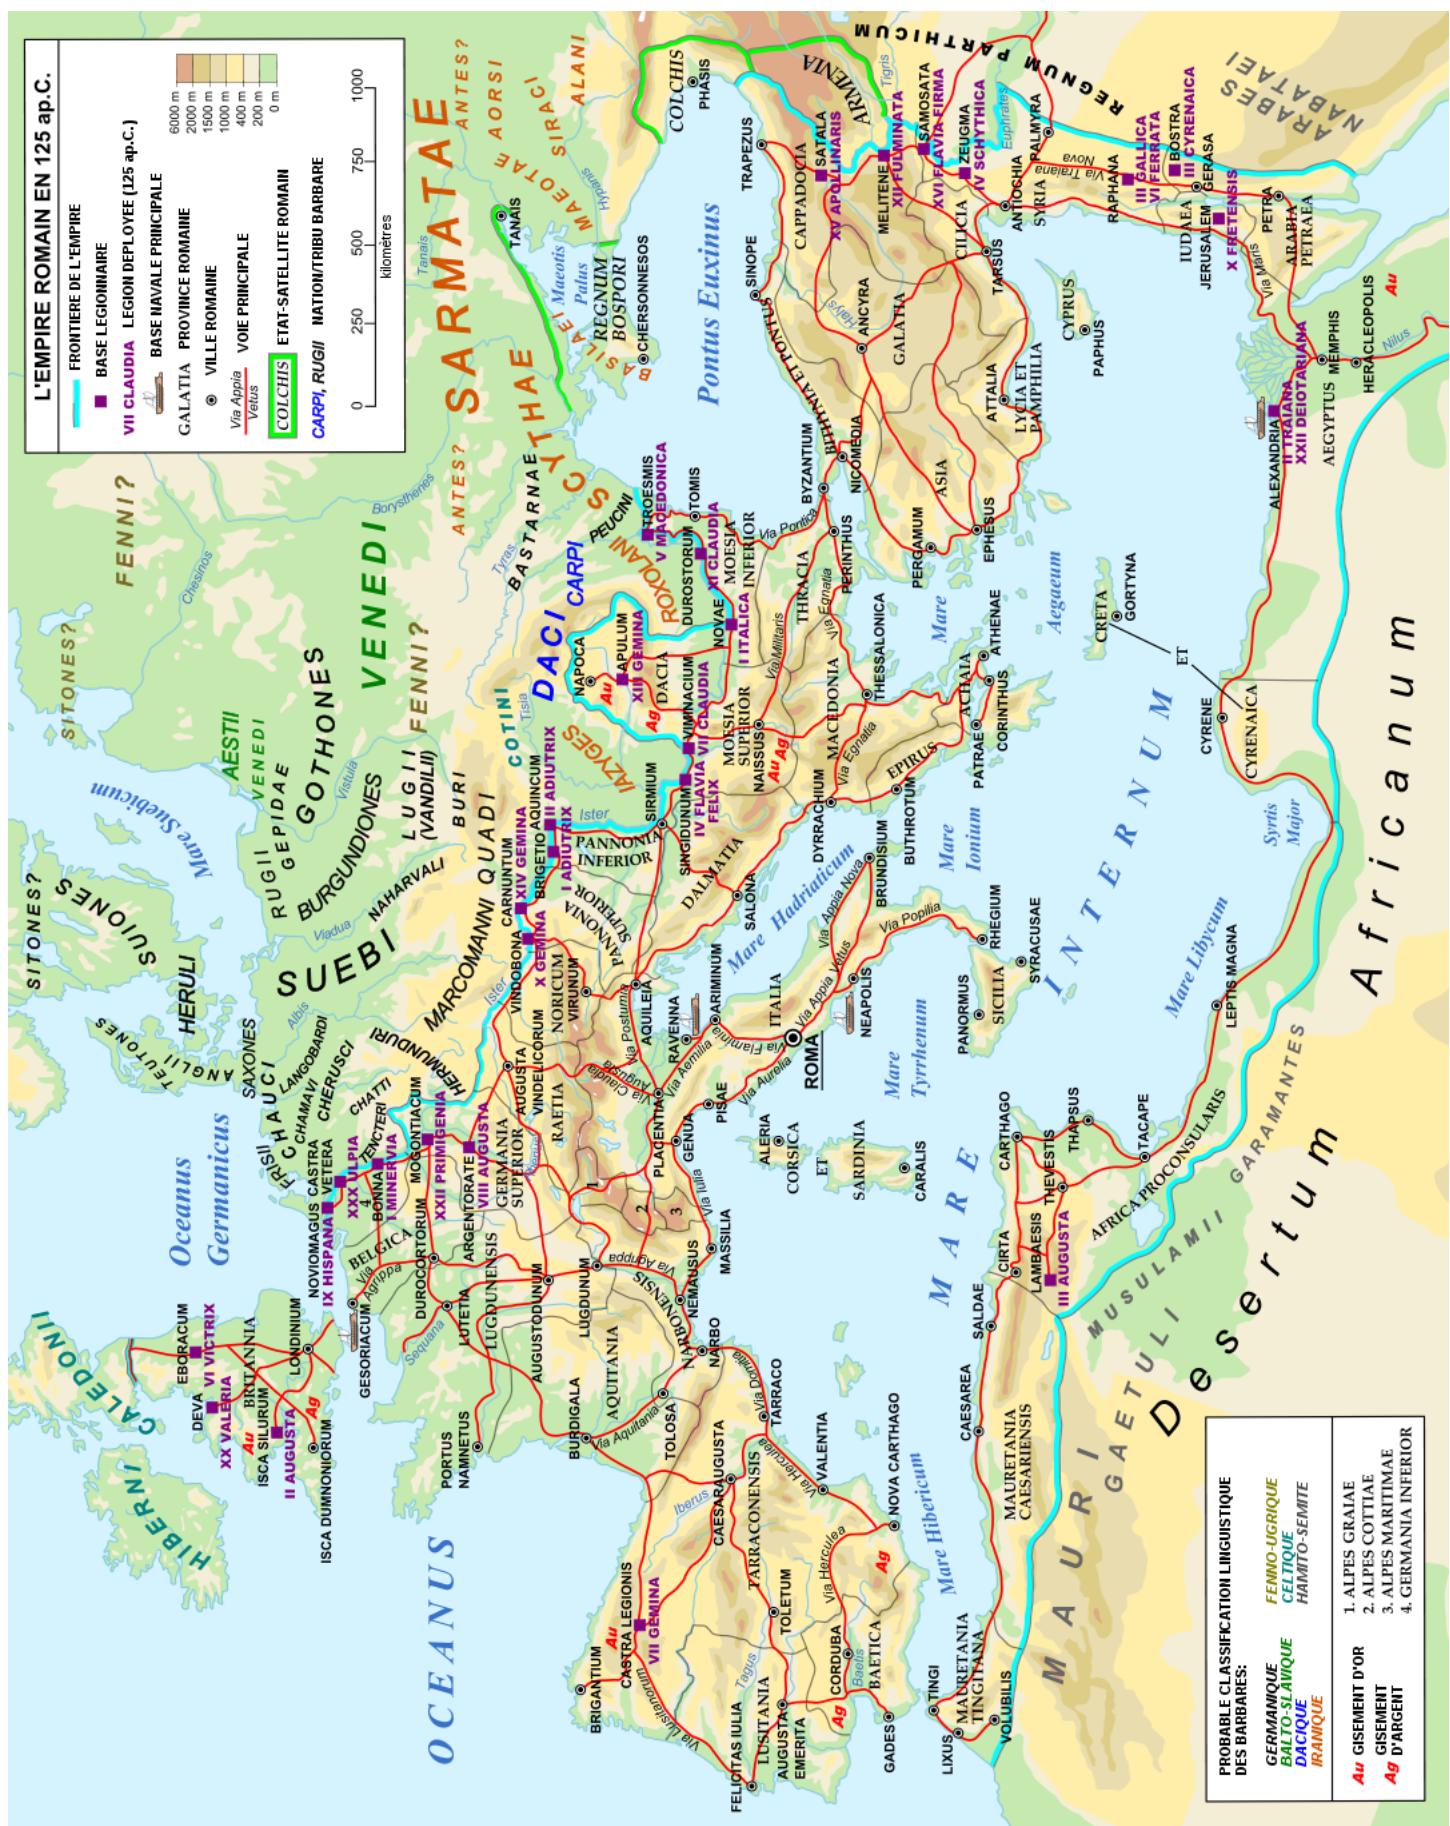

Figure 6.5: Roman Road Network AD: By Andrein - Own work, CC BY-SA 3.0, <https://commons.wikimedia.org/w/index.php?curid=6654575>

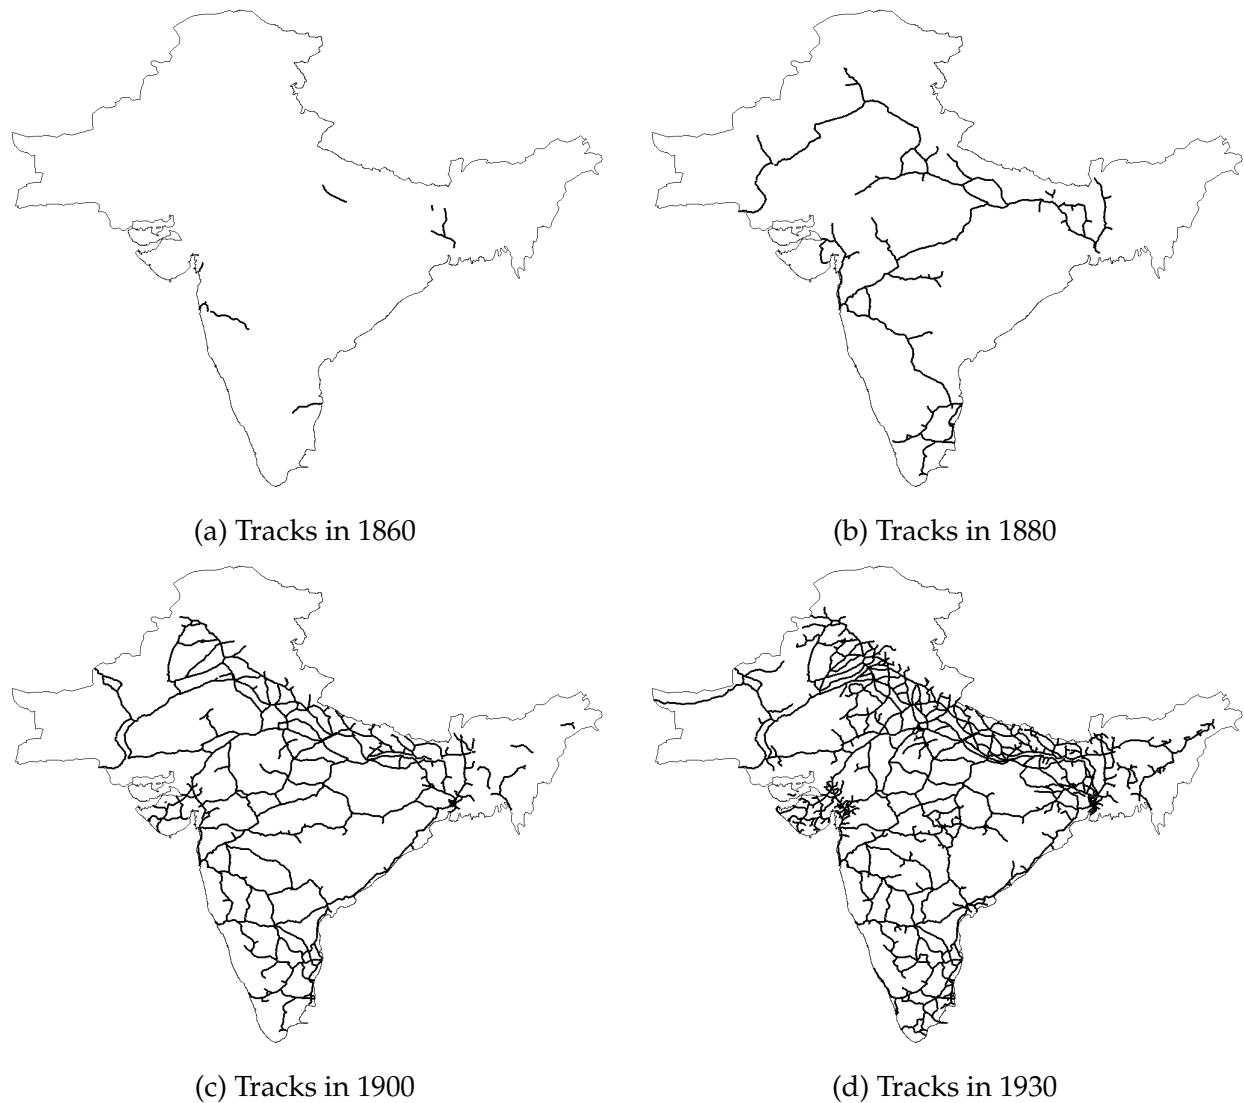

Figure 6.6: Expansion of Indian Railways 1860-1930. Courtesy Dave Donaldson.

The original plan was to build five “trunk lines” to connect India’s major provincial capitals – Delhi, Bombay, Madras, Calcutta and Lahore – so as to maximize the “political advantages” of a railroad network. These lines were built by 1869. The expansion of the train network is presented in Figure 6.6. We see that the network eventually spanned out to all corners of the country, reflecting the strategic considerations underlying its construction. Another aspect of the network was that it is dense in the Northern plains and relatively sparse in central India and in the north (in Kashmir). Over this period, 1850-1930, the train network was the dominant form of public investment in colonial India. The total mileage of the Indian railways has remained relatively unchanged through the twentieth century. The Indian Railways is one of the largest employers in the world and the major carrier for freight and passenger traffic in twenty first century India. ■

### RAILROADS IN AMERICA

We next take up the development of the American Railroads. The construction of train networks in America started in the 1820’s and by 1900, 215,000 miles of tracks had been laid. The presentation here draws on Britannica [2000] and Donaldson and Hornbeck [2016].

In the 1820’s a number of cities on the East Coast such as New York, Boston, Baltimore and Charleston began exploring railroad routes to access raw materials and agricultural produce from the inland and to lower transport costs to ship their manufactured goods to the inland markets. The first phase of American railroad development, from 1828 until about 1850, involved connecting pairs of large cities that were close neighbours: New York City and New Haven, Connecticut; Richmond, Virginia, and Washington, D.C.; and Syracuse, New York, and Rochester, New York.

The growth of the railroads stepped up significantly with an extension into the interior of the continent and from the Atlantic to the Pacific. In 1862, the Pacific Railroad Act chartered the Central Pacific and the Union Pacific Railroad Companies, tasking them with building a transcontinental railroad that would link the United States from east to west. The first transcontinental railroad was completed on May 10, 1869. The effects of this railroad on travel times were dramatic: in the 1850’s, it took four to six months to travel from the Missouri River to California by wagon. In 1870, it took approximately seven days to travel on the transcontinental line from New York to San Francisco. Figures 6.7 and 6.8 present an overview of the expansion of the railroads through the period 1830-1900.

By 1871, approximately 45,000 miles of track had been laid. Beginning in the early 1870s, railroad construction increased dramatically and between 1871 and 1900, another 170,000 miles were added to the railroad system. Much of this growth can be attributed to the transcontinental railroads. By 1900, four additional transcontinental railroads con-

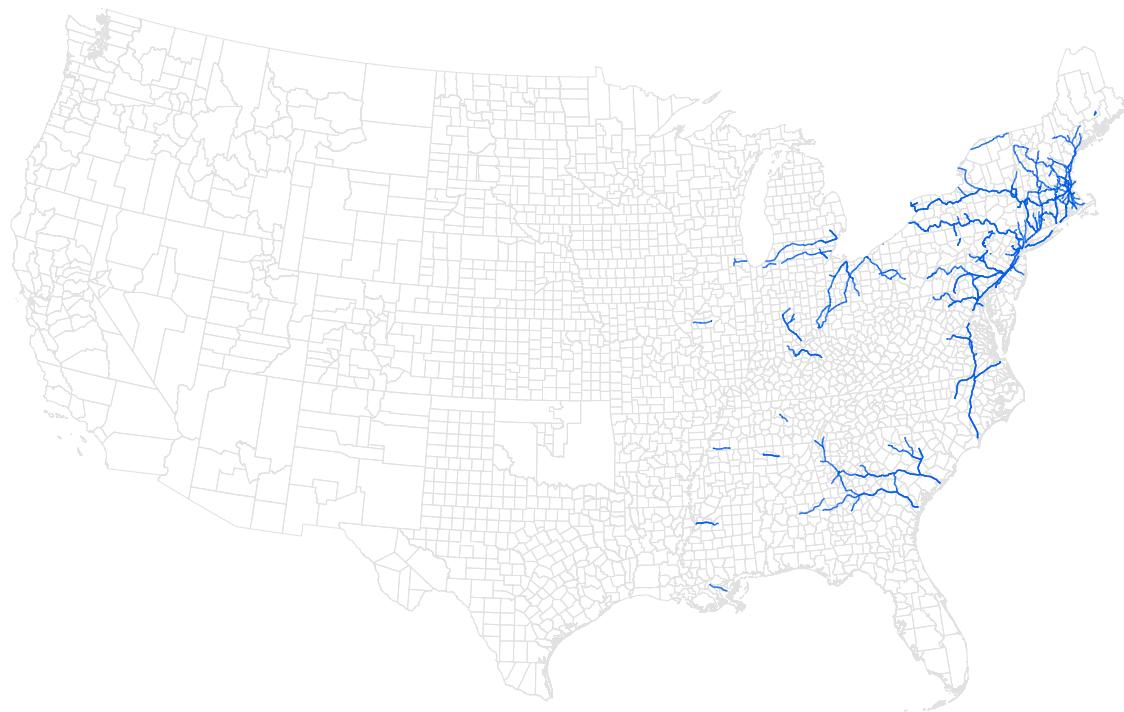

nected the eastern states with the Pacific Coast.

The state and the federal governments supported private companies in the construction of this railroad network. The governments offered millions of acres of public land to railroad companies to lay tracks and to earn revenue by selling the land. At the start of the twentieth century, railroads were the primary carrier for both passengers and freight. Over the twentieth century, passenger traffic has declined as people have shifted to automobiles and air travel, but the share of American Railroads in freight has remained high. At the start of the twenty first century, the railroads carried over 40% of all freight in America. ■

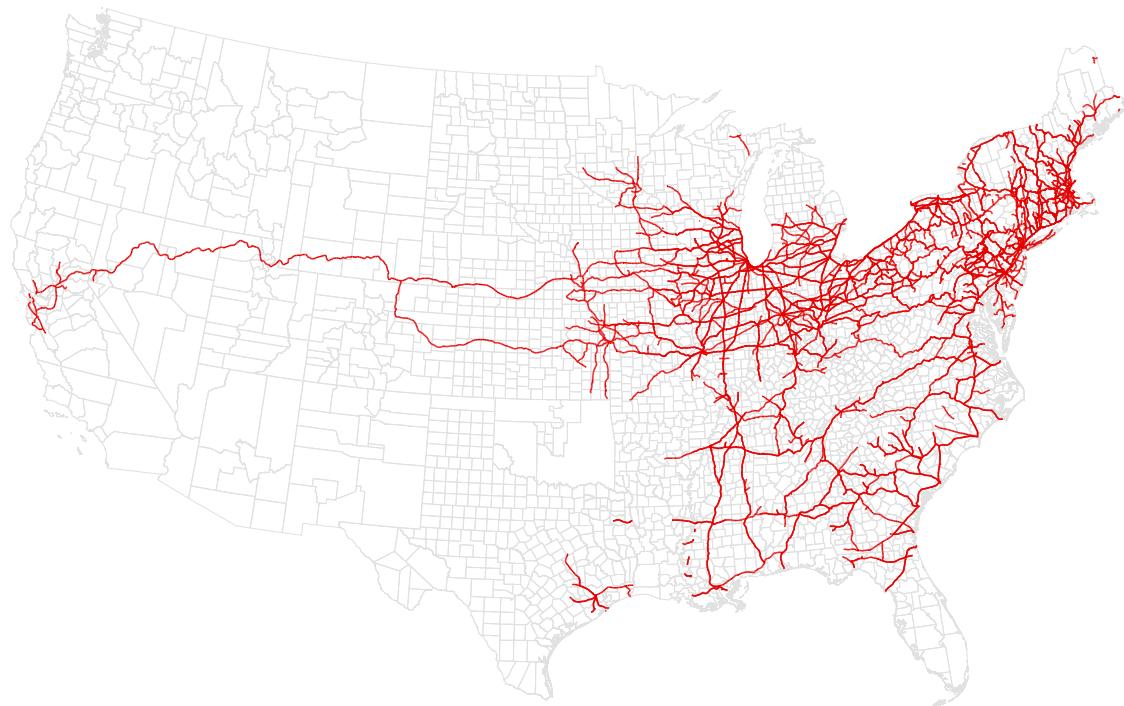

These networks date from different periods in history and are located in different parts of the world. One feature they share is that they were truly monumental in their scale and in the resources that were devoted to their construction. A second point pertains to the objectives of the network builders: in the case of Roman Roads and the Indian Railways, strategic considerations relating to conquest and consolidation of empire were critical. By contrast, the building of the American Railroads was driven by primarily by economic considerations. However, irrespective of their objectives, builders faced great resource constraints: the network that emerged may therefore be seen as a 'preferred choice' in the face of resource (and geographical) constraints. Finally, the case studies draw attention to the topology of the network. All three networks have considerably richer structure as compared to the airline networks that we discussed in the previous section.

We now turn to the relation between transport networks and economic activity. Historians and economists have studied the role of train networks extensively. The following passage gives us an impression of the powerful claims that have been made on the economic impact of trains.

Research ... has further buttressed the idea that the railroad was an imperative of economic growth. Christopher Savage, in his recent *Economic History of Transport*, states that the influence of the railroad in American development "can hardly be over-emphasized" since "agricultural and industrial development and the settlement of the West would scarcely have been possible" without it.' W. W. Rostow has administered an even stronger fillip to this view-point. In the projection of his concept of a "take-off into self-sustained growth," Rostow assigns railroads a crucial role. The railroad, he argues, was "historically the most powerful single initiator of take-offs." It "performed the Smithian function of widening the market," it was a "prerequisite in many cases to the development of a major new and rapidly expanding export sector," and most

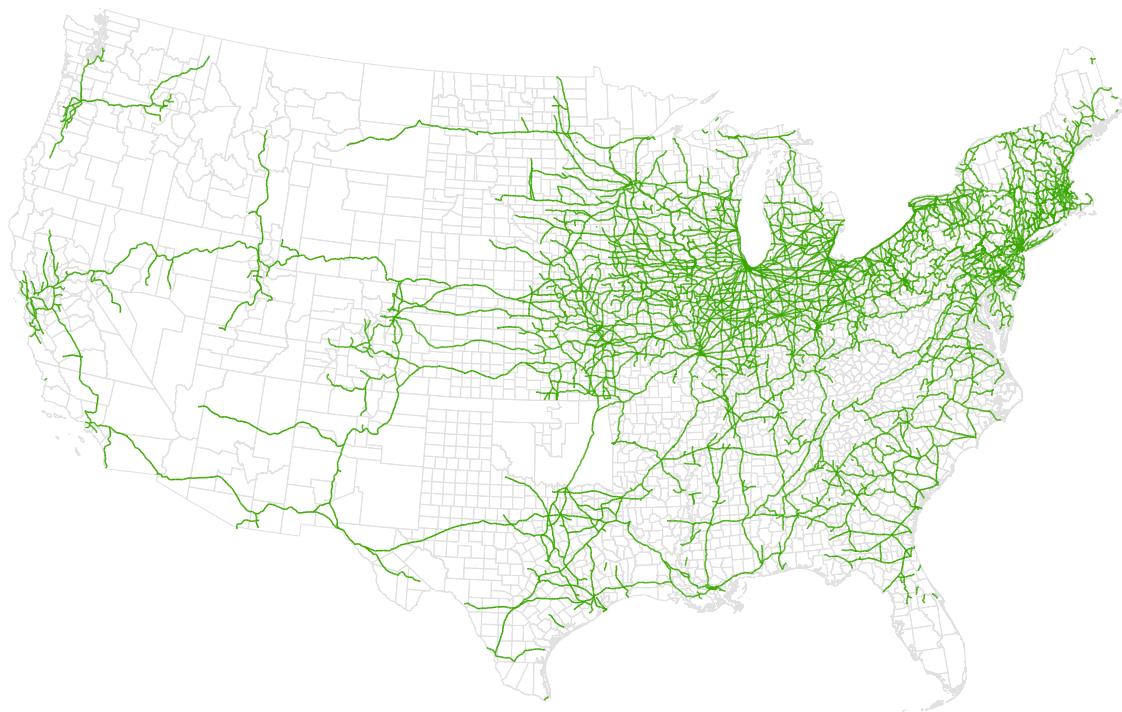

(a) Network in 1850

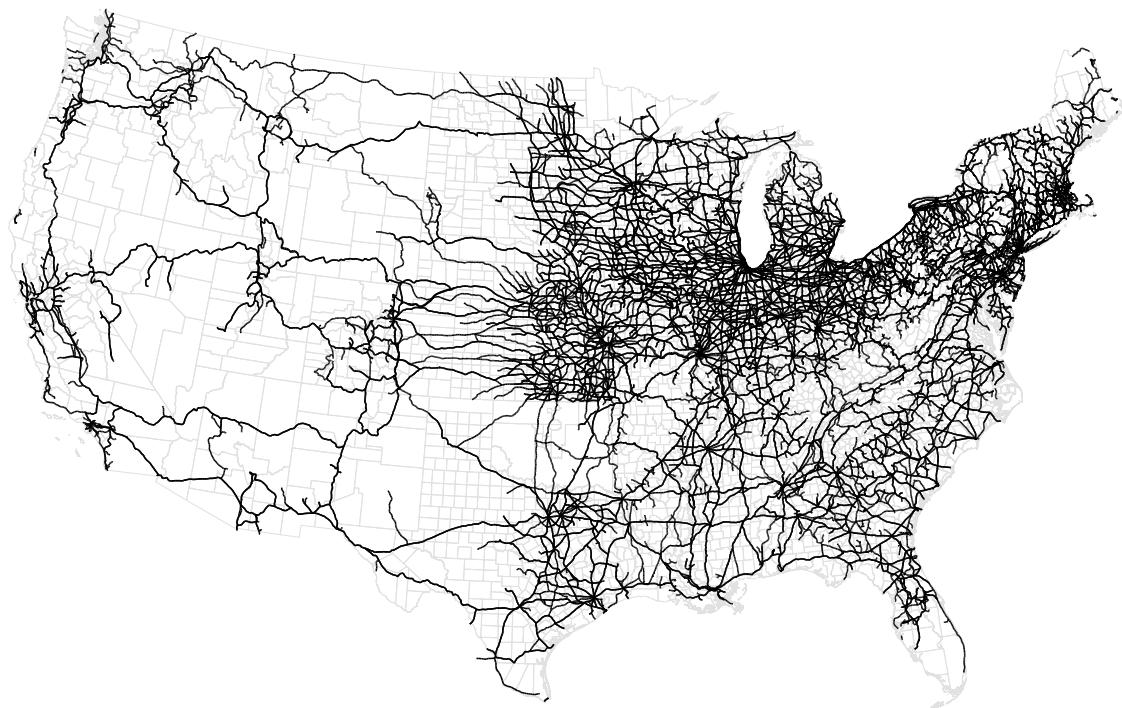

(b) Network in 1870

Figure 6.7: Expansion of U.S Railroads 1830-1870. Source Donaldson and Hornbeck [2016]

(b) Network in 1900

Figure 6.8: Network Expansion 1870-1900. Source Donaldson and Hornbeck [2016]

important, it “led on to the development of modern coal, iron and engineering industries.” Rostow lists the United States first among the countries in which the influence of the railroad was “decisive”. Fogel [1962], Page 163-164.

There are a number of ways in which railroads may be important for economic activity. For example, they enable cheaper and speedier transportation of perishable products, they may benefit manufacturing through increased scale and coordination, and by facilitating movement of people they may also facilitate better flow of ideas and encourage technological growth. For concreteness, we will focus on one channel: we will examine the impact of lower costs of moving goods from one location to another. We present a theoretical framework that allows us to study the implication of this cost reduction. We will use the model to comment on the quantitative impact of the American Railroads and Indian Railways and then we will use the model to discuss the optimal design of transport networks.

## 6.4 Theoretical Framework for Trains and Roads

Following on our discussion in the previous section, we will consider a theoretical model where the primary benefit of a transport link between two locations is that it allows producers in one location to access and sell goods to consumers located in the other location. The costs of a link depend on its quality (a four lane highway costs more than a single lane road) and on the geography (a river or a mountain lying between the locations may necessitate a bridge or a detour that is costly). The costs of transporting a good in turn depend on the quality of the link – a regular train service or a multi-lane highway may help move goods faster and possibly also at a lower cost. In this perspective the principal benefits of a transport system are better access to markets. The aim is to understand how location and geography shapes the network and how the network formation in turn shapes the scale and the spatial distribution of economic activity.

The model is taken from Fajgelbaum and Schaal [2020]. The economy consists of a set of locations  $\mathcal{J} = \{1, \dots, J\}$ . There are  $L_j$  workers at location  $j \in \mathcal{J}$ ;  $L = \sum_j L_j$  is the total number of workers. Workers consume a bundle of traded goods and a non-traded good (land or housing, that is in fixed supply). The utility of an individual worker who consumes  $c$  units of the traded goods bundle and  $h$  units of the non-traded good is  $U(c, h)$ . The utility function  $U$  is homothetic and concave in both of its arguments.  $C_j$  is the aggregate demand of the traded goods bundle at location  $j$ , and the per capita consumption of traded goods is  $c_j = C_j / L_j$ .

There are  $n = 1, \dots, N$  traded goods/sectors. These goods are ‘combined’ to obtain  $C_j$ :

$$C_j = D_j(D_j^1, \dots, D_j^N) \quad (6.11)$$

where  $D_j^n$  is consumption of good  $n$  in location  $j$ . The aggregator function  $D_j(\cdot)$  is assumed to be concave and homogenous of degree 1. In addition, in the examples below, we will assume a constant elasticity to substitution function.

Suppose for simplicity that production uses only labour and that output is linear in labour input. In the basic model, we will assume that labour is immobile across locations but mobile across production sectors of a location. Thus production of good  $n$  at location  $j$  is given by

$$Y_j^n = L_j^n. \quad (6.12)$$

where  $L_j^n$  is the number of workers assigned to sector  $n$  at location  $j$ . In some of the examples below we will allow for differences in productivity across locations.

The locations  $J$  are arranged on an undirected graph  $g = (J, \mathcal{E})$ , where  $\mathcal{E}$  denotes the set of edges (i.e., unordered pairs of  $J$ ). For each location  $j$ , there is a set  $N_j(g)$  of connected locations or neighbors. Goods can only be shipped through connected locations; that is, goods shipped from  $j$  can be sent to any  $k \in N_j(g)$ , but to reach any  $k \notin N_j(g)$ , they must transit through a sequence of linked locations. The transport network is given by  $\{I_{jk}\}_{j \in J, k \in N_j(g)}$ .

A natural interpretation is that  $j$  is a geographic unit such as a county,  $N_j(g)$  are its bordering counties, and shipments are done by land. More generally, the neighbors in the model do not need to be geographically contiguous, since it could be possible to ship directly between geographically distant locations by land, air, or sea. The fully connected case in which every location may ship directly to every other location,  $N_j(g) = J$  for all  $j$ , is one special case.

Goods may transit through several locations before reaching a point where they are consumed. Let  $Q_{jk}^n$  be the quantity of goods in sector  $n$  shipped from  $j$  to  $k \in N_j(g)$  (regardless of where the good was originally produced). There are a number of different ways in which transport costs can be modeled. For simplicity we will assume ‘iceberg’ costs – there is no congestion in transportation across goods but there is congestion for individual goods.

Transporting a unit of good  $n$  from location  $j$  to location  $k$  requires  $\tau_{jk}^n$  units of the good itself. So  $1 + \tau_{jk}^n$  corresponds to the iceberg cost. This per-unit cost is specified as a function of the total quantity  $Q_{jk}^n$  of good  $n$  shipped on the link  $jk$  and of the quality of infrastructure

$I_{jk}$  on that link:

$$\tau_{jk}^n = \tau_{jk}(Q_{jk}^n, I_{jk}) \quad (6.13)$$

Congestion is an important feature of this model: per unit cost of transporting is increasing in the quantity shipped:

$$\frac{\partial \tau_{jk}(Q, I)}{\partial Q} \geq 0 \quad (6.14)$$

In short, the more that is shipped, the higher the per-unit shipping cost. This captures higher travel times or road damage, decreasing returns to scale in transportation due to land-intensive fixed factors such as warehousing or specialized inputs.

A second assumption of the model is that better infrastructure lowers the transport costs.

$$\frac{\partial \tau_{jk}(Q, I)}{\partial I} \leq 0 \quad (6.15)$$

The transport technology  $\tau_{jk}(Q, I)$  may also depend on  $jk$ , capturing variation in shipping costs across links for the same quantity shipped and for the same infrastructure. This variation may reflect geographical considerations such as distance or physical landscape. In principle, the per-unit cost function  $\tau_{jk}(Q, I)$  may depend on the direction of the flow; for example, if elevation is higher in  $j$  than  $k$  and it is cheaper to drive downhill, then  $\tau_{jk}(Q, I) < \tau_{kj}(Q, I)$ .

It follows that at every location, the balance of these flows must hold: for every good  $n = 1, \dots, N$ , and for all locations  $j = 1, \dots, J$

$$D_j^n + \sum_{k \in N_j(g)} (1 + \tau_{jk}^n) Q_{jk}^n \leq Y_j^n + \sum_{i \in N_j(g)} Q_{ij}^n. \quad (6.16)$$

The left-hand side describes location  $j$ 's consumption  $D_j^n$  of good  $n$ , exports to neighbours  $Q_{jk}^n$ , and inputs to the transport sector  $\tau_{jk}^n Q_{jk}^n$ . These flows must be less than the local production  $Y_j^n$  and imports from neighbors  $Q_{ij}^n$  of good  $n$ .

We let  $P_j^n$  be the price of good  $n$  at location  $j$ . This price reflects society's valuation of a marginal unit of good  $n$  in location  $j$ .

#### 6.4.1 The economic returns to train networks

We use the theoretical framework proposed above to make some observations on the economic returns to transport networks. We first take up the American Railroads. In a famous

early contribution, Fogel [1964] proposed to measure the benefits in terms of cost savings generated by the railroads. Viewed in terms of our theoretical framework, this may be seen as calculating the impact of railroads on the total transport costs,  $Q_{jk}^n \tau_{jk}^n$ , across all goods and all locations.

As transport of agricultural produce from the American Midwest was a central motivation for the building of the railroads, Fogel [1964] focused on cost savings in that sector in the year 1890. This cost saving may be computed as the sum of savings on inter-regional trade and the savings on intra-regional trade. Inter-regional trade covered trade from 9 primary markets in the American Midwest to 90 secondary markets in the East and South of the country: here shipping costs were only moderately cheaper with railroads as compared to natural waterways and canals. The total savings in costs was the difference in shipping costs (with and without railroads) times the quantity of transported agricultural goods. Fogel [1964] showed that this number was no more than USD 73 million (or 0.6% of GNP).

Intra-regional trade covers the shipments from farms to primary markets. In the absence of railroads, farms would have incurred substantially higher costs in transporting goods by wagon to the nearest waterway before it could be shipped to the closest primary market. In farms more than 40 miles from a waterway, wagon transportation may have become prohibitively expensive. Fogel [1964] deemed all land farther than 40 miles from a navigable waterway as lying in the “infeasible region”: he bounded the loss in these areas by the value of agricultural land in these areas and arrived at a figure of USD 154 million lost in annual rent. He then estimated the savings in transportation costs for the feasible region (lying within 40 miles of a waterway): he bounded these by USD 94 million using a similar approach to the inter-regional analysis. Thus the total annual intraregional cost saving was bounded above by USD 248 million (or 2.1% of GNP).

The total social saving estimate of USD 321 million – 2.7% of GNP – is generally regarded as indicating a limited impact of the railroads on the American economy.

Fogel [1964]’s approach has been followed by a large body of research that studies the value of large infrastructure projects. A natural next step to the cost savings idea is to examine the effects on railroads network on production and income and consumption at different locations. This helps us develop a more aggregate economic picture of railroads.

Donaldson and Hornbeck [2016] present a measurement of this aggregate impact. Consider the county as the geographical unit. The railroads lowered the costs of transport between counties and thereby facilitated the integration of county markets. A county’s market access increases when it becomes cheaper to trade with another county, particularly when the other county has a larger population and higher trade costs with other

counties. So we can see that changes in market access can act a summary statistic for all direct and indirect impacts on each county from changes in the national railroad network. In an agricultural economy, greater prices and higher output response will result in higher farm incomes. These higher incomes will be reflected in higher land values. Donaldson and Hornbeck [2016] estimate that removing all railroads in 1890 would have lowered the total value of agricultural land in the United States by 60.2%. This reduction in agricultural land value generates annual economic losses equal to 3.22% of the GNP. The estimates of Donaldson and Hornbeck [2016] are thus slightly larger than the social saving estimates derived by Fogel [1964].

It is instructive to examine the effects of the Indian Railways from a market integration perspective. To begin to appreciate the scale of change brought about by trains, note that prior to the trains, bullocks were the principal model of transport for commodities. They travelled no more than 30 km per day along India's sparse network of dirt road. By contrast, railroads could transport commodities at over 600 km in a day, and at much lower per unit distance freight rates. As in the American case, let us examine the economic implications of the train network in terms of lower costs of transport. Lower transport costs will in principle allow a producer in one location to earn a higher price from selling his produce at other locations and also possibly to sell to new – more distant and erstwhile inaccessible – markets. Both these effects should raise their incomes. As India was a predominantly agricultural country at that time, let us consider changes in agricultural income. Using a theoretical framework as in the previous section, Donaldson [2018] shows that the train network did indeed have large effects. First, he shows that in line with the theoretical prediction, as transport costs declined, price differences across locations fell significantly. Moreover, when a district was connected to the rail network, farm incomes rose by 16 percent. To place this in perspective, it is worth noting that, over the period 1870-1930, Indian agricultural income grew by a mere 35%. Being connected to the railroad therefore made a very big difference to a farmer's income.

As transport links lower costs, the structure of the network and the strength of the links across locations will matter for economic activity. We now examine how these considerations shape the optimal design of transport networks and how that design affects economic activity.

## 6.5 Optimal Spatial Transport Networks

We now turn to the study of optimal transport networks. To formulate the optimal design problem, we introduce the final ingredient of the model: the costs of networks. Build-

ing transport infrastructure requires a resource (such as stones, concrete or asphalt) that is available in fixed supply,  $K$ . The idea is that the resources are sunk but that they must be allocated across the different possible edges of the network. Thus the opportunity cost of building infrastructure between two locations is simply the value of foregoing infrastructure elsewhere. Building infrastructure  $I_{jk}$  on the link  $jk$  requires an investment  $\delta_{jk}^I I_{jk}$  units of  $K$ . The network-building constraint is

$$\sum_j \sum_{k \in N_j(g)} \delta_{jk}^I I_{jk} \leq K \quad (6.17)$$

We note that the infrastructure matrix  $\{I_{jk}\}$  defines a weighted directed graph. Thus  $I_{jk}$  and  $I_{kj}$  may be different.

We are now ready to state the optimal network design problem. The planner chooses a network ( $I_{jk}$ ) and production ( $L_j^n$ ) and consumption ( $c_j, D_j^n, h_j$ ) at each location and flows across locations ( $Q_{jk}$ ) to maximize sum of utilities across locations. The planner's optimization problem consists of three sub-problems: (i) allocating consumption and labour use across production sectors (ii) optimal flows across locations, (iii) the allocation of resources to construct transport links across locations. Let us define  $\omega_j$  as the weight that the planner assigns to the utilities in location  $j$ .

The optimization problem can be written as consisting of three nested problems:

$$W = \max_{I_{jk}} \max_{Q_{jk}^n} \max_{c_j, h_j, D_j^n, L_j^n} \sum_j \omega_j L_j U(c_j, h_j) \quad (6.18)$$

subject to

(i) availability of traded commodities

$$c_j L_j \leq D_j(D_j^1, \dots, D_j^N), \forall j; \quad (6.19)$$

and availability of non-traded commodities

$$h_j L_j \leq H_j, \forall j; \quad (6.20)$$

(ii) the balanced flow constraint

$$D_j^n + \sum_{k \in N_j(g)} (1 + \tau_{jk}(Q_{jk}^n, I_{jk})) Q_{jk}^n \leq Y_j^n + \sum_{i \in N_j(g)} Q_{jk}^n, \forall j, n. \quad (6.21)$$

where  $Y_j^n$  is the production of good  $n$  in location  $j$ .

(iii) the network building constraint

$$\sum_j \sum_{k \in N_j(g)} \delta_{jk}^I I_{jk} \leq K. \quad (6.22)$$

(iv) local labour-market clearing

$$\sum_n L_j^n \leq L_j, \forall j; \quad (6.23)$$

(v) non-negativity constraints on consumption, flows, and factor use:

$$lcrC_j^n, c_j, h_j \geq 0, \quad \forall j \in N_j(g), \quad (6.24)$$

$$Q_{jk}^n \geq 0, \quad \forall j, k \in N_j(g), n, \quad (6.25)$$

$$L_j^n \geq 0, \quad \forall j, n. \quad (6.26)$$

The key to understanding the economics of the problem is to recall that given a transport network,  $(I_{jk})_{jk}$ , we are in a production and consumption economy that meets all the usual technical assumptions (for an exposition of the standard general equilibrium model with production see Mas-Colell, Whinston, and Green [1995]). So there exist equilibrium prices such that all consumers are maximizing utility and that input and local product markets clear. These prices reflect the marginal utility of consumption in different locations. A variation in prices of a good across two location defines the potential benefits of flows across locations. These benefits in turn give us a measure of the advantages of investing in transport links and will be central to working out the optimal transport networks.

With these observations in mind, let us turn to some properties of the optimal flow and allocation. At an optimum it must be the case that the price differential for a good between two locations must be smaller than the costs of transporting the good between the two locations (and this must also account for the increase in marginal cost of transporting).

$$\frac{P_k^n}{P_j^n} \leq 1 + \tau_{jk}^n + \frac{\partial \tau_{jk}^n}{\partial Q_{jk}^n} Q_{jk}^n, \quad (6.27)$$

Also note that this expression must hold with equality if  $Q_{jk}^n > 0$ .

Observe that in the absence of congestion,  $\partial \tau_{jk}^n / \partial Q_{jk}^n = 0$ , this price differential would be bounded by the trade cost. This no-arbitrage condition helps us understand the nature of flow between locations. Suppose the transport cost  $Q_{jk}^n \tau_{jk}^n$  is convex in the quantity shipped. Then the expression can be inverted and we can conclude that gross trade flow,

$Q_{jk}^n$ , is increasing in the price differential.

Turning to the optimal transport network, let  $P_K$  be the multiplier of the network-building constraint. This reflects the shadow price of the infrastructure network. For any positive quality link,  $I_{jk}$ , at the optimum network, the marginal cost of link must be greater than or equal to the marginal returns from the link:

$$P_K \delta_{jk}^I \geq \sum_n P_j^n Q_{jk}^n \left( -\frac{\partial \tau_{jk}^n}{\partial I_{jk}} \right) \quad (6.28)$$

The left-hand side is the opportunity cost of building an extra unit of infrastructure along  $jk$  – the multiplier  $P_K$  of the network-building constraint times the rate  $\delta_{jk}^I$  at which that resource translates to infrastructure. The right-hand side is the reduction in per-unit shipping costs,  $-\partial \tau_{jk} / \partial I_{jk}$ , applied to the value of the goods used as inputs in the transport technology.

With these general considerations in mind, we now study examples to understand the role of transport networks in shaping economic activity. The first set of examples will have only one traded good and one non-traded good and locations are organized in a  $w \times h$  symmetric grid. Preferences are constant relative risk aversion (CRRA) over a Cobb-Douglas bundle of traded and non-traded goods:

$$U = \frac{(c^\alpha h^{1-\alpha})^{1-\rho}}{1-\rho} \quad (6.29)$$

with  $\alpha = 0.5$  and  $\rho = 2$ . The total transport costs for the single good being transported are given by:

$$T(Q, I) = \frac{1}{1+\gamma} \frac{Q^\beta}{I^\gamma} \quad (6.30)$$

where  $\beta \geq 0$  and  $\gamma \geq 0$ .

Observe that the parameters  $\beta$  and  $\gamma$  measures the sensitivity of costs of transport to changes in quantity and to transport investment. If  $\gamma \leq \beta$  a proportional increase in quantity and transport investment will lead to higher per unit costs of transport, the converse is true when  $\gamma > \beta$ . We shall refer to the former as *decreasing returns case* and the latter as the *increasing returns case*. The paper by Fajgelbaum and Schaal [2020] develops a number of general results on the nature of the optimization problem and how the optimal network varies with parameters  $\gamma$  and  $\beta$ . We will use simple examples to illustrate the economics of optimal transport networks.

### 6.5.1 The Size of Infrastructure Budget

This section shows that as the infrastructure budget grows the network is able to reach more deeply from a source into the hinterland thereby lowering price differentials across space, making consumption more uniform and enhancing social welfare.

Suppose that  $\beta = \gamma = 1$ . Thus quantity and transport quality have proportional effects on costs of transport. There is a single traded good and there are no geographic frictions, i.e., for any pair of locations  $jk$ ,  $\delta_{jk}^\tau = \delta_{kj}^\tau = \delta_{distance}$ .

Figure 6.9 presents the geographic configuration and the productivity parameters. The geography is represented as  $9 \times 9$  grid, in which every location is connected to eight neighbors. Suppose that labour productivity is 1 at the central location (one unit of labour yields 1 unit of output) and 0.10 at all other locations. All other features of locations are perfectly symmetric,  $(L_j, H_j) = (1, 1)$ , for all locations  $j \in \mathcal{J}$ .

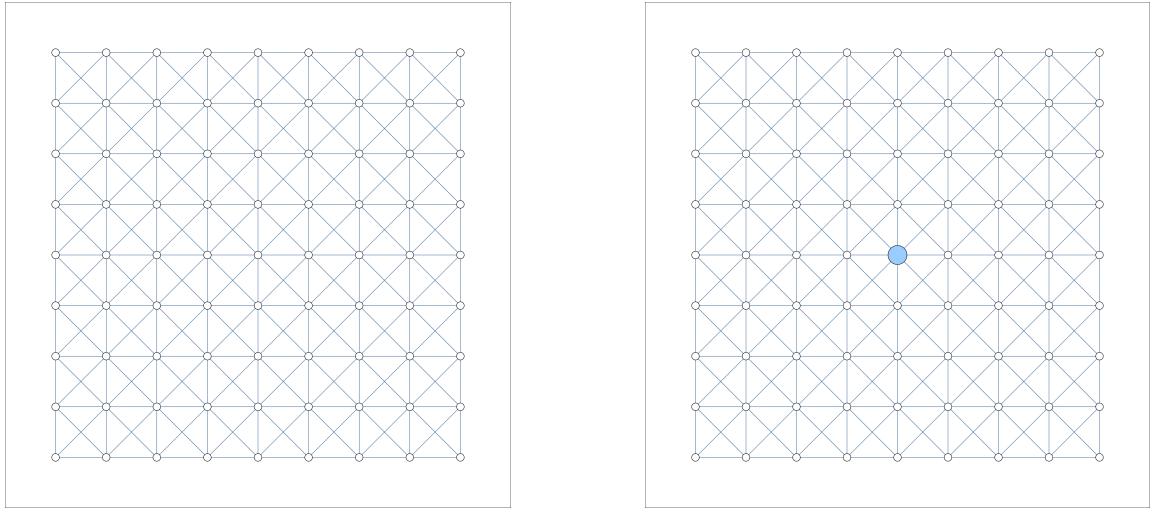

Figure 6.10 presents the optimal network and its economic implications as we raise the infrastructure budget from  $K = 1$  to  $K = 100$ . Panel A (top) corresponds to  $K = 1$  and Panel B (bottom) presents the case for  $K = 100$ . The optimal link investments radiate from the centre and this is reflected in the level of shipments. The quality of the network has large economic effects on prices and on utility. This is reflected in the heat diagrams plotted in the lower half of each of the panels. The tradeable goods are scarcer in the outskirts of the network, as a result the price and the marginal utility is higher. Larger infrastructure budget leads to a strengthening of the transport network: it now grows further afield – as a result the price differentials and the difference in marginal utility shrink across space.

### 6.5.2 Role of the Transport Technology

We now turn to a study of the returns to transport technology – specifically whether  $\beta/\gamma > 1$  or  $\beta/\gamma \leq 1$  – in the design of the optimal transport network. The discussion will develop the following basic intuition: with decreasing returns it is more economical to have multiple routes between a source and destination, whereas with increasing returns it is more economical to have broader single highways connecting a source and destination. Thus in the former case optimal networks are dense and consist of weak transport links while in the latter case they will be trees.

To bring out this point clearly, let us first consider 20 locations randomly situated in a space where each location has eight neighbors. The top left picture in Figure 6.11 presents the layout of the cities. Labour  $L_j = 1$  in each of the twenty cities and is zero elsewhere. Assume that productivity is 1 at the central city and 0.10 at the other nineteen locations.

Figure 6.12 presents the optimal networks and optimal flows. The top panel (a) covers

(a) A grid with 8 neighbours

(b) Productivity Levels

Figure 6.9: Productivity levels

the convex case, when  $\beta = \gamma = 1$ . The top left figure shows that the optimal network radiates outward from the centre to reach all destinations. Due to congestion on routes, some destinations are reached through multiple routes. But to reach some faraway locations such as the one in the northwest, there is only one route. The figure on the top right shows optimal flows of the good away from the principal producing unit.

Panel (b) presents optimal networks and flows with increasing returns to network building,  $\gamma = 2 > \beta = 1$ . We observe a qualitative change in the network: fewer but larger roads are built. As a result, there is only one route linking any two destinations – the network is a tree in which nodes have a similar number of offshoots. To elaborate further on the role of transport technology on shaping location of economic activity we consider a richer setting in which labour is mobile.

To elaborate on the effects of transport technology, we next consider multiple locations for production and to bring out the full impact of transport networks, it extends the baseline spatial economic model to allow for labour to move to more attractive locations. This means that, given a network, a profile of prices defines an equilibrium if in addition to conditions (i)-(iii) and (v), it is also the case that no person wishes to change location and aggregate labour demand equals labour supply. Let us write these conditions formally for completeness.

(vi) no one wishes to move to another location:

$$U(c_j, h_j) \geq u \quad \forall j. \quad (6.31)$$

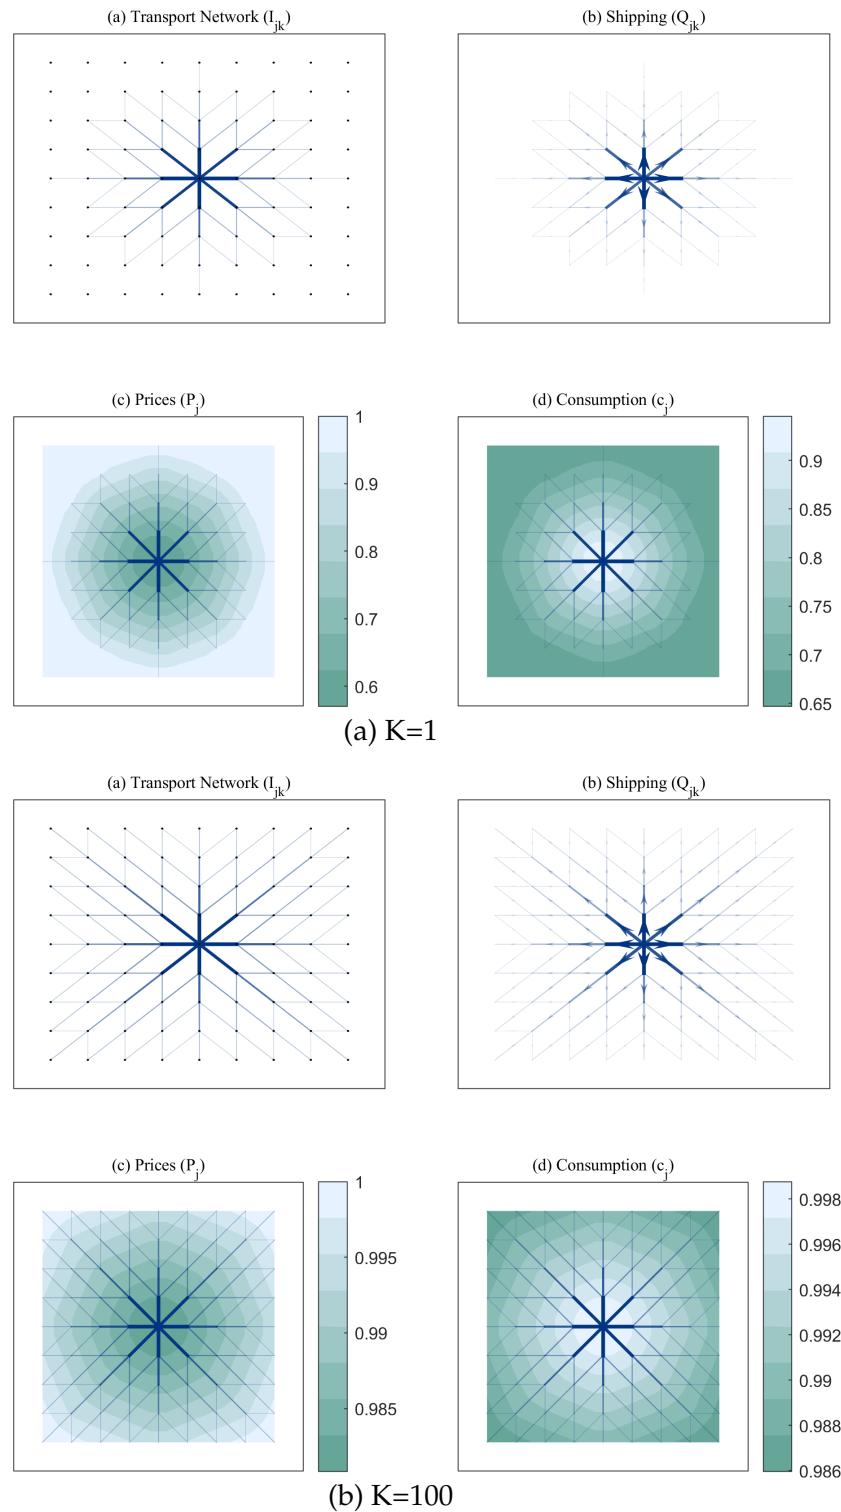

Figure 6.10: Optimal Networks: Effects of Infrastructure Budget

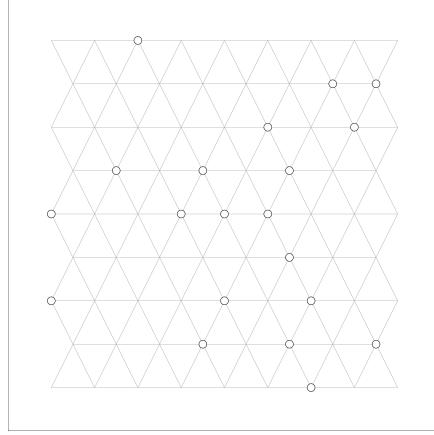

Figure 6.11: Spatial Configuration of Cities

(vii) aggregate labour market clearing condition:

$$\sum_j \sum_n L_j^n = L, \quad (6.32)$$

where  $\sum_j L_j = L$ .

We compute the optimal transport network in a simple example with 5 industrial products and one agricultural good. The industrial goods are each produced at only one city, the agricultural good is produced at all locations outside the cities. The agricultural good is labeled 1, so we have  $z_j^1 = 1$  in all “countryside” locations and  $z_j^1 = 0$ , in all cities. The five goods labelled  $j = 2, 3, 4, 5, 6$ , are each produced in one city, so that  $z_j^n = 1$  in only one city  $j$  each and  $z_j^n = 0$ , otherwise. These goods are combined via a constant elasticity of substitution aggregator with elasticity of substitution  $\sigma = 2$ . Labor continues to be the sole factor of production. As before, labour and non-traded goods are equal at all locations,  $L_j = H_j = 1$ , for all  $j \in \mathcal{J}$ .

Figures 6.13a and 6.13b presents optimal networks in the decreasing and increasing returns case respectively. A comparison reveals that, as in the one good case, in the presence of economies of scale in transportation, the optimal network becomes significantly sparser with fewer but wider “highways.” With  $\gamma = \beta = 0.5$  the optimal network connects every industrial city through multiple routes to other locations. By contrast, under  $\gamma = 4$ , the optimal network links each industrial city through a unique wide highway to all other locations; similarly for the supply of agricultural locations.

Let us summarize what we have learnt in this section. We presented a theoretical model with spatial features in which the costs of transport are the central force shaping economic activity. The theoretical model allowed us to draw out principles for the design of optimal

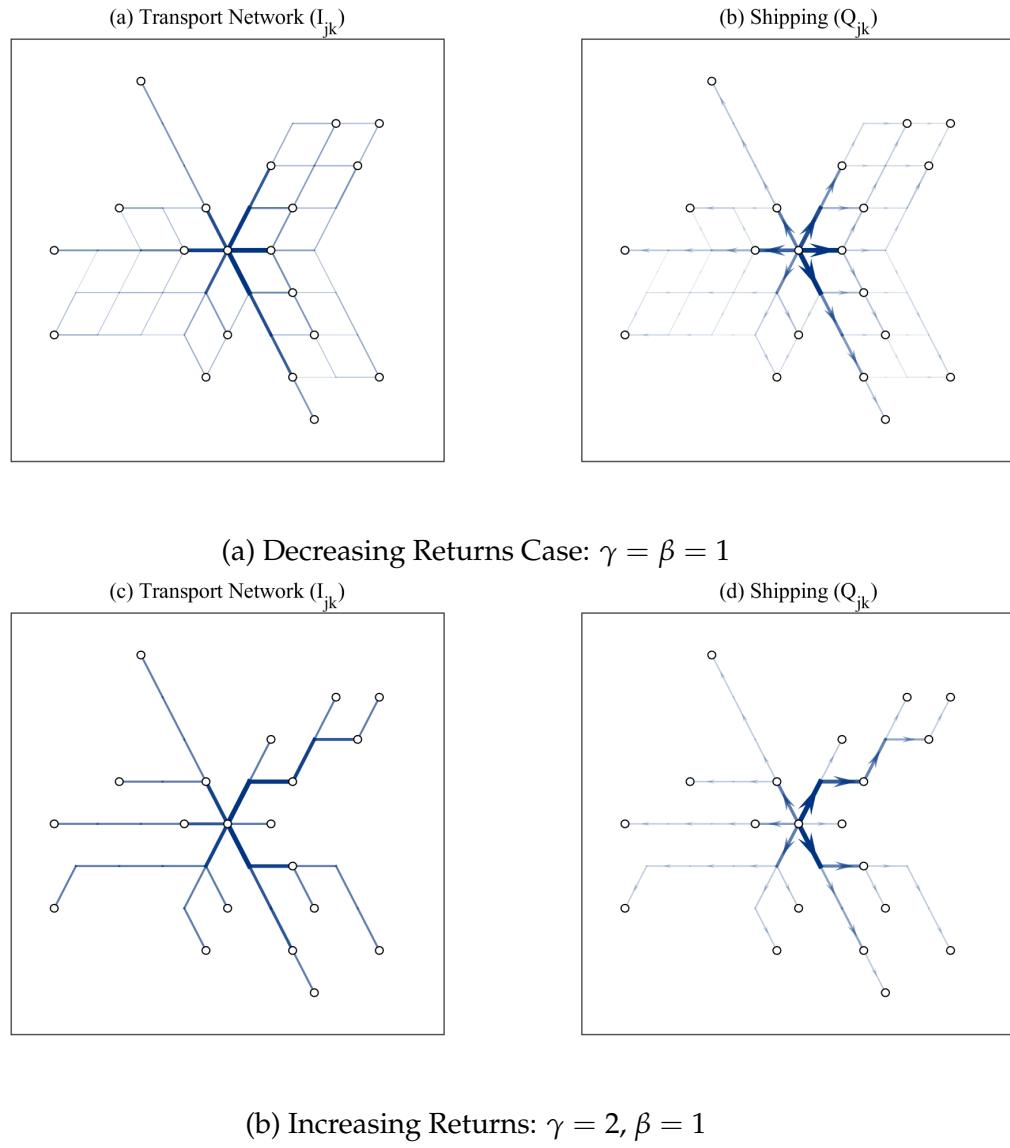

Figure 6.12: Optimal Networks: Effects of Transport Technology

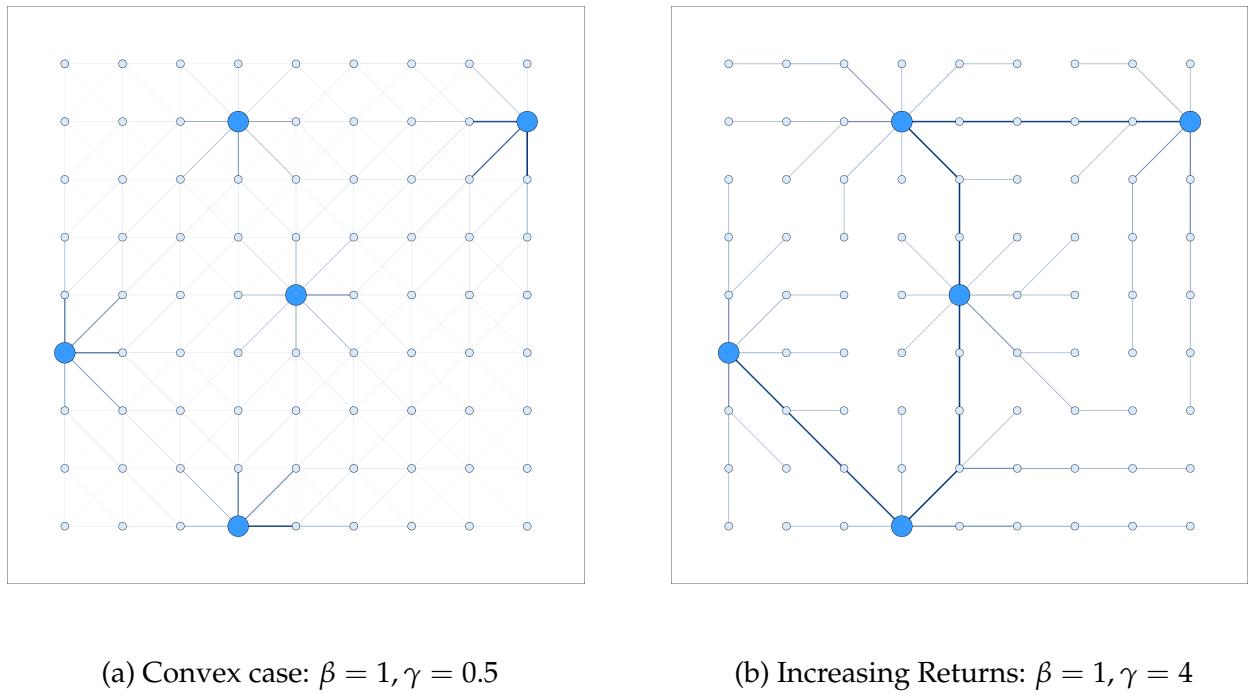

(a) Convex case:  $\beta = 1, \gamma = 0.5$ (b) Increasing Returns:  $\beta = 1, \gamma = 4$ 

Figure 6.13: Optimal Networks: Effects of Transport Technology

spatial transport networks: in particular, on the role of returns to transport technology. When these returns are diminishing, the optimal network has many links but each of the links is weak (an example is a complete network). By contrast, under increasing returns to scale, the network is sparse and each of the transport links is strong (examples include tree graphs and variants of hub-spokes networks). As increasing returns to transport push toward hub-spoke networks they could amplify agglomeration forces and lead to greater concentration of economic activity.

## 6.6 Belt and Road Initiative

China's Belt and Road Initiative (BRI), sometimes referred to as the New Silk Road, was launched in 2013 by President Xi Jinping. It is a vast collection of development and investment initiatives that would stretch from East Asia to Europe and Africa (a more elaborate version also includes projects in Australia and Latin America). The Initiative calls for close cooperation among countries and is expected to improve the region's infrastructure, put in place a secure and efficient network of land, sea and air passages, enhance trade and investment, establish a network of free trade areas, increase financial integration, and enhance cultural exchanges. The BRI has subsequently become an important part of Chinese planning and general policy – it was incorporated into the 13<sup>th</sup> Five Year Plan (2016-2020)

and was included in the Chinese Communist Party Constitution in October 2017. The discussion here draws on a number of sources – OECD [2018], official Chinese government documents, and Maceaes (2018).

The BRI aims to run through the continents of Asia, Europe and Africa, connecting East Asia economies at one end with the developed European economies at the other, and covering a number of countries with huge potential for economic development both in Eurasia and Africa. There are two components to the infrastructure element – the Silk Road Economic Belt that is on land and the 21<sup>st</sup> Century Maritime Silk Road that covers sea ports and sea routes. Figure 6.14 aims to provide an impression of the vast scope of the Belt and Road Initiative. Let us look more closely at some of the principal components of the BRI.

On land, the Silk Road Economic Belt consists of three broad routes – one, from Northwest China and North East China to Europe and Baltic Sea via Central Asia and Russia, two, from Northwest China to the Persian Gulf and the Mediterranean Sea, passing through Central Asia and West Asia, and three, from South West China through Indochina Peninsula to the Indian Ocean. These three routes divide into six economic corridors:

1. New Eurasia Land Bridge: involving train connections from China to Europe via Kazakhstan, Russia, Belarus, and Poland.
2. China-Mongolia-Russia Economic Corridor: this would involve rail links and highways and would also link to the land bridge.
3. China-Central Asia-West Asia Economic Corridor: this will involve Kazakhstan, Kyrgyzstan, Tajikistan, Uzbekistan, Turkmenistan, Iran and Turkey.
4. China-Indochina Peninsula Economic Corridor: this will involve Vietnam, Thailand, Lao People's Democratic Republic, Cambodia, Myanmar, and Malaysia.
5. China-Pakistan Economic Corridor: connecting Kashgar (in Xinjiang) through a highway to the Pakistan port of Gwadar. The road passes through the Karakoram Mountains in the Himalayas. Gwadar is a deep water port that can be used both for commercial and military purposes.
6. China-Bangladesh-India-Myanmar Economic Corridor: investment in infrastructure development and joint exploration and development of mineral, water, and other natural resources.

The economic corridors will involve broad economic integration along different dimensions, but physical integration will be an important feature. This will be facilitated

by a transport network consisting of railways, highways, sea routes and air routes, together with electric power transmission and telecommunication networks, and oil and gas pipelines.

The Maritime Silk Road runs from the Chinese coast to the south via a number of South East Asian cities (Hanoi, Jakarta, Singapore and Kuala Lumpur), through the Strait of Malacca to Sri Lanka. It then carries on through the southern tip of India via Male to East Africa (Mombasa and Djibouti). The route then continues through the Red Sea via the Suez Canal to the Mediterranean Sea (via Haifa, Istanbul and Athens) to Italy (Trieste). The route then continues via sea and overland connections to Central Europe and the North Sea. Figure 6.14 illustrates the broad outlines of the Maritime Silk Road.

BRI's geographical scope is constantly evolving as new countries sign up to joint projects and other countries withdraw from them. By 2018, the BRI covered over 70 countries, accounting for about two thirds of the world's population and around one-third of the world's Gross Domestic Product.

Let us next place the BRI in a broader context. Resilient infrastructure is a part of the 17 Goals of Sustainable Development but it is generally agreed that at the global level there is a large gap in infrastructure. For instance, in 2020, over 840 million people live more than 2 kilometers from all-weather roads, 1 billion people lack electricity, and 4 billion people lack Internet access. For a number of years now, multilateral development institutions such as the World Bank have prioritized infrastructure funding in developing countries. From a Chinese perspective, the Belt and Road Initiative is expected to help by providing better access to markets for its manufactured goods. Closer integration markets across Eurasia will increase demand for its manufactured products and integration with Central Asia and West Asia will raise the reliability of its oil and gas and other natural resource supplies. Closer economic integration between Northwest China and Central and West Asia will help less developed provinces like Xinjiang. At a more general level, closer integration with the resource rich but less developed economies of central Asia will help China transit out of a middle income level by gradually relocating certain industries out of China. The BRI may therefore be seen as an attempt by China to fit its policy goals with a leading global challenge – the shortage of infrastructure.

Let us consider the financing of the BRI. The Initiative calls for very large investments – in excess of USD 1 Trillion for the decade starting in 2017 – and so financing these projects is a major challenge. Large Chinese state financial institutions – Industrial and Commercial Bank of China, Agricultural Bank of China, Bank of China and China Construction Bank – are expected to play an important role. But entirely new institutions such as the Asian Infrastructure Investment Bank (AIIB) have the BRI as a priority too: by mid-2016, the AIIB

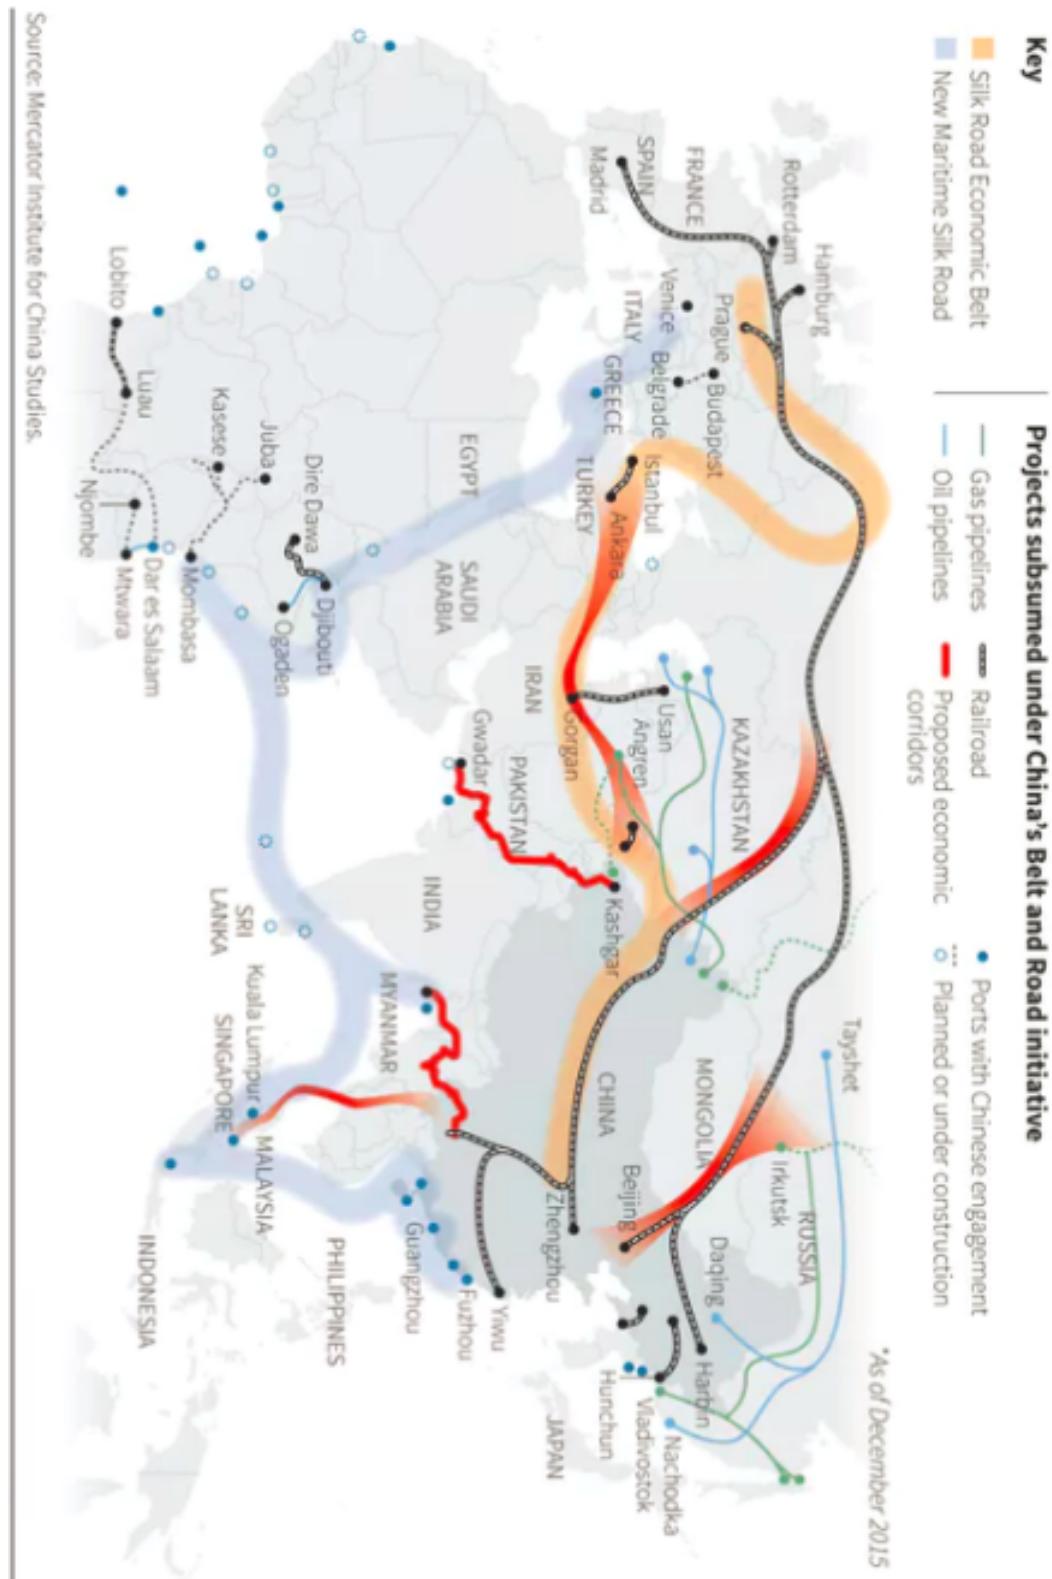

approved funding in excess of USD 500 million for projects in Bangladesh, Indonesia, Pakistan and Tajikistan (these countries lie in the core economic corridor of the BRI). Similarly, the Silk Road Fund was set up to facilitate funding of a variety of projects ranging across hydropower plans in Pakistan, fund acquisition of Italian tyre-maker Pirelli; and to make investments in Russia-based Yamal Liquified Natural Gas project.

Let us briefly note a few key aspects of the network in the BRI: the transport network envisaged by the BRI involves a vast number of nodes (that are located in over 70 countries) and a rich combination of different types of edges – that include roads, train tracks, sea routes, oil pipelines, internet cables and financial links. Figure 6.14 draws attention to the importance of oil and gas pipelines. Turning to the topology of the network, the BRI hopes to make Xinjiang the hub for the Silk Road Economic Belt and Fujian as the hub for the 21st Century Maritime Silk Road. There is thus an important sense in which this extraordinarily large and complex network seeks to exploit the network advantages of the hub-spoke structure.

The BRI envisages close integration of transport infrastructure across Eurasia and Africa with hubs based in China, proposes the financing of this infrastructure through a number of financial institutions based in China, and advances the idea of greater domestic and trade policy coordination across countries. These features have led researchers and commentators to speculate on the longer term implications of BRI.

To place the BRI in a broader perspective, recall that this chapter has covered a range of different transport networks. The discussion drew attention to the scale of train and road networks, on the goals of the network builder and how they interact with resource constraints and physical geography to shape the network. We have also presented a theoretical framework that allows us to explore the economic effects of transport networks and the determinants of optimal networks design. Keeping these ideas in mind, we conclude this chapter with a general comment on the Belt and Road Initiative.

The Belt and Road Initiative is the name for a global order infused with Chinese political principles and placing China at its heart. In economic terms this means that China will be organizing and leading an increasing share of global supply chains, reserving for itself the most valuable segments of production and creating strong links of collaboration and infrastructure with other countries, whose main role in the system will be to occupy lower value segments. Politically, Beijing hopes to put in place the same kind of feedback mechanism that the West has benefitted from: deeper links of investment, infrastructure, and trade can be used as leverage to shape relations with other countries even more in its favor. The process feeds on itself. Maceaes [2018] (2018, page 30).

## 6.7 Reading Notes

Transport networks come in different forms. The aim of the chapter was to bring out the close relation between these networks and economic activity. This chapter discusses roads, trains, and airlines, and briefly comments on a shipping network.

As air travel has grown, economic issues in the airline industry have attracted increasing attention. For an overview of developments in airlines, see Petzinger [1996] and Borenstein [1992]. A striking and widely commented feature of airlines is the hub-spoke network structure. Hendricks, Piccione, and Tan [1995] developed a model in which the basic trade-offs between dense and sparse networks could be studied. This chapter draws on their work to develop an analysis of the optimality of different networks. The discussion focuses on the case of a single airline. Similar arguments can be used to show that competing airlines will create hub-spoke networks, for a formal model of competing airline networks see Hendricks, Piccione, and Tan [1999]. For an exploration of the role of hub-spoke networks as an entry deterrence device see Hendricks, Piccione, and Tan [1997].

The study of spatial transport networks has a long and distinguished history. Perhaps the best known work is the study of the effects of American railroads on economic growth by Robert Fogel. Fogel [1964] studied the impact of railroads through a method of counterfactuals – how would the American economy have fared in the absence of any railroads? He examined the cost savings brought about railroads relative to alternative existing modes of transport such as rivers and canals. Fogel argued that small differences in freight rates caused some areas to thrive relative to others, but railroads had only a small aggregate impact on the U.S. agricultural sector. This ‘social saving’ methodology has been widely applied to transportation improvements; for an alternative approach that suggests rather larger effects, see Fishlow [1965]. For a comprehensive reevaluation of this hypothesis and a summary of the state of the literature, see Donaldson and Hornbeck [2016]. For a general overview of economic issues relating to economic effects of market integration, see Donaldson [2015]. Special thanks are due to Dave Donaldson for kindly sharing materials on the Indian train network.

In order to appreciate the general ideas underlying the benefits of transport networks and the possible trade-offs in building different types of networks, the chapter then presents a theoretical model of optimal spatial transport networks. This model builds on the large literature in international trade and economic geography and bridges it with the research on optimal flows in networks. For an overview of the trade and geography literature, see Eaton and Kortum [2002], Redding and Rossi-Hansberg [2017]. For an introduction to optimization methods in transport networks, see Galichon [2016]. The model presented is

taken from Fajgelbaum and Schaal [2020]. The exposition here also draws heavily on their paper. Special thanks are due to Edouard Schaal for extensive discussion of a number of issues arising from their paper and for kindly sharing supplementary material relating to their work.

The Belt and Road Initiative (BRI) is one of the most ambitious infrastructure projects ever undertaken. There is a very large popular literature on different aspects of the BRI. However, it is also a very controversial initiative due to its vast economic scope and the large political and strategic elements in it. The discussion here draws on a number of official documents and on a general introduction to the initiative by Maceaes [2018]. Other documents include an OECD study of the BRI OECD [2018] and official Chinese Government Reports taken from <http://english.www.gov.cn/beltAndRoad/>.

## 6.8 Questions

1. There are  $n$  cities,  $n \geq 3$ . Suppose that demand for any city pair travel is only a function of the price of the ticket and is given by

$$D(p) = kp^{-\alpha}, \quad \alpha \geq 1, \quad k \geq 0$$

Marginal costs of flying are constant and given by  $c$ . Compute optimal prices for direct and indirect (two-step) flights. Then compute the profits for the monopoly airline in the complete and the hub-spoke networks. Finally, compute the threshold value of costs of links  $f^*$  such that the optimal network is complete below  $f^*$  and hub-spoke above  $f^*$ .

2. Consider a setting with one airline operating a network to serve  $n$  cities. Suppose that there are two types of cities, large and small. The demand for air travel is high ( $H$ ) between every pair of large cities and low ( $L$ ) between every other pair of cities. There is a cost  $F$  per link between any pair of cities. Direct flights between cities yields profit equal to the size of the demand between the pair of cities, while an indirect (two-step) flight yields profit equal to one half of the demand. Thus a direct flight between two large cities yields profit  $H$ , while an indirect flight yields profit  $H/2$ . Similarly, a direct flight between a pair of cities (in which at least one is not large) yields profit  $L$ , while an indirect flight yields gross profit  $L/2$ . Reason carefully and describe the nature of the optimal routing network as a function of the parameters  $F$ ,  $L$  and  $H$ .

3. This question takes up competition among airlines and is based on Hendricks, Piccione, and Tan [1999]. There are two airlines  $i = A, B$  and  $N = \{1, 2, \dots, n\}$ ,  $n \geq 3$  cities. Let  $i, j$  index cities. Airlines choose routing networks,  $X^A$  and  $X^B$ . The size of an airline's routing network is  $m^i = \sum_{g,h} X^i(g,h)/2$ . Let there be a fixed cost per city-pair link  $f > 0$  (as in model in section 6.2.2). Let  $\pi(z^i z^j)$  denote the revenue in a city pair for airline  $i$  with path length  $z_i$ , faced with a path length  $z^j$ . Denote by  $\pi_M(z) = \pi(z^i, \infty)$  the monopoly revenue from path length  $z^i$ . Let us assume that  $\pi(z, y) \geq \pi(z+1, y)$ . Given  $X^i$  define path length  $r : N \times N \rightarrow \{1, 2, \dots, n\}$ . Define set of city pairs of length  $r$ :  $\Gamma(z) = \{(g, h) | r(g, h) = z\}$ . We write payoff to an airline as:

$$\Pi(X^i, X^j) = \sum_{z=1}^{\infty} \sum_{\gamma^i(z)} \pi(z, r^j(g, h)) - fm^i \quad (6.33)$$

Assume (i)  $f(\frac{n(n-1)}{2}) > n(n-1)\pi_M(1)$  (ii)  $(n-1)2\pi_M(1) + (n-1)(n-2)\pi_M(2) > f(n-1)$ : part (i) says that point-to-point network is not profitable even for a monopolist, part (ii) says that hub-spoke network is profitable for a monopolist. Assume (iii)  $\pi(z, y) + \pi(y, z) \leq \pi_M(\min y, z)$  (iv)  $\pi(z, y) \leq \pi_M(z)$ ; part (iii) says profits of duopoly cannot exceed profits of monopoly on the shorter route. Part (iv) says duopoly profit is smaller than monopoly profit. Finally, assume that (v)  $\Pi_M(z) > 0$  is strictly declining in  $z$ , i.e., a longer path lowers profits.

- (a) Define aggressive competition:  $\pi(z, y) = 0$ , if  $z \geq y$ . Show that under (i)-(v) and aggressive competition the following is true. A. two hub-spokes cannot arise in Nash equilibrium and B. one airline operating a hub-spoke and the other firm staying out of market is a Nash equilibrium.
- (b) Next consider moderate competition: let  $(n-2)(n-3)\pi(2, 2) > f(n-1)$ . We will say that  $\pi$  is quasi-submodular if for any pair of positive integers  $(z, y)$ ,

$$\pi(z, y) + \pi(y, z) \geq \pi(z, z) + \pi(y, y). \quad (6.34)$$

The payoff is quasi-supermodular if the converse inequality holds.

- i. Suppose assumptions (i)-(v) hold and competition is moderate. Suppose that  $i$  creates a full hub-spoke network. Show that the best response of  $j$  is either a hub-spoke network of size  $n-1$  or a hub-spoke network of size  $n-2$  (that omits the hub node of  $i$ ).
- ii. Define  $F_1 = 2\pi(1, 1) + 2(n-2)\pi(2, 1)$ . Suppose that  $f < F_1$ . Show that if  $\pi$  is quasi-supermodular then two full competing hub-spokes centred on the

same hub constitute an equilibrium. If  $\pi$  is quasi-submodular then  $X^A, X^B$  with two distinct hub nodes constitutes an equilibrium.

4. This question considers the effects of transport links on market access, trade and welfare and it based on Goyal and Joshi [2006a]. Suppose there are  $n$  cities each with its own market and with a single monopoly firm that can sell in the local city market as well as in other cities. Suppose that, at the start, transport costs across cities are prohibitive. However, any two cities can build a road that lowers these costs and makes trade economical.
5. Let  $N_i(g)$  be the set of cities with whom city  $i$  is connected by road. Let the output of firm  $j$  in city  $i$  be denoted by  $Q_i^j$ . The total output in city  $i$  is then given by  $Q_i = \sum_{j \in N_i(g)} Q_i^j + Q_i^i$ . In each country  $i \in N$ , there is an identical inverse linear demand given by  $P_i = \alpha - Q_i$ ,  $\alpha > 0$ . Assume that all firms have zero fixed costs and a constant and identical marginal cost of production,  $\gamma > 0$ . Assume that  $\alpha > \gamma$ . Let the initial pre-road costs of transport be  $T > \alpha$ . A road lowers these costs to zero.
  - (a) Given a network of roads  $g$ , the number of active firms in city/market  $i$  is  $d_i(g) + 1$  (where  $d_i(g)$  is the degree of city  $i$  in network  $g$ ). Show that if a firm  $i$  is active in market  $j$ , then its output is given by  $Q_j^i = (\alpha - \gamma) / (n_j(g) + 2)$ .
  - (b) Define  $W(g)$  welfare in a city as sum of firm profits and consumers surplus. Show that welfare of a city  $i$  in a network  $g$  is given by:
$$W_i(g) = \frac{1}{2} \left[ \frac{(\alpha - \gamma)(d_i(g) + 1)}{d_i(g) + 2} \right]^2 + \sum_{j \in N_i(g)} \left[ \frac{\alpha - \gamma}{d_j(g) + 2} \right]^2 \quad (6.35)$$
  - (c) Consider the social planner who seeks to maximize sum of the welfare of cities. Show that if the costs of road building are small then the optimal road network is complete: every city pair is connected by a road.
  - (d) Next consider the incentives to build roads. Recall that a network is pairwise stable if every link that is present benefits the two cities involved (at least weakly) and the addition of every link that is missing makes at least one of the two cities strictly worse off. Show that if road costs are small then the complete network is pairwise stable. Is there any other pairwise stable road network?
  - (e) Discuss how the cost of making roads – whether they exhibit increasing or decreasing returns to transportation – will shape the optimal road network and pairwise stable road network.

6. Discuss how the budget for infrastructure and the nature of the transport technology (whether it is increasing or decreasing returns) shapes the scale and location of economic activity.
7. Present economic arguments to explain the similarities and the differences between airline and train networks.

# Chapter 7: Security

## 7.1 Introduction

Our nation's critical infrastructure is crucial to the functioning of the American economy... (It) is increasingly connected and interdependent and protecting it and enhancing its resilience is an economic and national security imperative. US Office of Infrastructure Protection. Department of Homeland Security [2012].

Infrastructure networks include highways, aviation, shipping, pipelines, train systems, and telecommunication. These networks face a variety of threats ranging from natural disasters (such as floods, storms, and earthquakes) to human attacks (such as guerrilla attacks, attacks by an enemy country, or non-violent protests). In this chapter we study questions relating to the protection and design of infrastructure networks.

To set the stage for a study of the threats, we need a measure of the value of a network and how it is impacted by shocks. We present a concept of network value that rests on two ideas: one that the value of a network is equal to the sum of value of its components and two, that the value of a component is increasing and convex in its size. Attacks on the network are therefore harmful because they reduce its connectivity. This formulation of network value is the basis of the different models we study.

We take the view that the goal of the defender/designer is to maximize the value of the network in the worst case. This is a realistic assumption in some settings (such as human attacks) because the adversary is intelligent and wishes to maximize damage. In other settings (such as natural disasters) even when the attacks are random it may be wise to take the worst contingency as a benchmark so as to guard against especially bad outcomes. This leads us to a model in which the designer/defender moves first and then the adversary moves. The designer/defender anticipates the optimal attack of the adversary and chooses a strategy (of defence or design) that maximizes the network value given this optimal attack.

Section 7.3 takes up the study of the design and defence of infrastructure networks that face threats that damage or destroy particular nodes (and links). A network can be made robust to such threats through additional investments in equipment and in personnel. As networks are pervasive, the investments needed can be very large; so it is important to target resources at specific parts of the network. What are the ‘key’ parts of the network that should be protected to ensure maximal functionality? Taking a longer term view, we then study how networks should be designed to resist attacks?

The first question we take up pertains to the defence of a given network. As the network value function is increasing and convex in the size of the components, the adversary will find it attractive to target nodes that fragment the network; these are referred to as *separators*. Anticipating this, the designer/defender will choose to block these separators, i.e., choose the most effective *transversals* of the sets of separators.

We then study the question of how to design and protect a network that faces threats. The network’s connectivity can be maintained through adding links and via protecting nodes. When the adversary’s resources are limited, we show that this gives rise to a trade-off between creating a dense network (that uses extra links to sustain connectivity) and large protection investments in key (hub) nodes that sustain connectivity of the network. Our analysis shows that there is a simple resolution of this trade-off: either the optimal network is *k-connected* (the network remains connected after the removal of any  $k$  nodes) or it is a *hub-spoke network with a protected hub*.

Section 7.4 takes up the question of threats that spread via connections. As energy, communication, travel, and consumer interaction increasingly adopt digital networks, cybersecurity has emerged as a major concern. Relative to other infrastructure, a distinctive feature of many cybersecurity threats is that attacks can travel across the links to capture and control progressively larger sections of a network. This creates a tension between the benefits of connectivity and its costs (in terms of the enhanced dangers of contagion) and motivates the study the design and defence of networks that face contagious threats. We develop a model of a defender who can design and defend a network and an adversary who chooses which nodes to attack and how to route his attack on the network. The model helps us in identifying circumstances under which a highly centralized network with the protected center is optimal and when a network with multiple hub-nodes or multiple components is desirable.

## 7.2 The Value of a Network

The value of an infrastructure network comes from goods, services and people being able to move smoothly from one point to another. Similarly, the value of a communication network like the internet comes from the possibility of information moving from one person to another (or one node to another). In both instances, connectivity of the network is central to its value.

The network consists of nodes and edges. The set of nodes is denoted by  $N = \{1, \dots, n\}$ , where  $n \geq 2$ . A link between two nodes  $i$  and  $j$  is represented by  $g_{ij} \in \{0, 1\}$ : we set  $g_{ij} = 1$  if there is a link between  $i$  and  $j$ , and  $g_{ij} = 0$  otherwise. Links are undirected, i.e.  $g_{ij} = g_{ji}$ . The nodes and the links together define a network  $g$ .

We will use notions of paths, components, and connectedness; the reader should refer to chapter 1 for definitions. Let  $\mathcal{C}(g)$  be the set of components of  $g$  and  $C_i(g)$  is the component containing node  $i$ . We let  $|C|$  indicate the cardinality (or size) of the component  $C$ . A maximum component of  $g$  is a component with maximal cardinality in  $\mathcal{C}(g)$ . A network  $g'$  on  $N'$  is a sub-network of  $g$  if and only if  $N' \subseteq N$ , and  $g'_{ij} = 1 \Rightarrow g_{ij} = 1$  and  $i, j \in N'$ . We let  $\mathcal{G}(g)$  denote the set of all sub-networks of  $g$ .

Following Myerson [1977b], we assume that the value of a network is the sum of the value of the different components and that the value of any component is a function of its size only. Let the function  $f : \mathbb{N} \rightarrow \mathbb{R}_+$  specify a value to component size. We shall assume that this value is increasing and convex in the size of a component.

**Assumption 7.1.** *The value of network  $g$  is given by*

$$\Phi(g) = \sum_{C \in \mathcal{C}(g)} f(|C|). \quad (7.1)$$

where  $f$  is (strictly) increasing, (strictly) convex and  $f(0) = 0$ .

Increasing and convex network value functions arise naturally in different contexts. Let us consider some examples.

In the models presented in the chapter on costs and benefits of links, the simplest setting is one where the value of a network to an individual is equal to the number of individuals she can access, in other words the size of the component. With this payoff function, it follows that the aggregate value to all individuals in a network component of size  $x$  would be  $x^2$ . Moreover, the value of the network will be the sum of the value of the components. This is consistent with Metcalfe's Law on telecommunication networks.

A second example concerns collaborative work. Suppose that every subset of individuals can perform a task and the value of a task is 1. Individuals need to coordinate their activities. A task is carried out by a group of individuals only if they are connected. The value of the network is the total value of all tasks that can be carried out. A component with  $m$  nodes thus generates value  $2^m - 1$  (as there are exactly  $2^m - 1$  tasks which  $m$  nodes can perform). This yields a network value that is the sum of the network components and exponential in the size of components. This is consistent with Reed's Law on networked systems.

## 7.3 Infrastructure Networks

To develop a feel for the issues involved in the defence of networks, for concreteness, we present the network structure of metro-train services in two major cities, London and Beijing.

Figure 7.1 presents the network of the London Underground. The network consists of 309 nodes, representing metro stations, and 370 links, representing direct journey connections between stations. This is therefore a relatively sparse network. The average distance between stations is 13.1, the diameter is 36, the average degree is 2.38. This sparseness is reflected in a number of long branches reaching out into distinct parts of the sprawling city.

Next we discuss the Beijing Metro Network. The network is presented in Figure 7.2. The Beijing Metro consists of 287 stations, the number of direct links is 326, the diameter of the network is 45 and the average degree is 2.27. This is therefore a relatively sparse and again a spread out network. As in the London Tube, there is a core set of stations and a number of long branches reaching out into distant parts of the city.

The governments in London and Beijing wish to minimize possible disruption in their transport networks. We develop a theoretical model that explores the economic trade-offs that arise when nodes are subject to shocks.

In the case of infrastructure such as trains, pipelines, or canals, alterations in the structure of the network takes time, so it is reasonable to take the network as a given in the short to medium run. We therefore first study the problem of how to protect a given network. Taking a longer term perspective we then take up the question of optimal design of networks that face threats.

A threat to the network may come from natural sources (such as storms or earthquakes or floods) or from human activity (such as violent or peaceful political protestors). In both types of attack, as we explained in the introduction, it is useful to take the perspective that the attack will seek to minimize the value of the network and so the task is to design and

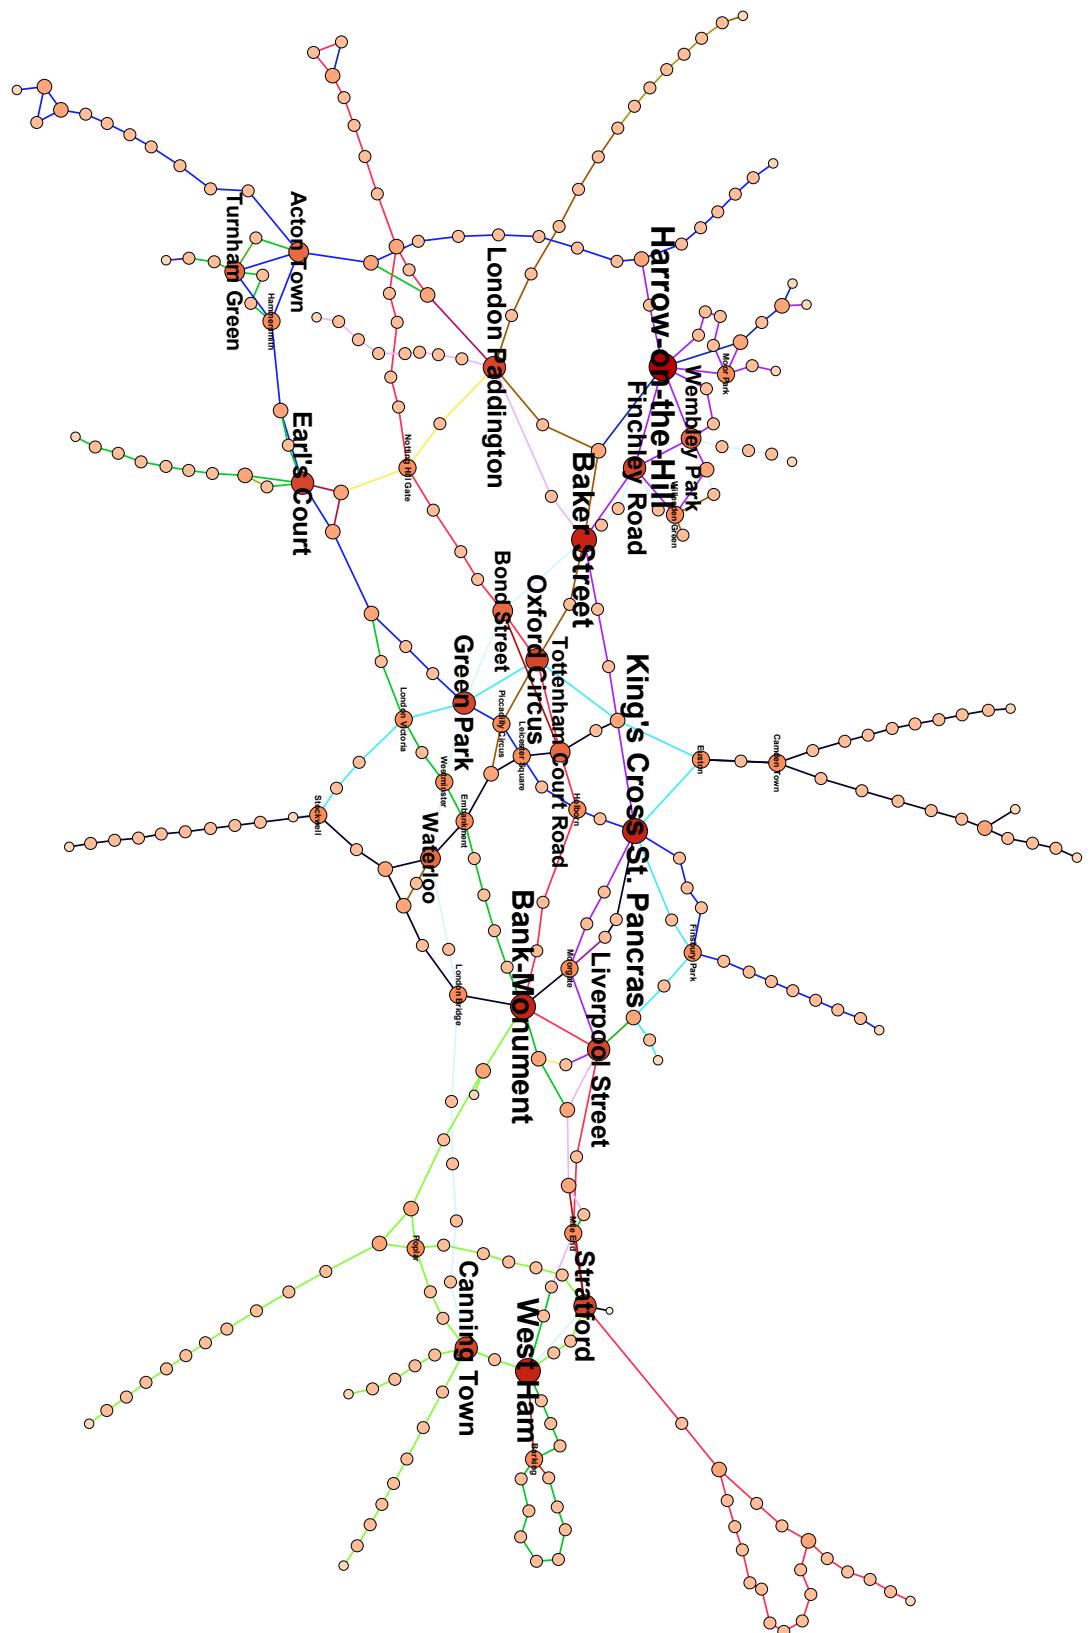

Figure 7.1: The London Tube Network.  
Data Source: <https://github.com/jaron/railgraph/blob/master/graphs/tubeDLR.gephi>

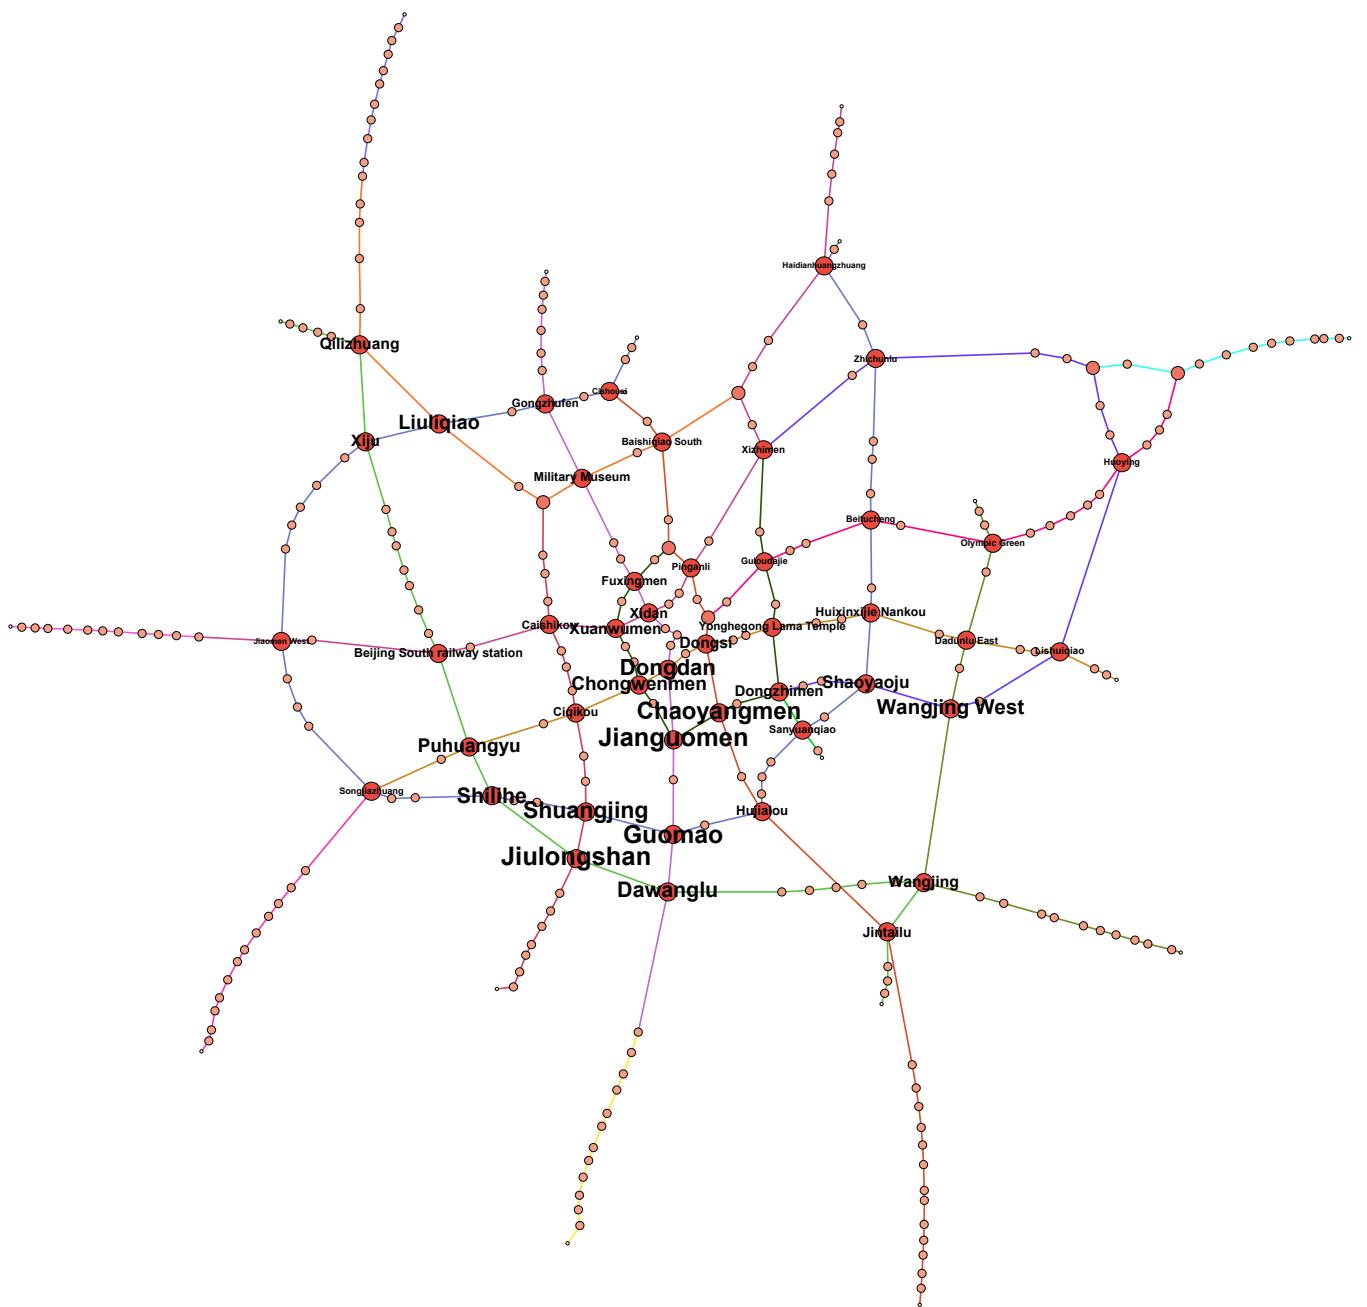

Figure 7.2: The Beijing Metro Network. Data Source:  
<http://dvop.github.io/%E5%9C%B0%E9%93%81/2016/01/11/DiTie.html>

defend the network in the face of such an attack. Building on this idea, we will proceed to construct a game of conflict with two players – a Designer and an Adversary.

### 7.3.1 Defence of a Network

We study a game of conflict that has the following form: in the first stage, the network Defender chooses an allocation of defence resources. In the second stage, after observing the defended network, the Adversary chooses the nodes to attack. Successfully attacked nodes (and their links) are removed from the network, yielding a residual network. The goal of the Defender is to maximize the value of the residual network, while the goal of the Adversary is to minimize this value. The model is taken from Dziubiński and Goyal [2017].

Consider a given network  $g = (N, E)$  that consists of vertices  $N = \{1, \dots, n\}$  and edges between these vertices. There are two players, the Defender and the Adversary. The Defender chooses a set of nodes to protect given by  $\mathcal{D} \subseteq N$ . Observing this defence, the Adversary then chooses a set of nodes  $X \subseteq N$  to attack (the attack strategy is thus formally a function of the defence). For simplicity, we shall assume that defence is perfect, ie., a protected node cannot be removed by an attack. On the other hand, attack on an unprotected node leads to the elimination of that node and its links. Given defence  $\mathcal{D}$  and attack  $X$ , define  $Y = X \setminus \mathcal{D}$  as the nodes that are removed from the network. This yields a *residual network*  $g'$  on  $N \setminus Y$  nodes with edges,  $\{ij \in g : i, j \in N \setminus Y\}$ .

Defence is costly: the cost of defending a node is  $c_D > 0$ . Similarly, attack is costly: the cost of attacking a node is  $c_A > 0$ . Given a network  $g$ , the Defender's payoff from strategy  $\mathcal{D} \subseteq N$ , when faced with Adversary's strategy  $X \subseteq N$ , is

$$\Pi^D(\mathcal{D}, X; g, c_D) = \Phi(g - (X \setminus \mathcal{D})) - c_D |\mathcal{D}|. \quad (7.2)$$

Given a defended network  $(g, \mathcal{D})$ , the payoff to the Adversary from strategy  $X \subseteq N$  is

$$\Pi^A(\mathcal{D}, X; g, c_A) = -\Phi(g - (X \setminus \mathcal{D})) - c_A |X|. \quad (7.3)$$

We shall refer to this as the *Network Defence game*.

A sub-game perfect equilibrium is a profile of strategies  $(\mathcal{D}^*, X^*(\mathcal{D}))$ , such that  $X^*(.)$  maximizes payoff of the Adversary given a defence  $\mathcal{D}$  and  $\mathcal{D}^*$  maximizes the payoff of the Defender given attack strategy  $X^*(.)$ .

A preliminary observation is that as this is a two stage sequential game with full information and a finite number of actions for both players, we can compute the sub-game

perfect equilibrium through backward induction. It follows from standard considerations that (for most – i.e., ‘generic’ – parameters of the model) the equilibrium is unique in terms of player’s payoffs, sizes of defence and attack, and the value of residual network. In what follows, we will study the nature of this unique equilibrium.

To develop a feel for the economics of the defence and attack, it is helpful to start with the star network.

**Example 7.1. Defence and Attack on the Star**

Figure 7.3 presents a star network with four nodes. The network value function is  $f(x) = x^2$ .

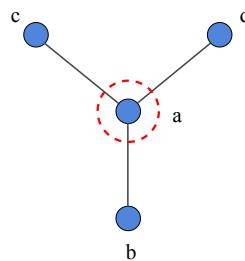

Figure 7.3: Star network ( $n = 4$ )

As is standard, we solve the game by working backward, starting at the second stage. Given a defended network,  $(g, \mathcal{D})$ , we compute the optimal response of the Adversary,  $X^*(g, \mathcal{D})$ . The Defender compares his payoffs under different  $(g, \mathcal{D})$  and picks the one that gives him the highest payoffs. Suppose the Defender protects the hub. In that case, the Adversary can only hope to eliminate single nodes (without affecting the connectivity of the residual network). The payoff to a Defender from the elimination of a single node is  $f(3)$ . By contrast, if the hub is not protected, and the Adversary eliminates the hub, he reduces the size of the network and fragments it completely, yielding the Defender a payoff of  $3f(1)$ . As network value  $f(\cdot)$  is increasing and convex  $f(3) > 3f(1)$ . This comparison brings out the interaction between the network architecture and the value function in shaping the conflict between the Defender and the Adversary. The Adversary would prefer to attack in a manner so as to disconnect the network and anticipating this the Defender would like to block such attacks. The details of the equilibrium outcomes are summarized in Figure 7.4.

In this equilibrium two points are worth noting. First, for much of the parameter range, attack and defence centres on the hub node,  $a$ . There is a threshold cost of attack level, 7, the Adversary either attacks  $a$  or does not attack at all when  $c_A > 7$ . Second, consider the intensity of conflict defined as the resources allocated to defence and attack. When the cost

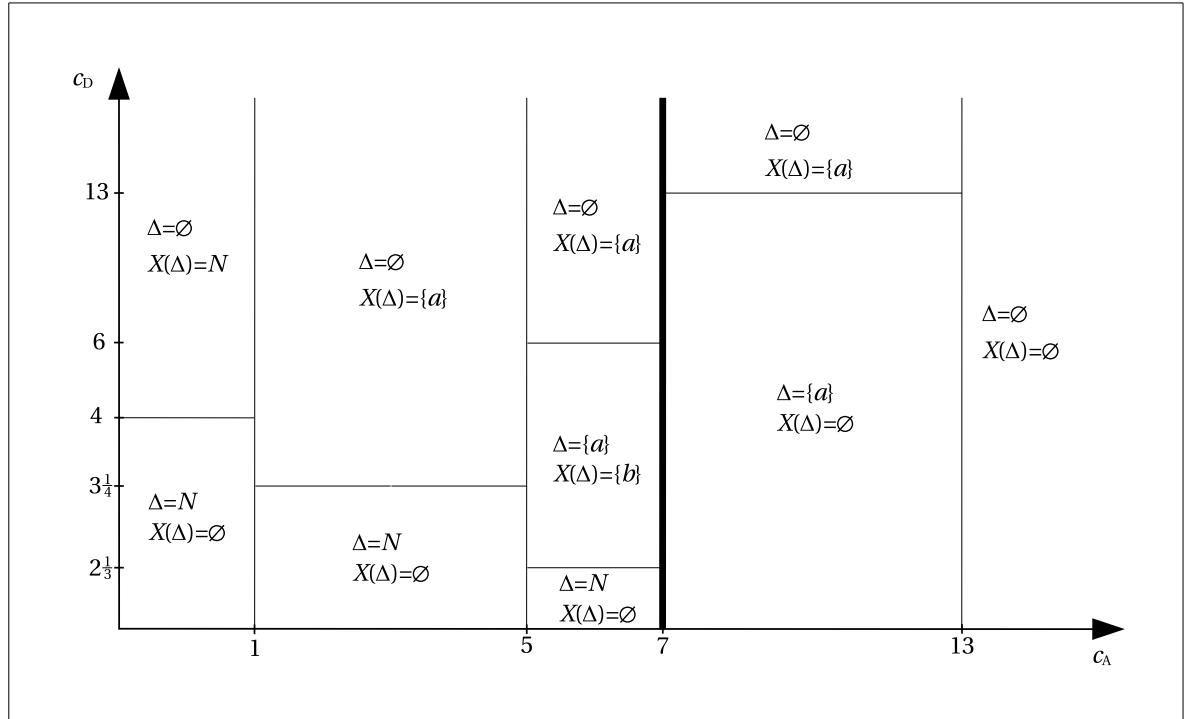

Figure 7.4: Equilibrium outcomes: star network ( $n = 4$ ) and  $f(x) = x^2$ .

of attack is large, i.e., 13, there is no threat to the network and hence no need for defence. The intensity of conflict is 0. If the cost of attack is small,  $c_A < 1$ , the intensity of conflict hinges on the costs of defence. When defence cost is small all nodes are protected and there is no attack implying that the intensity of conflict is given by  $nc_D$ . If defence costs are high, there is no defence and all nodes are eliminated so that the intensity of conflict is  $nc_A$ . For intermediate cost of attack and defence, both the Defender and the Adversary are active.

■

Let us next consider defence and attack in general networks. A set  $X \subseteq N$  is a *separator* of the network  $g$  if  $|\mathcal{C}(g)| < |\mathcal{C}(g - X)|$ , in other words, a separator is a set of nodes the removal of which strictly increases the number of components in the network. A network will typically contain multiple separators: as the Adversary seeks to maximize his payoffs, he targets the most economical separators. A separator  $S \subseteq N$  is *essential* for network  $g \in \mathcal{G}(N)$ , if for every separator  $S' \subsetneq S$ ,  $|\mathcal{C}(g - S)| > |\mathcal{C}(g - S')|$ , i.e., a strict subset of eliminated nodes results in a strictly smaller number of components. The set of all essential separators of a network  $g$  is denoted by  $\mathcal{E}(g)$ . Figure 7.5 illustrates the essential separators in a simple network:  $\{a\}$ ,  $\{a, b\}$  and  $\{a, c\}$ .

Example 7.1 suggests that the network defence problem can be divided into two parts, depending on the cost of attack. In the low cost case, the elimination of single nodes is

Figure 7.5: Essential separators.

attractive for the Adversary, while in the high cost case elimination of a node is only justified if it results in disconnecting the residual network. Let  $\Delta f(x) = f(x+1) - f(x)$  be the marginal increase in the value of a component of size  $x$  when a single node is added to it. Under our Assumption 7.1,  $\Delta f(x)$  is strictly increasing. For purposes of exposition, it is helpful to consider two types of costs – high and low – high costs occur when  $c_A > \Delta f(n-1)$  and imply that the Adversary does not want to eliminate single nodes, low cost occurs when he may wish to eliminate single nodes,  $c_A < \Delta f(n-1)$ .

With a high attack cost, an active Adversary must disconnect the network, i.e., choose a separator or not attack the network at all. Given a cost of attack  $c_A$  and network  $g$ , we define the set of individually rational separators

$$\mathcal{E}(g, c_A) = \{X \in \mathcal{E}(g) : \Phi(g) - \Phi(g - X) \geq c_A |X|\} \quad (7.4)$$

When cost of attack is low, it may be profitable for the Adversary to use attacks that merely remove nodes from the network, without disconnecting it. A set  $R \subseteq N$  is a *reducing attack* for a network  $g$ , if there is no  $X \subseteq R$  for which  $X$  is a separator for  $g$ . For a given network, the set of all reducing attacks is denoted by  $\mathcal{R}(g)$ .

The attack of the Adversary can be decomposed into two parts. First, the Adversary fragments the network by removing a minimal set of nodes needed to obtain the desired components – this is the essential separator. Second, the Adversary reduces the size of the components (but without disconnecting any of them).

Anticipating this attack, the Defender chooses a defence. It is instructive to start with the setting where the cost of attack is high as we can restrict attention to attacks that disconnect the network. In this case, given the costs of attack, the Adversary will only use separators  $\mathcal{E}$  and will not use  $\mathcal{R}$ . The optimal strategy of the Defender is to block a subset of the separators in the most economical way. The study of such blocking strategies requires the use of the notion of a *transversal*.

Figure 7.6: Minimum transversal,  $\{a\}$ , of essential separators  $\{\{a\}, \{a,b\}, \{a,c\}\}$ .

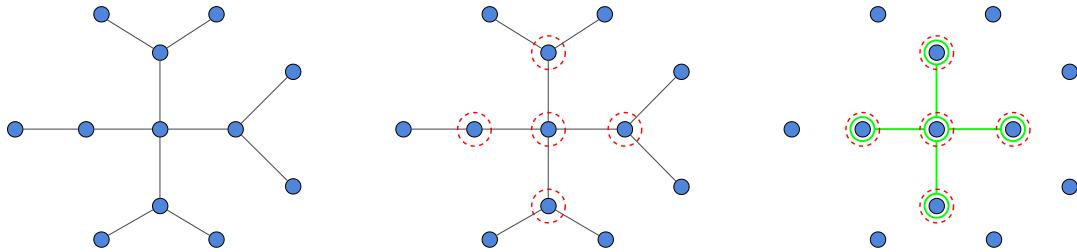

Figure 7.7: Tree: separators (in red) and transversals (in green) ( $n = 12$ )

Given a family of sets of nodes,  $\mathcal{H}$ , and a set of nodes  $M$ , define

$$\mathcal{B}(M, \mathcal{H}) = \{Z \in \mathcal{H} : Z \cap M \neq \emptyset\} \quad (7.5)$$

as the sets in  $\mathcal{H}$  that are blocked (or *covered*) by  $M$ . The set  $M$  is called a *transversal of  $\mathcal{H}$*  if  $\mathcal{B}(M, \mathcal{H}) = \mathcal{H}$ . The set of all transversals of  $\mathcal{H}$  is denoted by  $\mathcal{T}(\mathcal{H})$ . Members of  $\mathcal{T}(\mathcal{H})$  that are minimal with respect to inclusion are called *minimal transversals* of  $\mathcal{H}$ . Elements of  $\mathcal{T}(\mathcal{H})$  with the smallest size are called *minimum transversals* of  $\mathcal{H}$ . Let  $\tau(\mathcal{H})$  denote the *transversal number* of  $\mathcal{H}$ , i.e., the size of a minimum transversal of  $\mathcal{H}$ . Figure 7.6 illustrates the minimum transversal in a simple network.

To appreciate the concepts of separator and transversal let us next consider two well-known networks, *trees* and *core-periphery networks*.

**Trees:** In any tree network, every non-empty set of internal nodes (nodes which are not leaves) constitutes a separator. Essential separators are non-empty sets of nodes such that any node in a set has at least two neighbours outside of that set. Transversals of essential separators are subsets of internal nodes. In particular, there is a unique minimal transversal of the set of all essential separators: the set of all internal nodes. Minimal essential separators and transversal for tree networks are illustrated in Figure 7.7.

**Core-periphery networks:** Each node of the periphery is connected to exactly one node of the core while the core constitutes a clique. Every subset of the core nodes is an essential separator. There is a unique minimal transversal: the set of all core nodes. Minimal essential separators and transversals for core-periphery networks are illustrated in Figure 7.8.

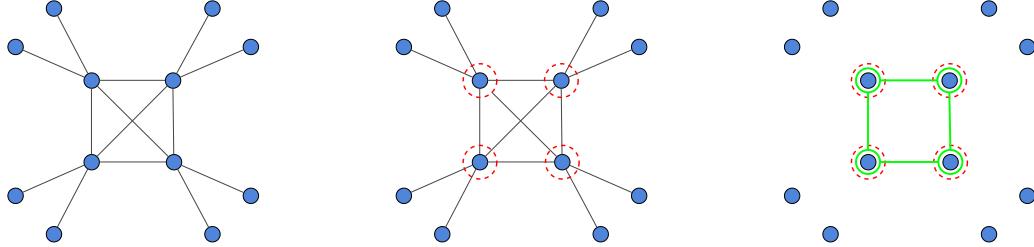

Figure 7.8: Core-periphery: separators (in red) and transversals (in green) ( $n = 12$ )

We build on the star example and the discussion of separators and transversal to develop the following result on defence and attack in networks.

**Proposition 7.1.** *Consider the Network Defence game. Suppose the network value function is given by (7.1) and the network  $g$  is connected. Let  $(\mathcal{D}^*, X^*)$  be an equilibrium.*

1. If  $c_A < \Delta f(n - 1)$  then

- $\mathcal{D}^* = N$  or  $\mathcal{D}^*$  is a minimal transversal of  $\mathcal{B}(\mathcal{D}^*, \mathcal{E}(g, c_A))$ .
- $X^*(\mathcal{D}) = E \cup R$ , where  $E \in \mathcal{E}(g, c_A)$  and  $R \in \mathcal{R}(g - E)$ , with  $X^*(\mathcal{D}) \cap \mathcal{D} = \emptyset$ .

2. If  $c_A > \Delta f(n - 1)$  then

- $|\mathcal{D}^*| \leq \tau(\mathcal{E}(g, c_A))$  and  $\mathcal{D}^*$  is a minimum transversal of  $\mathcal{B}(\mathcal{D}^*, \mathcal{E}(g, c_A))$ .
- $X^*(\mathcal{D}) = \emptyset$ , if  $\mathcal{D} \in \mathcal{T}(\mathcal{E}(g, c_A))$ ;  $X^*(\mathcal{D}) \in \mathcal{E}(g, c_A)$  with  $X^*(\mathcal{D}) \cap \mathcal{D} = \emptyset$ , otherwise.

A first message is that no attack will target a protected node. The more general point of the analysis is that essential separators (that are effective at fragmenting the network) are key to optimal attack and economical transversals (that block these separators) are key to optimal defence. A third point is that, if the defender goes beyond blocking the separator and protecting nodes that expand the size of a component then, due to convexity of the network value function, it is optimal for him to protect all nodes in the network.

We now outline the arguments underlying the proof of this proposition. Let us start with part 1: when the costs of attack are small, if defence exceeds a minimal transversal (of covered essential separators) then it must include a node that is being protected purely to prevent it from removal. This protection is being done to protect the size of the component.

This must mean that, in the absence of defence, the node will be eliminated in the subsequent optimal attack. As  $f$  is convex, the marginal return of expanding size of a component is increasing in its size. Since the cost of node defence is linear, once the defender decides to protect nodes beyond the minimal transversal it must be optimal for him to defend all nodes.

Turning to part 2: if the costs are large the Adversary will not use reducing attacks. So, an optimal attack must be either empty or must be an essential separator. Clearly, optimal defence  $\mathcal{D}^*$  cannot be larger than the size of the minimum transversal of  $\mathcal{E}(g, c_A)$ , as that would be wasteful for the Defender. If  $|\mathcal{D}^*| = \tau(\mathcal{E}(g, c_A))$ , then  $\mathcal{D}^*$  must be a minimum transversal of  $\mathcal{E}(g, c_A)$ . If  $|\mathcal{D}^*| < \tau(\mathcal{E}(g, c_A))$ , then  $\mathcal{D}^*$  is a minimum transversal of  $\mathcal{B}(\mathcal{D}^*, \mathcal{E}(g, c_A))$  in  $\mathcal{E}(g, c_A)$ .

■

To appreciate the concepts of separators and transversal more fully we next discuss the problem of defending the London Underground.

### Application: London Tube

Let us compute some separators and corresponding tranversals for the London Tube. There are 135 separators of size 1: the large number of separators is due to the many long paths emanating from the core of the network with the key junctions. It then follows that the transversal number  $\tau(\mathcal{M}(g, c_A)) = 135$  (where  $\mathcal{M}(g, c_A)$  is the set of all minimal separators, given a network  $g$  and the cost of attack  $c_A$ ). Consider next separators of size 2: there are 209 additional such separators. This in turn raises the transversal number to 195. Finally consider separators of size 3: there are 130 such additional separators and faced with this attack, the transversal number is 205. One point to note is that as we allow for larger separators, there is only a very modest increase in the transversal number.

Let us summarize what we have learnt about optimal defence of infrastructure networks. We have shown that an intelligent Adversary will use an attack strategy that combines separators and reducing cuts. Anticipating this strategy, the Designer will focus on protecting the nodes that block the separators, and this gives rise to a transversal based defence. In the model considered, and indeed throughout the chapter, we will focus on the case with a single Designer and a single Adversary. This is a natural baseline and it offers us some intuitions. However, in many contexts defence may be left to the nodes (as in cities or states making choices on protection of their infrastructure). We conclude this

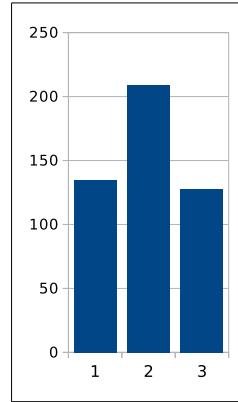

Figure 7.9: Minimal separators of London Tube

section with a discussion of some issues that arise when we level the nodes choose the level of protection.

### Decentralized defence

We consider a two-stage game. In the first stage, each of the nodes in the network decides whether to protect itself or to stay unprotected. These choices are observed by the adversary who then chooses the nodes to attack.

Let  $N = \{1, 2, \dots, n\}$ , with  $n \geq 3$  be the set of players and let  $S_i = \{0, 1\}$  denote the strategy set of node  $i \in N$ . Here  $s_i = 1$  means that the node chooses to defend itself and  $s_i = 0$  refers to the case of no-defence. These choices are made simultaneously. There is a one-to-one correspondence between a strategy profile of the nodes,  $\mathbf{s} \in \{0, 1\}^N$ , and the resulting set of defended nodes  $\Delta \subseteq N$ . So we will use  $\Delta$  to refer to the strategy profile of the nodes in the first stage.

In the second stage the adversary observes the defended network  $(g, \Delta)$  and chooses an attack  $X \subseteq N$ , which leads to a residual network  $g - (X \setminus \Delta)$ . The payoff to the adversary remains as in the case of the centralized defence and is defined in Equation (7.3). The payoff to a node depends on whether the node is removed by the attack or not. A removed node receives payoff 0. Each of the surviving nodes receives an equal share of the value of its component in the residual network.

$$\Pi^i(\Delta, X; g, c_D) = \begin{cases} 0 & \text{if } i \in X \setminus \Delta, \\ \frac{f(|C(i)|)}{|C(i)|} - s_i c_D & \text{otherwise,} \end{cases} \quad (7.6)$$

where  $C(i)$  is the component in the residual network  $g - (X \setminus \Delta)$  containing  $i$ .

This completes the description of the *Decentralized Defence Game*. As in the two player

game, we study the sub-game perfect equilibria of this game. We focus on equilibria with no-active conflict (these are equilibria in which either the nodes do not defend or the adversary does not attack) as we are able to provide a characterization and also because these equilibria suffice for us to discuss the inefficiencies that arise when defence decisions are decentralized. All other equilibria in decentralized defence game could be characterized in the same spirit as the characterization provided in Proposition 7.1 for the centralized defence game.

As usual, we solve the game backwards, starting from the second stage. As in the two player game, the adversary chooses either the empty attack or an attack being a combination of an essential separator and a reducing attack. If cost of attack is low and there is no active conflict, then either the adversary removes all the nodes, or all nodes are protected. In any other outcome the adversary must remove at least one node. If cost of attack is high and there is no active conflict then either none of the nodes protects or, anticipating the strategy of the adversary, the nodes choose a defence configuration that blocks all the individually rational essential separators. Therefore, in equilibrium, they must choose a minimal transversal of  $\mathcal{E}(g, c_A)$ . We build on these observations to provide the following characterization of equilibria with no active conflict in the decentralized defence game.

**Proposition 7.2.** *Consider the Decentralized Defence Game on a connected network  $g$ . Let  $\Delta^*$  be the equilibrium defence.*

1. *If  $c_D > f(n)/n$  then  $\Delta^* = \emptyset$  is the unique equilibrium defence.*
2. *If  $c_D \leq f(n)/n$* 
  - (a)  *$c_A < f(n) - f(n-1)$ , then  $\Delta^* = N$  is an equilibrium defence.*
  - (b)  *$c_A > f(n) - f(n-1)$ , then any minimal transversal of  $\mathcal{E}(g, c_A)$  is an equilibrium defence.*

*The equilibrium strategy of the adversary is as in Proposition 7.1.*

We now discuss inefficiencies that may arise due to decentralized protection. This is done via a comparison of the aggregate welfare of the nodes in the equilibrium of the two-player game with the aggregate welfare in the decentralized defence game. Let  $\Pi^{D^*}(g, c_A, c_D)$  denote the equilibrium payoff in the two player game on network  $g$  with cost of defence  $c_D$  and cost of attack  $c_A$ . Aggregate welfare in the two player game, starting from network  $g$ , and costs  $c_A$  and  $c_D$ , are:

$$W^F(g, c_A, c_D) = \Pi^{D^*}(g, c_A, c_D). \quad (7.7)$$

Aggregate welfare under defence profile  $\Delta$  and attack  $X$ , of the  $n + 1$  player game starting from network  $g$ , and given cost of defence  $c_D$ , are:

$$W^D(\Delta, X; g, c_D) = \sum_{i \in N} \Pi^i(\Delta, X; g, c_D). \quad (7.8)$$

We study the cost of decentralization in terms of the *price of anarchy*: the ratio of welfare in the two player game to the welfare in the worst equilibrium of the decentralized defence game. Let  $E(g, c_A, c_D)$  denote the set of equilibria of the  $n + 1$  player game on network  $g$  with cost of attack  $c_A$  and cost of defence  $c_D$ . The price of anarchy

$$\text{PoA} = \max_{g, c_A, c_D} \left( \frac{W^F(g, c_A, c_D)}{\min_{(\Delta, X) \in E(g, c_A, c_D)} W^D(\Delta, X(\Delta); g, c_D)} \right) \quad (7.9)$$

We first take up the issue of positive externalities: an individual's protection decision creates benefits for other nodes (that she does not take into account). This can lead to very large welfare losses. To see this, consider a star network and suppose that cost of attack is high,  $c_A > f(n) - f(n - 1)$ , and  $c_D \in (f(n)/n, f(n))$ . In the equilibrium of the two player game, the aggregate welfare  $f(n) - c_D$ . By contrast, in the equilibrium of the decentralized game, the central player does not find it profitable to defend itself as  $c_D > f(n)/n$ . So aggregate welfare in equilibrium of the  $n + 1$  player game is 0. Thus the ratio of the two is unbounded for the range of costs  $c_D \in (f(n)/n, f(n))$ .

Protection choices exhibit a threshold property: for a node to find it profitable to protect it is necessary that other nodes belonging to the same minimal transversal also choose to protect. In other words, protection decisions are strategic complements. This complements property can give rise to coordination failures. To see this consider a tree with two hubs each of whom are linked to  $(n - 2)/2$  distinct nodes. Suppose that

$$f(n) - f(n - 1) < c_A < f(n/2) - (n - 2)f(1)/2$$

so the adversary will only attack hub nodes. If  $2f(n/2)/n < c_D < f(n)/n$  then the first best outcome is to defend the two hubs. One hub protecting itself gives incentives to the other hub to protect: two protected hubs is an equilibrium outcome. However, one its own, a hub node does not have sufficient incentives to protect itself: zero protection is an equilibrium outcome. In this zero protection equilibrium the aggregate payoffs equal  $(n - 2)f(1)$  as compared to first best outcome of  $f(n) - 2c_D$ . Given that  $f()$  is convex, the cost of decentralization can be unbounded.

Third, at the local level, the game is clearly one of strategic substitutes. A node in a

separator has incentives to protect only if no other node in the separator protects itself. As we will see when we study public good games on networks (c.f. Bramoullé and Kranton [2007]), the network protection game therefore displays multiple equilibria. This can generate very large efficiency losses. As an example consider network  $g$  depicted in Figure 7.10.

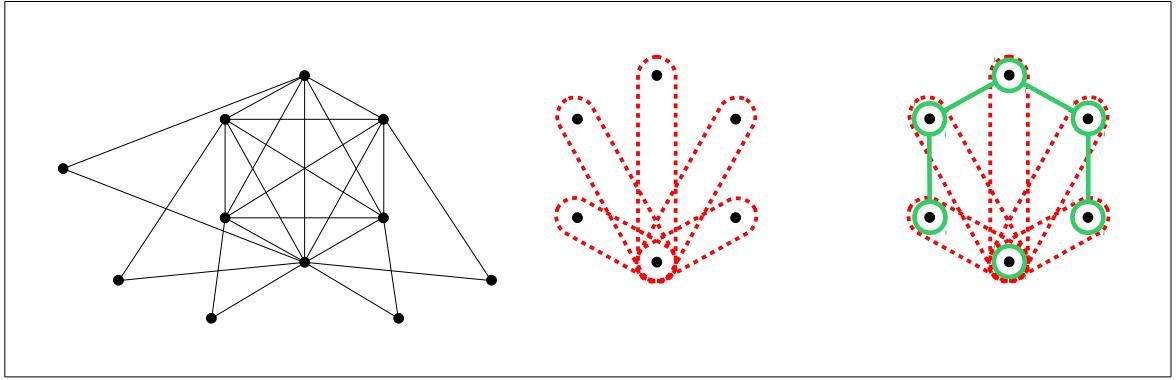

Figure 7.10: Network with essential separators of size 2 having two minimal transversals: one of size 1 and one of size 5.

Suppose that  $f(x) = x^2$ ,  $c_A \in (21, 28)$  and  $c_D < 11$ . Given this cost of attack, the adversary will not remove a node without disconnecting the network. The set of individually rational essential separators is a combination of sets depicted in Figure 7.10. Notice that the minimum transversal of  $\mathcal{E}(g, c_A)$  is the node belonging to each of the separators, while the largest minimal transversal consists of one distinct node from each of the two element separators. The POA will be proportional to the ratio of extra nodes that protect, and this is of order  $(n - 1)/2$ . In other words, the POA is unbounded.

To summarize, our study of decentralized defence shows that the equilibrium choices of nodes and the adversary can be usefully studied in terms of transversals and separators of the underlying network. Moreover, we have shown that the strategic structure of the problem is very rich admitting features of both strategic substitutes and complements (for definitions of these concepts refer to the chapter on social structure and human behaviour). The welfare gap between decentralized equilibrium and first best outcomes is unbounded: interestingly, individual choice may lead to too little or to too much protection, relative to the choice of a single (centralized) defender.

### 7.3.2 Design and Defence

In the previous section, we studied the problem of defending a given network. In many contexts, it is reasonable to suppose that a network is given in the short or medium run but

that it can be altered through appropriate investments in the long run. With this idea in mind, we now move on to the longer term and consider the question of design and defence of a network that faces threats.

We use a model taken from Dziubiński and Goyal [2013]. There are 2 players, a Designer (D) and an Adversary (A). There are two stages in the game. In the first stage, the Designer chooses a network and a subset of nodes to defend. In the second stage, the Adversary observes the network and defence and then chooses a subset of nodes to attack.

As before, let  $N = \{1, \dots, n\}$ , with  $n \geq 3$  be a given finite set of nodes. The Designer chooses links between pairs of nodes to create a network  $g$ , and chooses to protect a subset of the nodes  $\mathcal{D}$ . Thus he chooses  $(g, \mathcal{D})$ . In the second stage, the Adversary assigns his attack budget  $k > 0$  to a subset of nodes  $X \subseteq N$ , with  $|X| \leq k$ . The attack strategy is called a *cut*. Recall that given the network  $g$ , the removal of  $X$  nodes creates a *residual network*,  $g - X$ .

Defence is perfect: a protected node cannot be removed by an attack. On the other hand, an unprotected node is removed with certainty if it is attacked. Given a defence  $\mathcal{D}$  and a cut  $X$ , a set  $Y = X \setminus \mathcal{D}$  is removed from the network.

Both links and defence resources are costly: a link costs  $c_L > 0$  and the protection of a node costs  $c_D > 0$ . The cost of a defended network  $(g, \mathcal{D})$  is

$$c_L|g| + c_D|\mathcal{D}| \quad (7.10)$$

The payoff to the Designer from choosing  $(g, \mathcal{D})$  when the Adversary chooses a cut  $X$  is

$$\Pi^D(\mathcal{D}, X; g) = \Phi(g - (X \setminus \mathcal{D})) - c_L|g| - c_D|\mathcal{D}|. \quad (7.11)$$

The payoff to the Adversary is

$$\Pi^A(\mathcal{D}, X; g) = -\Phi(g - (X \setminus \mathcal{D})). \quad (7.12)$$

The objective of the Designer is to maximize his payoff, while the goal of the Adversary is to minimize the value of the residual network. We shall refer to this as the *Design and Defence Game*.

We study the (sub-game perfect) equilibrium of this game. In words, the Designer seeks the defended network that copes best with the worst attack the Adversary can launch. This is a setting in which the Designer and the Adversary have diametrically opposed interests.

Facing a defended network  $(g, \mathcal{D})$ , the Adversary will choose a set of nodes to eliminate,

$X$ , such that:

$$\Phi(g - (X \setminus \mathcal{D})) = \min_{\substack{Y \subseteq N \\ |Y| \leq k}} \Phi(g - (Y \setminus \mathcal{D})). \quad (7.13)$$

Therefore, the Designer chooses  $(g, \mathcal{D})$  such that for all cuts  $X$  with  $|X| \leq k$

$$\Pi^D(\mathcal{D}, X; g) \geq \max_{\substack{g' \subseteq g^N \\ \mathcal{D}' \subseteq N}} \left( \left( \min_{Y \subseteq N, |Y| \leq k} \Phi(g' - (Y \setminus \mathcal{D}')) \right) - (|\mathcal{D}'|c_D + |g'|c_L) \right). \quad (7.14)$$

To develop a feel for the economic forces at work, we start with the simple case where a network is valuable if and only if it is connected.

Formally, suppose that the value function  $\Phi$  of residual network is:

$$\Phi(g) = \begin{cases} 1, & \text{if the network is connected,} \\ 0, & \text{otherwise.} \end{cases} \quad (7.15)$$

Therefore, the Designer either chooses the empty network with no defence or selects a lowest cost network-defence strategy  $(g, \mathcal{D})$  such that for all  $X \subseteq N$  with  $|X| \leq k$ ,  $g - (X \setminus \mathcal{D})$  is connected.

Given  $k \geq 2$ , a network  $g$  is  $k$ -connected if either  $|N| = k + 1$ , or  $|N| \geq k + 2$  and there exists a separator  $X \subseteq N$  if and only if  $|X| \geq k$ . A  $k$ -connected network with the minimum number of links is called *minimal k-connected*. The set of minimal  $k$ -connected networks is denoted by  $\mathcal{M}(k, n)$ .

It is easy to see that every node of a  $k$ -connected network has degree at least  $k$ , as otherwise it could be separated from the rest of the network by removing fewer than  $k$  nodes. Thus the minimal number of links in such a network is  $\lceil nk/2 \rceil$ . Harary [1962] showed that this number of links is also sufficient. We provide some examples of Harary graphs in Figure 7.11.

**Proposition 7.3.** Consider the Design and Defence Game and suppose that  $k \leq n - 2$ . In equilibrium

1. The Designer chooses protected network  $(g, \mathcal{D})$  which is as follows:

- If  $c_L < 1/\lceil \frac{n(k+1)}{2} \rceil$  and  $c_D > c_L (\lceil \frac{n(k-1)}{2} \rceil + 1)$ , then  $g \in \mathcal{M}(k, n)$  and  $\mathcal{D} = \emptyset$ .
- If  $c_L(n - 1) + c_D < 1$  and  $c_D < c_L (\lceil \frac{n(k-1)}{2} \rceil + 1)$ , then  $g$  is a star and the central node is protected.

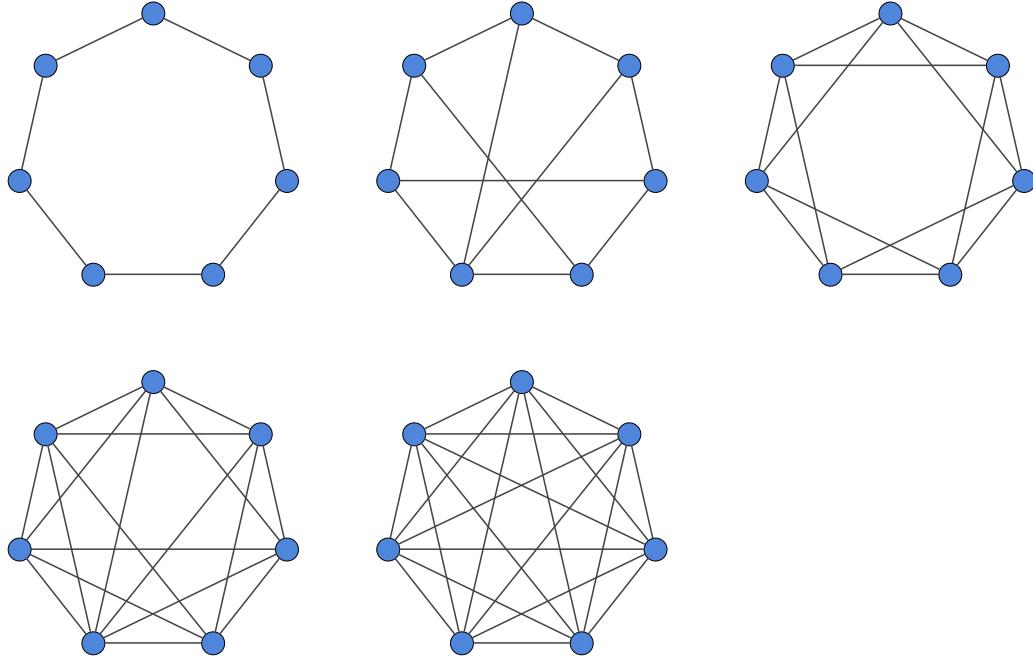

Figure 7.11: Harary networks over  $n = 7$  nodes with connectivity  $k = 2, \dots, 6$ .

- Otherwise  $g$  is empty and  $\mathcal{D} = \emptyset$ .
2. The Adversary chooses a separating cut for  $(g, \mathcal{D})$  if it exists and if it does not exist then all cuts yield the same payoff.

The analysis of the model reveals a very simple structure to the design and defend problem: faced with an Adversary who can eliminate  $k$  nodes, the Designer chooses one of three possible networks: a  $k$ -connected network (connectivity is maintained even after  $k$  nodes are eliminated), a centre-protected star network (connectivity is maintained through a protected hub, after spokes are eliminated) or the empty network. The formal statement delineates the costs of linking and protection under which each of these three networks are optimal. We now spell out the details of the computations.

The payoff to the Designer from the  $(k+1)$ -connected network, the centre-protected star and the empty network is respectively,  $1 - \lceil n(k+1)/2 \rceil c_L$ ,  $1 - c_D - (n-1)c_L$ , 0. The payoff to the Adversary is  $-1$  when faced with a  $(k+1)$ -connected network or a center protected star, and it is 0 when faced with the empty network. The optimal networks are presented in Figure 7.12.

The arguments underlying the result are as follows. In the first step we clarify the nature of networks under zero or positive defence. In case of no defence the network is either empty or connected. If it is connected, then the residual network must be connected as well, irrespective of any cuts. Thus in case of no defence the Designer must choose either

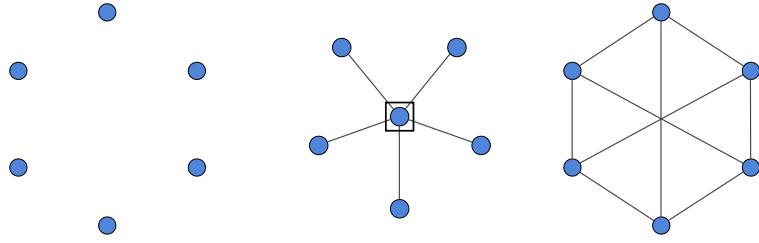

Figure 7.12: Optimal Networks in Connectivity Problem:  $n = 6, k = 2$

empty or minimal  $(k + 1)$ -connected network. In case of positive defence, the residual network must again be connected. So the initial network set up by the Designer must be connected. Observe that connectedness of the residual network can be guaranteed by a star network with 1 unit of defence assigned to the centre. This protected network has minimal number of links across all connected networks and minimal defence across all networks with positive defence. Any other network with the same number of links must be a tree, and any tree requires protecting all internal nodes (i.e. non-leaves) to stay connected after an attack of the Adversary. Thus the center-protected star is the only candidate for the Designer who is optimizing.

The payoff to the Designer from the empty network is 0. Observe that in a  $(k + 1)$ -connected network every node must have degree at least  $k + 1$ ; otherwise it can be isolated by the deletion of its neighbors. Harary [1962] proved that degree  $k + 1$  for every node (possibly but one, that has degree  $k + 2$ ) – so  $\lceil n(k + 1)/2 \rceil$  links in all – is also sufficient for  $k + 1$  connectedness. Applying this theorem, we can write the payoff from the minimal  $(k + 1)$ -connected network as

$$1 - c_L \left\lceil \frac{n(k + 1)}{2} \right\rceil. \quad (7.16)$$

Finally, the payoff from the centrally protected star is

$$1 - c_L(n - 1) - c_D \quad (7.17)$$

A comparison of the payoffs from the empty network, a minimal  $(k + 1)$ -connected network and a centrally protected star yields the desired parameter restrictions. ■

Figure 7.13 presents the optimal defended networks. We define  $R(n, k) = n(k + 1) \bmod 2$ , so  $R(n, k) = 1$  if  $n$  is odd and  $k$  is even, and  $R(n, k) = 0$ , otherwise. We can see that if the cost of linking,  $c_L$ , is higher than  $1/\lceil n(k + 1)/2 \rceil$ , then only a centrally protected star or the empty network can be optimal. Raising the cost of defence makes the empty network

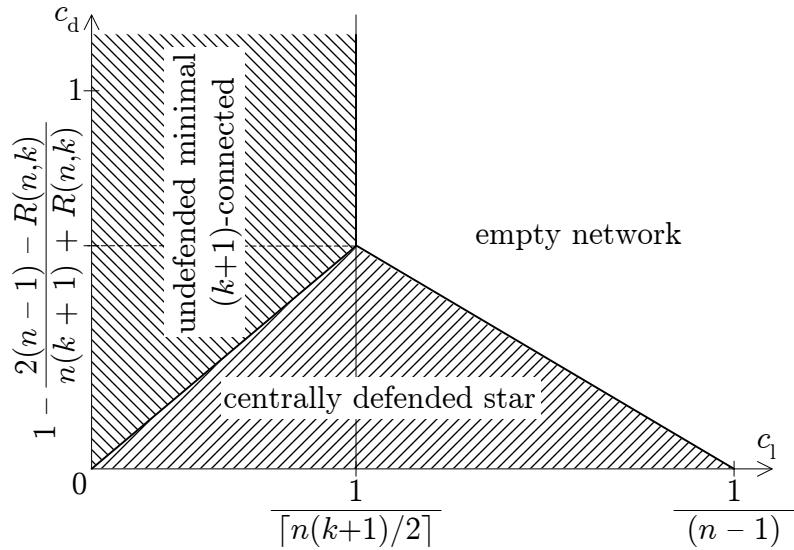

Figure 7.13: Optimal Defended Networks

more attractive. Similarly, if cost of defence,  $c_D$ , is higher than

$$1 - \frac{2(n-1) - R(n,k)}{n(k+1) - R(n,k)} \quad (7.18)$$

then only a minimal  $(k+1)$ -connected network or the empty network can be optimal (and raising the cost of linking makes the latter more attractive). On the other hand, if the costs are sufficiently low,  $c_L < 1/\lceil n(k+1)/2 \rceil$  and

$$c_D < 1 - \frac{2(n-1) - R(n,k)}{n(k+1) + R(n,k)}, \quad (7.19)$$

then either a minimal  $(k+1)$ -connected network or a centrally protected star is optimal, depending on the relation between the costs,  $c_D/c_L$ . If  $c_D/c_L$  is sufficiently low, i.e. lower than  $\lceil n(k-1)/2 \rceil + 1$ , then centrally protected star is optimal, and if it is higher, then minimal  $(k+1)$ -connected network is optimal.

The above description of optimal defended networks is obtained under the assumption of perfectly reliable defence. Our arguments can be used to study the case of imperfect defence. Suppose that there is a given probability of successful defence, less than 1. The Designer will be averse to creating a protected hub network if the protection level is low and this may lead him to create a network with multiple protected hubs. A question at the end of the chapter explores this line of reasoning.

More generally, consider the assumption that the budget of the Adversary is exogenous. Suppose that attacking each node has a cost  $c_A > 0$ , as in the previous section. Given the Designer's objective of keeping the network connected, the Adversary will choose a

maximum of  $k$  units of attack where  $k \cdot c_A \leq 1$ . So the Designer will play as in the game studied above with  $k = 1/c_A$  units of attack. This implies that as  $c_A$  increases, the maximum number of units of attack falls, and this makes the centrally defended star less attractive relative to the  $(k+1)$ -connected network. An increase in cost of linking,  $c_L$ , makes the center-protected star more attractive, while increases in cost of defence,  $c_D$ , result in a decrease of attractiveness of centrally-protected star.

Finally, we note that the analysis so far is restricted to the connectivity network value function. The arguments we have developed can be used to study more general network value functions that satisfy Assumption (7.1). Indeed, the analysis of the design and defence game with general network values functions yields us:

**Proposition 7.4.** *Consider the Design and Defence Game. Suppose  $1 \leq k \leq n$  and Assumption 7.1 holds. In equilibrium:*

1. *The Designer chooses defence  $|\mathcal{D}| = 0, 1$  or  $n$ . In case  $|\mathcal{D}| = 0$ , a variety of networks – including the empty network and a  $(k+1)$ -connected network – can arise. In case  $|\mathcal{D}| = 1$  the network is a star with a protected center. In case  $|\mathcal{D}| = n$  the network is either empty or minimally connected (a tree).*
2. *The Adversary chooses a separating cut if  $(g, \mathcal{D})$  permits such a cut. When  $(g, \mathcal{D})$  permits no separating cuts, every cut yields the same payoff to the Adversary and is optimal.*

Suppose that  $(g, \mathcal{D})$  is an equilibrium strategy of the Designer and  $|\mathcal{D}| = d > 0$ . We will show that either  $d = 1$  and  $g$  is a star with protected center or  $d = n$  and the network is either empty or a tree. The proof is constructive.

Let  $C_1, \dots, C_m$  be the components of  $g$  and  $g_1, \dots, g_m$  the subnetworks of  $g$  over these components. Suppose, without loss of generality, that component  $C_1$  contains a protected node (at least one such component must exist, since  $d > 0$ ). A component  $C_i$  contains at least  $|C_i| - 1$  links. Starting from  $g$  and keeping  $d$  constant, we construct a network  $g'$  with defence  $\mathcal{D}'$  as follows:

- Convert  $g_1$  into a star network  $g'_1$  with a protected node being the center.
- From each of the components  $C_2, \dots, C_m$  remove all but one node and connect each the removed nodes to the center of  $g'_1$ .
- If feasible, move defence from protected nodes in one-node components to unprotected nodes in the newly created star  $g'_1$ , thus obtaining a new defence,  $\mathcal{D}'$ .

Observe that  $g'$  has  $m$  components as does  $g$ , component  $C'_1$  contains  $n - (m - 1)$  nodes, while all the components  $C'_2, \dots, C'_m$  contain exactly one node. The number of links in  $g'$  is (weakly) smaller than the number of links in  $g$  (with equality only in the event that all components of  $g$  were minimally connected, i.e. trees). The value of the network  $g'$  is larger than the value of the network  $g$  as  $f(\cdot)$  is increasing and convex and  $f(0) = 0$ . Finally, any  $k$ -cut  $X$  applied to  $g'$  causes (weakly) less damage as compared to the cut on network  $g$  as it does not disconnect any paths between non-attacked nodes. Thus the pair  $(g', \mathcal{D}')$  yields a (weakly) higher payoff than  $(g, \mathcal{D})$ .

There are two cases to be considered corresponding to  $d = 1$  and  $d > 1$ .

**Case  $d = 1$**  In this case only the ‘center’ of the component  $C'_1$  is protected. As  $f$  is convex, it is optimal for the Adversary to attack component  $C'_1$  first. So  $(g', \mathcal{D}')$  dominates  $(g', \emptyset)$  only if  $|C'_1| > k + 1$ . As this is an optimal outcome, it follows that the marginal value of the last periphery node,  $n - (m - 1)$ , is greater than the cost of link  $c_L$ . It now follows from the convexity of  $f(\cdot)$  that linking an additional single node to the center of  $g'_1$  is strictly profitable. Iterating, we conclude that if  $d = 1$ , then the optimal network is a center-protected star.

**Case  $d > 1$**  The convexity of  $f$  implies that all the nodes must be defended and the network must be connected. First, as  $f(\cdot)$  is increasing and convex, the Adversary will start by attacking unprotected periphery nodes (if any) in component  $C'_1$ . Again, due to the convexity of  $f$ , it is better to protect a periphery node in component  $C'_1$  rather than a node in some other component. The convexity of  $f$  implies that marginal returns from protecting additional periphery nodes is increasing while the cost of protection is linear. Thus payoff to the Designer is strictly increased by protecting all periphery nodes in  $C'_1$ . Arguments analogous to those used in the case of  $d = 1$  imply that if there are singleton nodes with protection, then attaching them to the center of  $g'_1$  will strictly increase payoff to the Designer as well.

Finally, consider the situation in which all nodes from  $g'_1$  are protected and all singleton isolated nodes are not protected. If this is optimal, then the cost of linking and protection,  $c_L + c_D$ , is smaller than the marginal value  $-f(|C'_1|) - f(|C'_1| - 1)$  – of doing so. Convexity of  $f$  implies that the marginal value of adding an extra periphery node and protecting it is strictly larger, while the cost is still  $c_L + c_D$ . It follows that the star network with all protected nodes strictly payoff dominates configuration  $(g', \mathcal{D}')$ . Observe finally that the payoff in any tree with all nodes protected is equal. This completes the argument.

We now discuss the architecture of equilibrium networks when defence size  $|\mathcal{D}| = 0$ .

When  $k = 1$ , the equilibrium network is either empty or a cycle containing all nodes. It is not profitable to have more than  $n$  links since a cycle guarantees the maximal payoff  $f(n - 1)$  in the face of attack  $k = 1$ . A network with positive number of links less than  $n$  is not optimal due to the convexity of  $f$ . When budget of the Adversary is  $k = n - 2$ , the equilibrium network is either empty or the complete network: an (non-empty) incomplete network can be disconnected by the Adversary with budget  $k = n - 2$ , so depending on the costs of linking  $c_L$  the Designer will choose either the empty or the complete network. This completes the proof of the result. ■

Let us summarize what we have learnt about optimal defence and design of infrastructure networks. If defence is relatively cheap, it is best to protect a single node and create a hub-spoke network. By contrast, if defence is relatively costly, then it is best to economize on defence and instead to create a dense network, thereby minimizing the disruption caused by the elimination of some nodes of the network by the adversary. Chapter 5 on infrastructure shows that airlines, railways, and roads exhibit elements of hub-spokes. Our theoretical results point to the robustness of the such networks from a security perspective.

## 7.4 Protecting Networks against Contagious Threats

Our daily life, economic vitality, and national security depend on a stable, safe, and resilient cyberspace. We rely on this vast array of networks to communicate and travel, power our homes, run our economy, and provide government services. United State Department of Homeland Security (DHS)

Connections between individuals, cities, countries and computers facilitate the exchange of goods, resources and information and generate value. However, these connections may serve as a conduit for the spread of damaging attacks. The Internet reflects this tension clearly. Connectivity facilitates communication but is also used by hackers, hostile governments and firms, and ‘botnet’ herders to spread viruses and worms which compromise user privacy and jeopardize the functioning of the entire system. In this section, we will study the design and defence of networks in the face of threats that are contagious and that spread through connections of a network. We start with a brief discussion of cyberattacks.

Perhaps the first known instance of a worm that exploits programming weakness and the interconnections of the internet is the *Morris Worm*. The Morris Worm was launched in 1988 by Robert Morris a graduate student at Cornell University (USA), and appears to have infected around 10% of the then existing internet of roughly 60 thousand computers. We

next present examples of cyberattack that use weaknesses in computer programming and connections across the internet to compromise the functioning of physical infrastructure.

- Ransomware is a type of malicious software that infects a computer and restricts users' access to it until a ransom is paid to unlock it. We present one example of ransomware to illustrate how it works. The Colonial Pipeline transports gasoline, diesel, jet fuel and other refined products from the Gulf Coast to Linden, N.J., and provides roughly 45% of the fuel for the US East Coast. On the morning of May 7, 2021, an employee found a ransom note from hackers on a control-room computer informing them that the computer access had been blocked and that they would have to pay ransom to gain access. By that night, the company's chief executive officer has to pay the ransom. In return the company received a decryption tool to unlock the systems that the hackers had penetrated. The payment could not prevent a shutdown of the pipeline for six days. The stoppage led to a run on gasoline along parts of the East Coast that pushed prices to the highest levels in more than 6 years and left thousands of gas stations without fuel (Journal [2021]).
- On 23 December 2015, hackers successfully gained access and control of the supervisory data control and data acquisition systems (SCADA) of three energy distribution companies in Ukraine and temporarily disrupted the electricity supply to consumers. This attack led to roughly 230,000 people being without electricity for a period from 1 to 6 hours at the peak of winter.
- Stuxnet is a malicious computer worm first uncovered in 2010 and thought to have been in development since 2005. Stuxnet targets supervisory control and data acquisition systems (SCADA), as in the case of the Ukraine attack, and it caused lasting damage to the nuclear program of Iran. Although there is no official acknowledgement, it is widely believed that the Suxtnet attack on Iran arose out of a collaboration between Israel and USA.

We next turn to identity theft: in 2009, it was estimated that roughly 10 million computers were infected with malware designed to steal online credentials. The annual damages caused by malware is of the order of USD 11 billion in Europe, while in the US the annual costs of identity theft are estimated at USD 2.8 billion (Moore et al. [2009]). One indicator of the economic magnitude of the problem is the valuation of security firms: Intel bought McAfee in 2010 for USD 7.68 billion (bbc.co.uk; 19 August 2010). Finally, we mention the intellectual property theft. This theft could be from research laboratories, private firms and

from universities and it can involve corporate firms, independent operators, as well as national governments. By its nature, the theft is hard to measure and estimates of its value vary greatly.

Using data from actual attacks, in their influential paper on computer security, Stanford, Paxson, and Weaver [2002] identify stealth worms and viruses as the main threats to security in computer networks. They argue that adversaries scan the network to explore its topology and the vulnerabilities of nodes, prior to attack. In the first instance, the objective is to deploy a worm on selected nodes in the network. Deployed worms then exploit communication between nodes to progressively take control of neighboring nodes in the network. The likelihood of capture of a node and the spread of the worm in a network depends on the strength of the worm, the topology of connections, and on vulnerabilities of individual nodes.

The likelihood of successful infection of a host is higher the more sophisticated is the malware and the greater attention is devoted by the Adversary to a node. On the other hand, it is lower the higher the investments in security software and specialized personnel assigned to it. These features of the conflict between security and attacks call for a model of contest on the node.

Deployed worms propagate through the network by progressively taking control of neighboring hosts. The worm replicates and then attaches itself to packages of data sent between connected hosts. The probability that the worm succeeds in infecting neighboring hosts varies with the level of security installations on them and the quality of malware being used. This transmission of a worm via communication links, the (relative) immobility of security installations, and the subsequent conflict between the virus and the security installed on neighboring hosts is the basis of the contagion dynamics. In the next section, we will study the design and defence of networks that are subject to attack and contagion dynamics.

#### 7.4.1 A Model of Attack, Defence and Network Design

The theoretical model is taken from Goyal and Vigier [2014]. In this model there are two players – the Designer and the Adversary – and two stages. In the first stage, the Designer chooses a network and a profile of defence across the nodes. The Adversary observes these choices of the Designer and decides on how to allocate his resources to attack the network.

There is a collection of nodes  $N = \{1, \dots, n\}$ ,  $n \geq 2$ . The Designer chooses links between the nodes and allocates  $d \in \mathbb{N}$  resource units across the nodes. Let  $\underline{d} = (d_1, d_2, \dots, d_n)$  denote the vector of allocated resources, where  $d_i \in \mathbb{N}$  and  $\sum_{i \in N} d_i \leq d$ . The network-

defense pair  $(g, \underline{d})$  defines a strategy for the Designer. The strategy such that  $g$  is a star network and all defense resources are allocated to the central node (a center-protected star) plays a prominent role. We will refer to this particular strategy as a *CP-star*, and denote it  $(g^s, \underline{d}^s)$ .

The model supposes that there is a Designer who can choose links and protection to maximize some collective utility. Clearly, in practice, independent individuals will have varying degrees of freedom to choose links and protection. The analysis will therefore identify ‘first best networks’ that should be seen a benchmark against which more decentralized outcomes can be measured.

The value of a network is as in Assumption 7.1. Given a defended network  $(g, \underline{d})$ , let  $\mathcal{P}$  denote the subset of protected nodes and  $\mathcal{U}$  the subset of unprotected nodes. Further, for  $i \in N$  let  $\mathcal{U}_i \subsetneq \mathcal{U}$  denote the subset of unprotected nodes which can be reached from  $i$  through some path such that each node on that path lies in  $\mathcal{U}$ . Similarly, let  $\mathcal{P}_i \subset \mathcal{P}$  denote the subset of protected nodes which can be reached from  $i$  through some path such that each node on that path lies in  $\mathcal{U}$ .

The Designer moves first and chooses a strategy  $(g, \underline{d})$ . This is observed by the Adversary, who then chooses a strategy  $(\underline{a}, \mathcal{R})$ . The Adversary first allocates  $a \in \mathbb{N}$  units across the nodes,  $\underline{a} = (a_1, a_2, \dots, a_n)$ , where  $a_i \in \mathbb{N}$  and  $\sum_{i \in N} a_i \leq a$ . The matrix  $\mathcal{R} = (r_{ij})_{i,j \in N}$  describes subsequent routing of (successful) attack resources. Row  $i$  in the matrix  $\mathcal{R}$  specifies a ‘pecking order’ on  $\mathcal{P}_i$ : resources on node  $i$  relocate to node  $j_1 \in \mathcal{P}_i$  with  $r_{ij_1} = 1$ . If  $j_1$  has already been captured, resources are relocated to node  $j_2 \in \mathcal{P}_i$  with  $r_{ij_2} = 2$ , and so forth (in other words, we are taking the view that the Adversary has limited resources and cannot costlessly replicate the worm that has captured a node.) The details of the dynamics of attack are described below after a description of the contest on a node.

Attack resources  $a_i$  and defense resources  $d_i$  located on a node  $i$  engage in a *contest* for control of the node. If  $a_i + d_i > 0$  then, following Tullock [1980], we set

$$\text{probability of successful attack} = \frac{a_i^\gamma}{a_i^\gamma + d_i^\gamma} \quad (7.20)$$

where  $\gamma > 0$ . If  $a_i$  is 0 then the probability of successful attack is 0, irrespective of the value of  $d_i$ : a node is safe if it is not under attack. An important property of the contest success function is that it is homogenous of degree 0 in resources, so that scaling up the resources proportionately has no impact on the probability of winning. We assume that all contests are statistically independent, i.e., the probability of winning on a node  $i$  depends only on the resources allocated to it,  $a_i$  and  $d_i$ .

The discrete-time dynamics of attack then proceed as follows:

**At time  $t=0$ :** The attack begins with unprotected nodes. For all  $i \in \mathcal{U}$  such that  $a_i > 0$  the Adversary (i) captures  $i$ , (ii) captures  $\mathcal{U}_i$  and, (iii) relocates the  $a_i$  attack resources to node  $j = \arg \min_{k \in \mathcal{P}_i} \{r_{ik}\}$ . In particular, if there is only one element in  $P_i$  then Adversary allocates  $a_i$  resources to that node.

**At time  $t=1$ :** Let  $N^1$  denote the set of un-captured nodes at the beginning of period  $t = 1$  and  $\underline{a}^1$  the allocation of attack resources at that point in time (all attack resources now target protected nodes). A contest takes place at all  $i$  such that  $a_i^1 > 0$ , following the rules defined in (7.20).

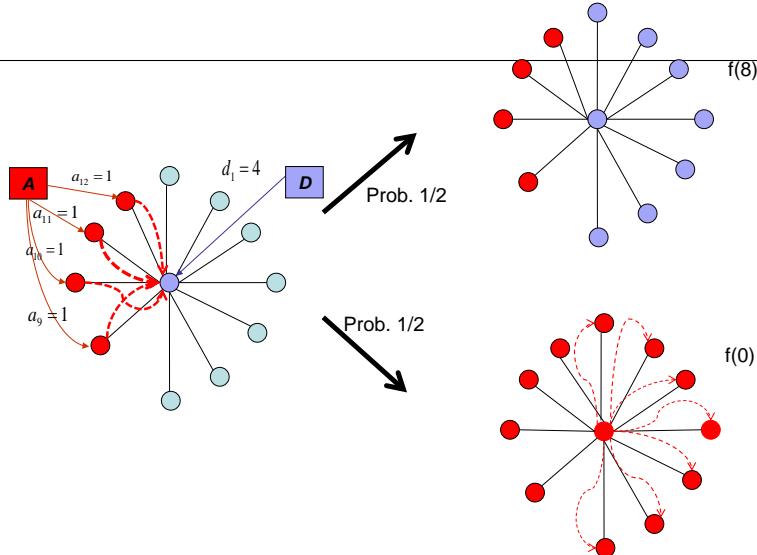

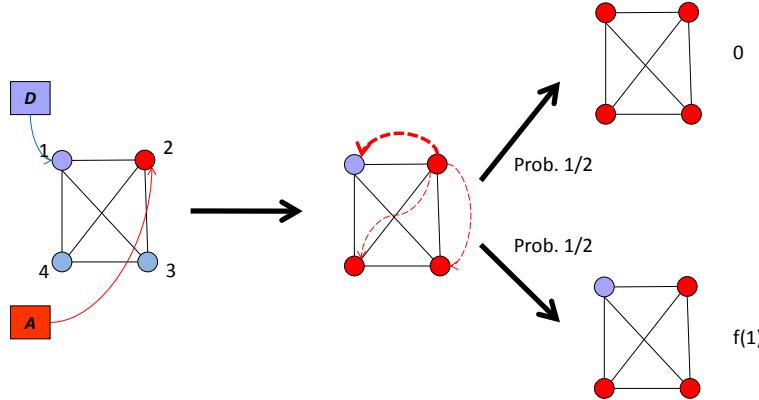

1. If *attack succeeds at  $i$*  then the Adversary (i) eliminates all  $d_i$  defense resources located there, (ii) captures node  $i$ , (iii) captures any remaining node in  $\mathcal{U}_i$  and, (iv) relocates the  $a_i^1$  attack resources to node  $j = \arg \min_{k \in \mathcal{P}_i \cap N^2} \{r_{ik}\}$ . If  $\mathcal{P}_i \cap N^2 = \emptyset$  then the  $a_i^1$  attack resources are eliminated.
2. If *defense succeeds at  $i$*  then the Designer eliminates all  $a_i^1$  attack resources located there.

**At time  $t=2$ :** Let  $\underline{a}^2$  denote the allocation of attack resources at the beginning of period  $t = 2$ , and  $N^2$  the set of un-captured nodes. If  $\underline{a}^2 = \underline{0}$  then the process terminates. Otherwise, it proceeds following the rules laid out as in period  $t = 1$  and this continues until no nodes remain.

To develop an appreciation of the dynamics of conflict it is helpful to locate them in specific network with resource configurations. Figure 13 considers the dynamics in a star network. The number of nodes is 12, and resources of Adversary and Designer are both equal to 4. The Designer allocates all 4 units to the central node, while the Adversary allocates 1 unit each to four unprotected peripheral nodes. These attack units capture the 4 peripheral nodes and then simultaneously attack the central node. Given Tullock contest, the Designer and Adversary face an equal probability of winning. If the Designer wins the contest, the attack resources are eliminated. There are 8 surviving connected nodes. In case the Adversary wins, the central node is captured and the defense resources are eliminated. The attack resources then capture the remaining 7 undefended peripheral nodes. The expected payoff of the Designer is

$$\frac{1}{2}f(8) + \frac{1}{2}f(0) = \frac{1}{2}f(8) \quad (7.21)$$

Figure 14 illustrates the dynamics of conflict in the complete network, with  $n = 4$  and  $a = d = 1$ . The Designer allocates his resource to node 1, while the Adversary allocates his

Figure 7.14: Dynamics of attack in a CP-star:  $n = 12, a = d = 4$ .Figure 7.15: Dynamics of attack in a complete network:  $n = 4, a = d = 1$ .

to node 2. Since node 2 is undefended, it is captured at time  $t = 0$ , followed by undefended nodes 3 and 4 which are linked to it. At time  $t = 1$ , the attacking unit then spreads to node 1. Given the Tullock contest function, Designer and Adversary win with equal probability. The expected payoff of the Designer is  $f(1)/2$ .

Let us now define the resulting networks, once conflict has played out. Note that by construction, in every round with both attack and defence resources, one of the two must decline strictly (by at least one unit). Thus the dynamics can last at most  $a + d$  rounds. Given a defended network  $(g, \underline{d})$  and attack strategy  $(\underline{a}, \mathcal{R})$ , the dynamics of conflict described above yield a probability distribution on  $\mathcal{G}(g)$ . Let  $\mathbb{P}(g' | g, \underline{d}, \underline{a}, \mathcal{R})$  denote the probability that the sub-network  $g'$  is the residual network of surviving nodes after all conflicts have ended. Define  $\Pi^e(g, \underline{d}, \underline{a}, \mathcal{R})$  to be the expected payoff of the Designer given defended

network  $(g, \underline{d})$  and attack strategy  $(\underline{a}, \mathcal{R})$ . Then

$$\Pi^e(g, \underline{d}, \underline{a}, \mathcal{R}) = \sum_{g' \in \mathcal{G}(g)} \mathbb{P}(g'|g, \underline{d}, \underline{a}, \mathcal{R}) \Pi(g'). \quad (7.22)$$

Let  $\bar{\Pi}^e(g, \underline{d})$  denote the minimum expected payoff of the Designer playing strategy  $(g, \underline{d})$ :

$$\bar{\Pi}^e(g, \underline{d}) = \min_{\underline{a}, \mathcal{R}} \Pi^e(g, \underline{d}, \underline{a}, \mathcal{R}).$$

**Definition 7.1.** A defended network  $(g, \underline{d})$  is optimal if  $\bar{\Pi}^e(g, \underline{d}) \geq \bar{\Pi}^e(g', \underline{d}')$  for all defended networks  $(g', \underline{d}')$ .

We start with the optimal architecture and defense at the level of a single component. Then we consider the pure problem of number of components, in the absence of any defense resources. Finally, we take up the optimal defended network when defense allocation, architecture of individual components, and the number of components are all decision variables for the Designer. Discrete optimization problems are marked by divisibility issues. For simplicity, let us start with the case where the ratio of attack to defence resources is an integer,  $a/d \in \mathbb{N}$ . The case  $a < d$  is taken up subsequently.

Consider the set of connected networks. A defended core network consists of (i) a protected set  $x \in \{1, \dots, d\}$  of nodes that constitute a connected sub-graph and (ii) the  $n - x$  unprotected nodes (if any exist) each have a single link to a protected node. We will show that such a *defended core network is optimal in the class of connected networks*.

The first step is to show that it is optimal for protected nodes to constitute a connected sub-graph. Suppose that there is a pair of protected nodes that is only connected via a path of unprotected nodes. Then, given our assumptions on conflict and contagion, adding a link between this pair of protected nodes is without loss for the Designer. Thus we can restrict attention to defended networks in which the set of protected nodes constitute a connected sub-graph.

Next we rule out a path of unprotected nodes between any two protected nodes. Observe that, by the previous step, these unprotected nodes play no role in connecting  $i$  and  $j$  (or any other pair of protected nodes). So the alternative network in which these unprotected nodes on the path between  $i$  and  $j$  have a single link to node  $i$  induces no loss for the Designer. Indeed, in the new network, these unprotected nodes' survival is contingent only on node  $i$ 's survival, whereas in the old network it was contingent on the survival of both nodes  $i$  and node  $j$ . So any outcome in which node  $j$  is captured but node  $i$  is not induces a strict gain for the Designer.

Finally, we show that a link between two unprotected nodes is never optimal. Suppose that  $i$  and  $j$  are unprotected and have a link between them. By the previous step it must be the case that these unprotected nodes are linked to the same protected node (say)  $k$ . Let  $I$  denote the set of unprotected nodes connected to  $k$  through a path of unprotected nodes. Given the dynamics of conflict spelled out earlier, it is then immediate that the alternative network in which all nodes in  $I$  have a single link to node  $k$  yields a (weakly) higher payoff to the Designer as compared to the original network (because connecting them can only result in some being infected at  $t = 0$  that would otherwise only be infected at  $t = 1$  if the protected node was infected).

The CP-star is an example of a defended core network. Faced with the CP-star the Adversary's best response is to allocate one resource unit to exactly  $a$  periphery nodes. The  $a$  periphery nodes are captured and the attack resources then mount a concerted attack on the central node. If attack succeeds on the central node, all remaining periphery nodes are subsequently captured. If attack fails, the Designer is left with  $n - a$  connected nodes. The expected payoff of the Designer in a CP-star is

$$\bar{\Pi}^e(g^s, \underline{d}^s) = \frac{d^\gamma}{d^\gamma + a^\gamma} f(n - a). \quad (7.23)$$

To develop intuition for the nature of optimal networks next consider a defended network with two hubs, as depicted in Figure 7.8. There are 12 nodes in all and  $a = d = 4$ . The network is a core-periphery network with two hubs: the Designer allocates 2 units of defense to each hub. In the mimic strategy, the Adversary allocates 2 resource units to peripheral nodes connected to one hub and 2 resource units to peripheral nodes connected to the other hub. In the first instance, the Adversary captures these 4 peripheral nodes. The resources then target their respective hub nodes.

There are four possible outcomes of this attack strategy: either both hubs survive, both hubs are captured or one hub survives and the other is captured. Given the equal resources engaged in contests, it follows that the first two outcomes each arise with probability 1/4. The two outcomes define terminal states of the dynamics, represented at the top and the bottom end of Figure 15. There is a probability 1/2 that one of the hubs survives and the other is captured (in the initial period). This is represented in the middle of the Figure 15. Capture of a hub triggers the capture of its respective peripheral nodes. All attack resources then target the surviving hub, inducing a second round of contests. With probability 1/2 the hub survives the attack, and with probability 1/2 it is captured. If the hub is captured then that triggers the capture of the remaining peripheral nodes.

To summarize, in the two-hub protected network, the probability  $P$  on surviving nodes

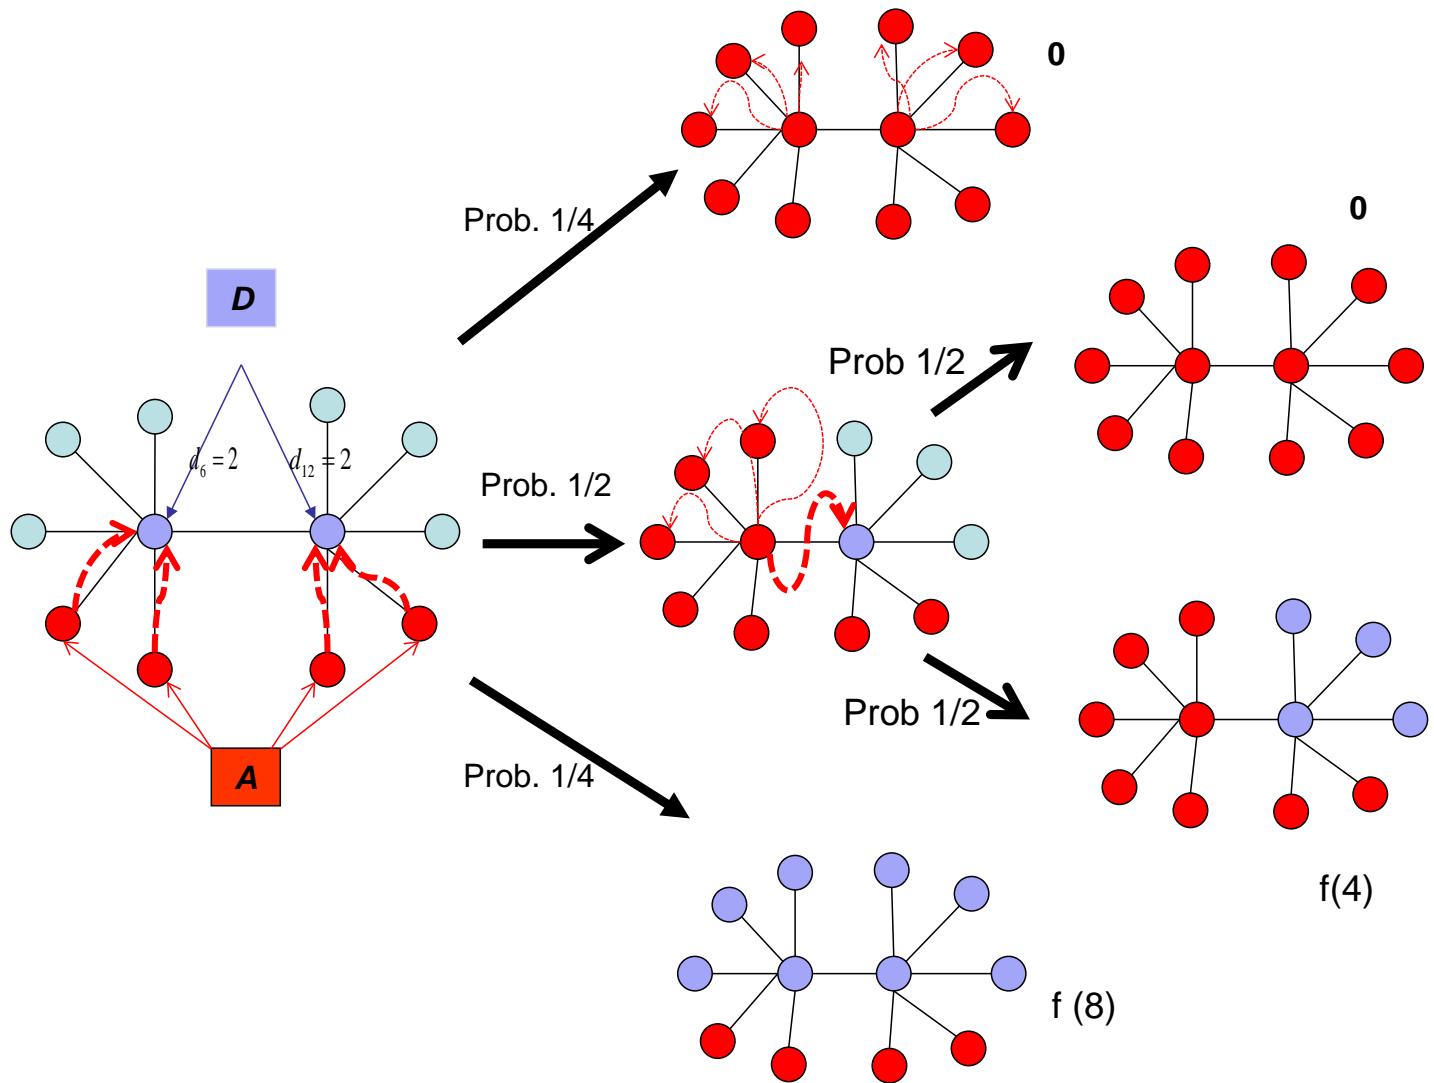

Figure 7.16: Attack and defence on a two-hubs network:  $n = 12, a = d = 4$ .

is as follows:

with probability 1/2 all nodes are captured,  
 with probability 1/4 four nodes survive  
 and with probability 1/4 eight nodes survive.

Consider the outcomes under the CP-star network: the Adversary optimally chooses to first capture 4 peripheral nodes and then mount an attack on the hub. Thus either all nodes are captured or none are captured. The probability of outcomes  $P''$  is as follows:

with probability 1/2 all nodes are captured  
 with probability 1/2 eight nodes survive.

Thus we have shown that the minimum payoff to the Designer from a CP-star payoff is larger than the payoff from two-hubs protected network for the Designer. Let us compute the expected payoffs to the Designer for a specific network value function:  $f(n) = n^2$ . The expected payoff to the Designer from the two-hubs network is

$$\frac{1}{2}0 + \frac{1}{4}16 + \frac{1}{4}64 = 20 \quad (7.24)$$

The expected payoffs to the Designer for the CP-star network are:

$$\frac{1}{2}0 + \frac{1}{2}64 = 32 \quad (7.25)$$

The computations for the example with CP-star and two-hubs network rely on a particular structure of attack strategy: the Adversary first captures  $a$  unprotected nodes and then launches concerted attacks on respective protected hubs nodes. This construction underlies the notion of a *mimic* attack strategy.

Let  $a = xd$ , where  $x \in \mathbb{N}$ , is an integer, and consider a defended network  $(g, \underline{d})$ . Label nodes in  $\mathcal{P}$  by  $i_1, i_2, \dots, i_k$ . For each node in  $\mathcal{P}$ , the Adversary allocates one resource unit to exactly  $x$  times  $d_i$  nodes in  $\mathcal{U}_i$  – the unprotected neighbourhood of  $i$  – thereafter relocating each of these resource units to node  $i$ . This attack strategy is referred to as a mimic strategy as it amounts to attacking every protected node with attack resources that ‘mimic’ the overall ration  $a/d$ .

We make the notion of mimic strategy more formal as follows. Given defended network  $(g, \underline{d})$ , say that  $(\underline{a}, \mathcal{R})$  *mimics* defence if and only if there exists a set of  $a$  distinct nodes,  $\{j_1, \dots, j_a\}$ , such that:

1.  $\{j_1, \dots, j_{\frac{a}{d}d_{i_1}}\} \in \mathcal{U}_{i_1};$

- 
- $\{j_{\frac{a}{d}d_{i_1}+1}, \dots, j_{\frac{a}{d}d_{i_1}+\frac{a}{d}d_{i_2}}\} \in \mathcal{U}_{i_2}; \dots;$   
 $\{j_{\frac{a}{d}d_{i_{k-1}}+1}, \dots, j_{\frac{a}{d}d_{i_{k-1}}+\frac{a}{d}d_{i_k}}\} \in \mathcal{U}_{i_k}.$   
 2.  $r_{j_s i_1} = 1, \forall s \text{ s.t. } s \leq \frac{a}{d}d_1;$   
 $r_{j_s i_2} = 1, \forall s \text{ s.t. } \frac{a}{d}d_1 + 1 \leq s \leq \frac{a}{d}d_1 + \frac{a}{d}d_2; \dots;$   
 $r_{j_s i_k} = 1, \forall s \text{ s.t. } \frac{a}{d}d_{k-1} + 1 \leq s \leq \frac{a}{d}d_{k-1} + \frac{a}{d}d_k.$

Part (i) refers to the initial allocation of attack resources and part (ii) pertains to the moves from initial success to subsequent protected nodes. Roughly speaking, successful attacks combine at the same protected node to maximize prospects of successful attack.

Figure 13 and Figure 15, with attack and defence resources both equal to 4, both offer instances of a mimic attack strategy.

Mimic strategies do not always exist. To see this, consider a defended core-periphery network with twelve nodes,  $n = 12$ , and attack and defence resources equal to 4,  $a = d = 4$ : the network has two hubs, with the first hub being linked to 9 peripheral nodes and the second hub being linked to one peripheral node. If the Designer allocates 2 units to each hub, then no attack strategy can mimic defense on this defended network.

**Remark.** Given defended network  $(g, \underline{d})$ , a mimic attack strategy exists if and only if the following condition holds:

$$\left| \bigcup_{s=1}^{k'} \mathcal{U}_{i_s} \right| \geq \frac{a}{d} \sum_{s=1}^{k'} d_{i_s} \quad \forall \{i_1, i_2, \dots, i_{k'}\} \subset \mathcal{P} \quad (7.26)$$

We are now ready to state the following result:

**Proposition 7.5.** Consider the game with contagious attacks. Assume that network value is given by Assumption 7.1,  $a/d \in \mathbb{N}$ ,  $n > a + 1$  and consider the class of connected networks. Then the optimal network is either the CP-star or a network that precludes a mimic strategy.

Consider a defended network  $(g, \underline{d})$  other than a CP-star, that admits a mimic strategy. We show that there exists an attack strategy  $(\underline{a}, \mathcal{R})$  that keeps the payoff of the Designer strictly below the payoff that is guaranteed from the CP-star. Suppose the defended network  $(g, \underline{d})$  contains  $\mathcal{P} = \{i_1, \dots, i_k\}$  protected nodes. Clearly, if  $k = 1$ , then there must exist two nodes in  $\mathcal{U}$  with a link between them. Allocating one resource unit to each of these unprotected nodes guarantees the elimination of  $a + 1$  nodes. As there is only one defended node and the networks are connected, under our attack dynamics, the probability of successful attack on the defended node is equal in the two defended networks (the given network and the CP-star). This means that the expected payoff to Designer

$$\Pi^e(g, \underline{d}, \underline{a}, \mathcal{R}) \leq \frac{d^\gamma}{d^\gamma + a^\gamma} f(n - a - 1) < \frac{d^\gamma}{d^\gamma + a^\gamma} f(n - a) = \bar{\Pi}(g^s, \underline{d}^s). \quad (7.27)$$

Next consider the case  $k \geq 2$  defended nodes. Construct the sequence of sets  $(N_{i_s})_{1 \leq s \leq k}$  recursively as follows:

$$N_{i_1} = \mathcal{U}_{i_1}; N_{i_2} = \mathcal{U}_{i_2} - N_{i_1}; \dots; N_{i_k} = \mathcal{U}_{i_k} - \bigcup_{s=1}^{k-1} N_{i_s} \quad (7.28)$$

Let  $n_{i_s} = |N_{i_s}|$ ,  $s = 1, \dots, k$ . Note that by connectedness of  $g$ ,  $\bigcup_{s=1}^k N_{i_s} = \mathcal{U}$ .

Suppose first that  $n_{i_s} \geq \frac{a}{d} d_{i_s}$ ,  $\forall s$ , and attack mimics defense in such a way that one resource unit is allocated to exactly  $\frac{a}{d} d_{i_s}$  nodes in  $N_{i_s}$ , each of these resource units thereafter relocating to node  $i_s$ .

Observe that, since  $N_{i_s} \subset \mathcal{U}_{i_s}$ , a necessary condition for nodes in  $N_{i_s}$  to survive the attack is that  $i_s$  itself survives the attack. Observe that a protected node  $i_s$  may be attacked through the attack resources allotted to nodes within  $\mathcal{U}_{i_s}$  or by resources originally allocated to an attack using resources that come via a successful attack on some other protected node  $i'_s$ . It therefore follows that the distribution of the total number of surviving nodes is first order stochastically dominated by the distribution of

$$(n_{i_1} + 1 - a_{i_1})I_1 + \dots + (n_{i_k} + 1 - a_{i_k})I_k, \quad (7.29)$$

where  $\{I_1, \dots, I_k\}$  denotes a set of independent Bernoulli random variables with  $\text{Prob}(I_s = 1) = \frac{d^\gamma}{d^\gamma + a^\gamma}$ ,  $\forall s \in \{1, \dots, k\}$ . This dominance relation holds because in the latter expression we are ignoring indirect attacks from successful attacks on other protected nodes. By way of illustration, note that in the example with two-hubs above, the probability distribution of surviving nodes after a direct attack,  $P'$  (directly eliminated nodes plus those unprotected nodes that are neighbours of the attacked nodes), is as follows: with probability 1/4 all nodes are captured, with probability 1/2 four nodes survive, and with probability 1/4 eight nodes survive. This distribution first order stochastically dominates the distribution of actual surviving nodes in the two-hubs network, that is given by  $P$ .

Since the network value function  $f$  is increasing we have

$$\Pi^e \leq \mathbb{E}[f\left(\sum_{s=1}^k (n_{i_s} + 1 - a_{i_s})I_t\right)].$$

The final step is to note that:

$$\mathbb{E}[f\left(\sum_{s=1}^k (n_{i_s} + 1 - a_{i_s}) I_s\right)] < \mathbb{E}[f\left((\sum_{s=1}^k n_{i_s} + 1 - a_{i_s}) I_1\right)] = \mathbb{E}[f\left((n - a) I_1\right)].$$

Let us discuss the derivation of this equation. First note that the probability distribution of eventually surviving nodes under the CP-star is a mean preserving spread of the distribution of surviving nodes under  $(n_{i_1} + 1 - a_{i_1})I_1 + \dots + (n_{i_k} + 1 - a_{i_k})I_k$ . By way of illustration note that, in the CP-star example, the probability distribution of surviving nodes is as follows: with probability 1/2 all nodes are captured, with probability 1/2 eight nodes survive. This distribution is a mean preserving spread of the distribution of surviving nodes  $P'$ . This observation combined with the assumption that the network value function  $f(\cdot)$  is increasing and convex yields the strict inequality.

■

Proposition 7.5 suggests that defended networks violating (7.26) may be attractive for the Designer, since they preclude the use of mimic strategies by the Adversary. Observe, for instance, that in a setting where  $n = 3$ ,  $f(n) = n^2$  and  $a = d = 2$ , a CP-star yields expected payoff 1/2 for the Designer. On the other hand, the complete network with two protected nodes (which violates (7.26)) yields at least 1. This shows that in some circumstances defended networks violating (7.26) may dominate a CP-star. It is possible to show that the attractiveness of networks that do not admit a mimic strategy depends on the number of nodes,  $n$ . Indeed, as  $n$  grows, we can generalize the arguments presented in Proposition 7.5 to show that CP-Protected networks are approximately optimal, across all possible defended networks. This point is further developed in a question at the end of the chapter.

Observe that we assume that resources of the Adversary are larger than the resources of the Defender,  $a \geq d$ . When  $a < d$ , the Designer may find it attractive to create a spread out network and to allocate his resources across more nodes. This is perhaps most easily seen in an example. Suppose that  $a = 1$ ,  $f(n) = n^2$ . The coefficient of conflict  $\gamma$  is very small, so that the probability of successful attack is close to 1/2, irrespective of the resources allocated to a node. Suppose next that the Adversary has only one unit  $a = 1$ , while the Designer has two units,  $d = 2$ . In a CP-star, the best the Adversary can do is to use the mimic strategy and target a periphery node, this means that the expected payoff of the Designer is roughly  $f(n - 1)/2$ . In a two-hubs network with both hubs protected, the best the Adversary can do is to target a periphery node. The probability of eliminating a single hub is 1/2, and the probability of eliminating both hubs is 1/4, so the expected payoff to

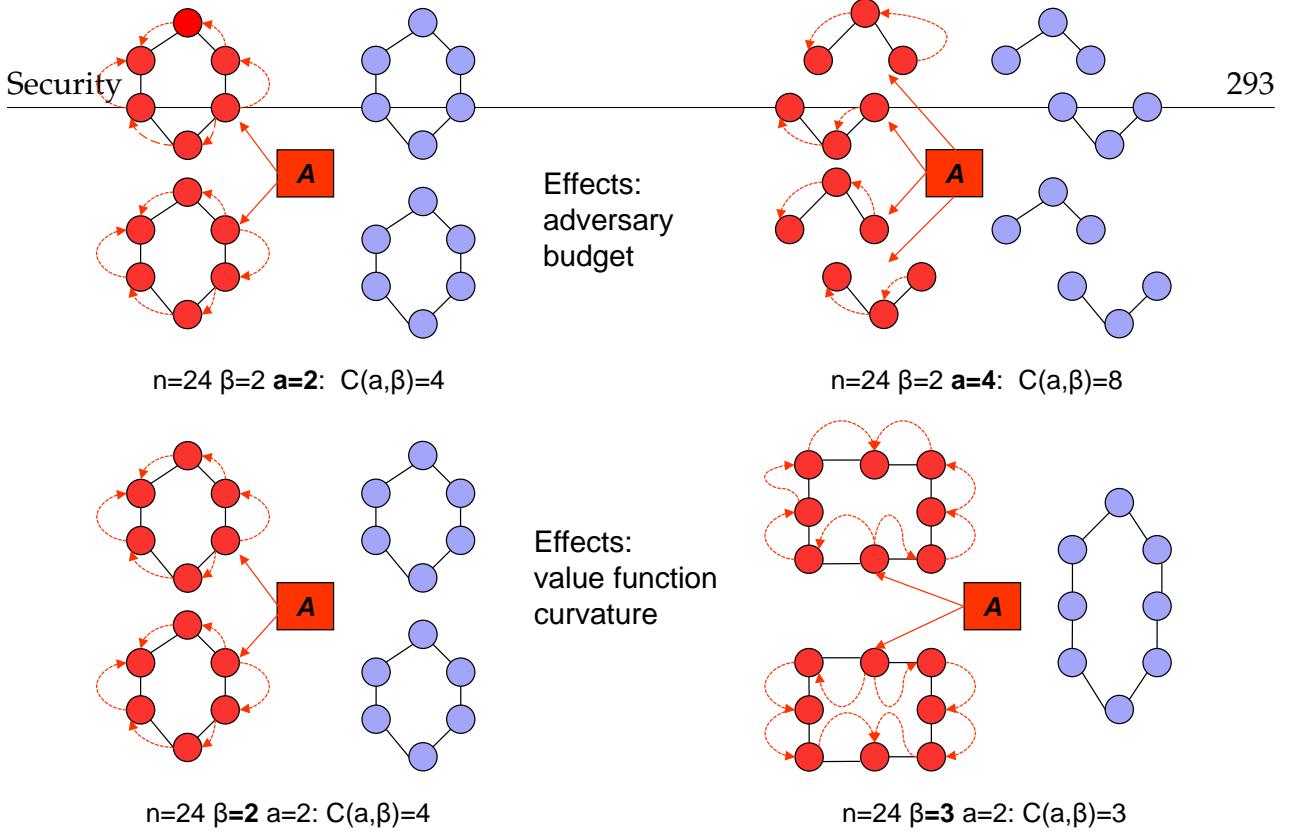

Figure 7.17: Optimal number of components:  $f(m) = (m)^\beta$ ,  $n = 24$ .

the Designer is roughly  $f(n - 1)/2 + f(n - 2)/4$ . It is clear that the two-hubs network dominates the CP-star.

So far we have restricted attention to connected networks: our final remark concerns the optimal number of components. Recall the pressure toward connectivity arises from the convexity of the network. This convexity is also central to an understanding of the desirable number of components. To see this, it is helpful to start with the case where  $d = 0$  and to consider network value functions  $f(n) = n^\beta$ , with  $\beta > 1$ . We interpret  $\beta$  as a measure of the convexity of the network value function. As unequal components will lead the Adversary to target the larger ones, it is better for the Designer to choose equal size components. A question at the end of the chapter works through this intuition. The exact number of components will depend on the  $\beta$  and on the magnitude of the Adversary's resources. To get a sense of these effects, Figure 7.17 illustrates the optimal number of components as we vary the attack resources and the degree of convexity. Consider the effects of attack resources. Given  $\beta = 2$ , the optimal number of components increases from 4 to 8, as we increase attack resources from 2 to 4. Next, consider the effects of convexity. Given attack resources  $a = 4$ , the optimal number of components falls from 4 to 3 as we raise the curvature by moving from  $\beta = 2$  to  $\beta = 3$ .

Let us summarize what we have learnt about optimal defence and design of networks in

the context of attacks that can spread through connections in the network. We have shown that so long as attack resources exceed defence resources, a highly centralized network with the protected center is optimal. This observation is consistent with the practice of traffic monitoring at key nodes by security personnel (Anderson [2020]). The optimality of a single protected node rests on the relative value of attack and defence resources and the convexity of the network value function. If the network value function is not always convex or the Defender has more resources than the Adversary then multiple hub-nodes or multiple components can be optimal.

## 7.5 Reading Notes

The problem of network defence has traditionally been studied in operations research, electrical engineering and computer science, for introduction and overviews of this research see e.g., Alpcan and Başar [2011], Aspnes, Chang, and Yampolskiy [2006], Smith [2008] and Grötschel, Monma, and Stoer [1995].

At a high level, the network interdiction problem involves an adversary intervening to damage links or nodes in order to compromise the flow in a network. Early studies of the network interdiction problem by Wollmer [1964] and Cunningham [1985] study the problem of network design and defence in which the conflict is on links. For instance, a link is eliminated if the Adversary assigns more resources than the Designer (thus conflict is modeled as an all-pay auction). The models presented in the paper build on this formulation through a consideration of contests on nodes (the all-pay auction is a special case and corresponds to the situation when the coefficient of the contest function becomes very large). Network interdiction remains a very active field of study. Gueye, Walrand, and Anantharam [2010] and Laszka, Szeszlér, and Buttyán [2012] study a model in which the network operator chooses a spanning tree of a given network to route messages, and simultaneously, the attacker chooses an edge to be removed. Aspnes, Chang, and Yampolskiy [2006] (and the literature that follows them) study protection choices by nodes faced with a viral infection; upon infecting a node, the virus travels through the network. This is related to the study of contagious threats presented in section 7.4.

The subject of network robustness has also received attention in the statistical physics and network science literatures. In an influential article, Albert et al. [2000] argue that highly unequal networks with hubs are vulnerable to strategic attacks since potential adversaries can significantly reduce their functionality by removing only a few hub nodes. By contrast, the theoretical models presented in this chapter bring out the attractiveness of these networks from the perspective of threats and security. How can we reconcile these

perspectives? The contrasting results offer complementary perspectives and highlight the importance of defence resources and the convexity of the network value function.

In these literatures, connectivity of the network is the goal. The network value function introduced in section 7.2 assumes that the value of a network is sum of the value of its components and that the value of a component is increasing and convex in its size. This formulation generalizes the idea of connectivity. The component additive and convex and increasing function builds on ideas in the research on communication networks, e.g., Metcalfe's and Reed's Law.

Sections 7.3.1 and 7.3.2 study of the two player conflict problem of optimal design and defence. For news coverage of the effects of natural disasters and human attacks on infrastructure networks, see Eun [2010], Kliesen [1995], India Today [2011] and Luft [2005]. Early theoretical work in this field includes Bier et al. [2006], Clark and Konrad [2007] and Kovenock and Roberson [2012]. This two stage model with observability of first stage actions is consistent with the approach in the large engineering literature on security and networks, see e.g., Tambe [2011] and Alpcan and Başar [2011]. The theoretical models are taken from Dziubiński and Goyal [2013] and Dziubiński and Goyal [2017]. The discussion on cybersecurity draws on Goyal and Vigier [2014] and Perlroth [2021]. Also see Schneider [2022] and Gordon and Rosenbach [2022] for discussion on cybersecurity as it relates to international relations.

The results on protected central nodes are related to the well known and widely studied 'key player' problem: what nodes should be targeted to attain some goal? For an introduction to 'key player' problems see Borgatti [2003] and Borgatti [2005]. For an early contribution to the study of key problems in economics, see Ballester, Calvó-Armengol, and Zenou [2006]. Another chapter in the book takes up the general problem of targeting. The discussion in the present chapter suggests that for the problem of attack and defence, the 'key players' are nodes that lie in separators and transversals. These nodes are typically distinct from nodes that maximize familiar notions of centrality. For a detailed discussion of differences the reader is referred to Dziubiński and Goyal [2017].

In section 7.3 we consider a two person game. There is also a strand of work that studies decentralized defence and linking by individual nodes. In section 7.3.1 we studied an example of decentralized defence and it provided us a first impression of the challenges of decentralization in security problems. We have not discussed decentralized choice of links (with or without contagion) for reasons of space. The interested reader is referred to Acemoglu, Malekian, and Ozdaglar [2016b], Goyal, Jabbari, Kearns, Khanna, and Morgenstern [2016] and Cerdeiro, Dziubiński, and Goyal [2017] for further exploration of this subject.

I am grateful to Ruohan Qin, Mikhail Safronov, Marcin Dziubinski, Fulin Guo, and

Bryony Reich for useful comments and for pointing out a number of errors in the original draft. I thank Ricky Vohra for suggestions on references.

## 7.6 Questions

1. Consider optimal defence of a given network that is under attack by an adversary. Suppose network value function is  $f(n) = n^2$ . The designer chooses which nodes to protect and observing these choices the adversary decides on which nodes to attack. The cost of defending a node is  $c_D$ , while the cost of attacking a node is  $c_A$ . A defended node cannot be damaged by attack, while an undefended node, if attacked, is eliminated along with its links. Write down the payoffs of the defender and the adversary. Suppose the designer seeks to maximize the value of the residual network net of the cost of defence, while the adversary seeks to minimize the value of the residual network less the cost of attack. Verify the threshold values for costs of defence and attack of the star with four nodes (as in Figure 3 in the chapter).
2. This is a question on the design and defence of networks with contagious attacks as discussed in lecture. Define  $C(a, \beta) = \frac{\beta a}{\beta - 1}$ . Observe that  $C(a, \beta)$  is increasing in the quantity of attack resources,  $a$ , and falling in the parameter of convexity,  $\beta$ . Assume that (A.1) holds,  $d = 0$ , and suppose  $f(n) = n^\beta$ , where  $\beta > 1$ . Show that if  $C(a, \beta) \in \{a + 1, \dots, n\}$  and divides  $n$ , then the unique equilibrium network consists of  $C(a, \beta)$  equal size components.
3. Consider the network design and defence game with contagion attacks as discussed in lecture. Suppose that  $n = 12$ ,  $a = d = 2$ , and the network value function is as follows:

$$f(n) = \begin{cases} n^2 & \text{for } 0 < n \leq 6 \\ 36 + 0.2(n - 6) & \text{for } 6 < n \leq 12. \end{cases} \quad (7.30)$$

Show that two protected hubs network yields a lower expected payoffs to the designer as compared to a center-protected star.

4. Consider the Designer-Adversary game with defence and design of network against stationary attacks. Suppose that units of attack  $1 \leq k \leq n - 2$ , and suppose that network value is component additive and the value of a component is increasing and convex in its size. The designer moves first and chooses the network and the defence of nodes. The adversary observes the choice of designer and then chooses to attack  $k$

nodes. The payoff to the Designer from choosing  $(g, \mathcal{D})$  when the Adversary chooses a cut  $X$  is

$$\Pi^D(\mathcal{D}, X; g) = \Phi(g - (X \setminus \mathcal{D})) - c_L|g| - c_D|\mathcal{D}|. \quad (7.31)$$

where  $c_L$  is cost of links and  $c_D$  is cost of perfectly protecting a node. The payoff to the Adversary is

$$\Pi^A(\mathcal{D}, X; g) = -\Phi(g - (X \setminus \mathcal{D})). \quad (7.32)$$

The objective of the Designer is to maximize his payoff, while the goal of the Adversary is to minimize the value of the residual network. Show that in a (sub-game perfect) equilibrium of this game

- The Designer chooses defence  $|\mathcal{D}| = 0, 1$  or  $n$ . In case  $|\mathcal{D}| = 0$ , a variety of networks – including the empty network and a  $(k+1)$ -connected network – can arise. In case  $|\mathcal{D}| = 1$  the network is a star with a protected center. In case  $|\mathcal{D}| = n$  the network is either empty or minimally connected (a tree).
- The Adversary chooses a separating cut if  $(g, \mathcal{D})$  permits such a cut. When  $(g, \mathcal{D})$  permits no separating cuts, every cut yields the same payoff to the Adversary and is optimal.

5. Consider the Network Defence Game. Suppose that  $n$  is large and that the cost of attack satisfies

$$f(n-2) - f(n-3) < c_A < f(n-1) - f(n-2)$$

- Show that with this cost of attack, the adversary removes 2 nodes from complete network over  $n$  nodes, 1 node from complete network containing  $n-1$  nodes, and does not remove any nodes from complete network containing  $n-2$  or less nodes.
- Suppose that the cost of defence satisfies

$$(f(n) - f(n-2) - f(1))/n < c_D < (f(n) - f(n-2))/n$$

With this cost of defence show that the defender protects all the nodes in a complete network with  $n$  nodes, because  $f(n) - nc_D > f(n-2)$ , (and we know that in a complete network the defender either protects all or no nodes in equilibrium).

- Now consider a network with  $n-1$  nodes in a clique with one node linked to

a single element of the core (let's call it  $i$ ). Show that if such a network is not protected, the adversary will remove node  $i$  only, disconnecting the network into a clique of size  $n - 2$  and a single isolated node. Then show that with the above cost of defence the defender is inactive.

- Complete the argument by showing that payoff to defender is larger in the core-periphery network as compared to the complete network.
6. Albert, Jeong, and Barabási [2000] consider the resilience of connectivity of a network to the removal of nodes. They show that networks with power law degree distribution are robust against random deletion of a fraction of nodes but that they are vulnerable to targeted elimination of a small fraction of most connected nodes. How can we reconcile this result with the result presented in the chapter on the optimality of centre-protected star networks?

# Chapter 8: Intermediaries and Platforms

## 8.1 Introduction

In many markets the benefit of consumers is a function of their ability to communicate with other users on the network. In these markets, network effects are *direct*: the more agents are present on a network, the larger the communication opportunities. Examples of products with direct effects include telephone, fax, email, and online networks such as Facebook and Twitter. In many other markets, it is helpful to think of products as consisting of components and the value of a product is increasing in the number of suppliers of products that are used in combination with the product. In such a market the network effect is said to be *indirect*. Examples of markets with indirect network effects include computer operating systems (Windows or Mac), smart phones, credit card systems (such as Visa and Mastercard), trading intermediaries (such as Amazon and Ebay), and video-game consoles (Playstation and Nintendo). This chapter studies the functioning of markets with such network effects.

We will start with a consideration of direct network effects. As the utility of a product is growing in its user base, as a product gains market share it becomes more and more attractive relative to other competitors. This creates a tendency for such markets to be dominated by a single product. Consumer preference for different products may offset this pressure. We explore the circumstances under which markets are covered by multiple and single firms, respectively. We then take up the issue of technological change in such markets. If a product or a technology is dominant, switching to a new product may entail a switch to a product with a very small user base. This may discourage technological change. We examine the circumstances under which technological change is excessive or too slow and we study price and non-price strategies of firms in such markets.

We then turn to markets with indirect effects. Consider a computer operating system: software developers want to create products for Windows (or for iPhone and Android) because of consumer base. Consumers in turn are attracted to an operating system if it offers a wider range of applications. Similarly people want to hold Visa cards because

they are widely accepted, and merchants want to accept them because most people carry them. Traders want to trade in markets where they can easily find counter-parties and where the market is liquid. Another example is online social networks (Facebook, LinkedIn and Twitter) that bring together individual users and software developers and firms that wish to advertise their products. A third example is a market maker who brings together buyers and sellers, examples include NYSE/Nasdaq exchanges for public equities, eBay or Amazon's e-commerce platforms, Apple's "app store" for developers and consumers, Google's "ad platform" for websites and advertisers. These examples suggest that markets with two-sided or multi-sided network effects are becoming increasingly important.

The chapter will focus on two aspects of a firm's strategy in such markets – pricing and openness. Pricing presents some novel features: for instance, the value to a user on one side of the market will depend on the number of users of the other side of the market. It is not uncommon that consumers are paid to carry a credit card, while merchants pay the credit card for the transaction. This motivates a study of the economic considerations that determine optimal prices on different sides of a market.

We next take up the notion of openness: a firm decides on how many sides of a market it is active. For instance, Apple markets both its hardware and its operating system, while Microsoft is focused on producing its operating system and allows independent producers to supply the hardware (this contrast has slightly changed with the launch of the Surface range of products). In this sense, Microsoft may be seen to be more open than Apple. We discuss the considerations that are involved in the choice of number of sides that a firm should be active. Another aspect of openness relates to competing platforms: should a firm seek to be compatible or incompatible with other firms (or partially compatible)?

An important and recurring theme throughout the chapter is the dynamics of competition between intermediaries. The chapter closes with an experimental examination of this competition. We present models of trading in which traders need connections to trade. Connections are costly, so that leads traders to economize on links. This in turn gives rise to intermediaries. The interest is in understanding the dynamics of competition among potential intermediaries and what are the circumstances under which we see a dominant intermediary.

## 8.2 Network Externalities

A key feature of many economic contexts is that the value of choosing a platform is increasing in the number of others who are already part of the network. A first observation is that 'network' effects naturally give rise to multiple equilibria. To see this in the simplest

setting consider the following example:

Suppose that there are  $n$  individuals, each of whom has a choice between two computer software programmes A and B. We shall suppose that individuals have the same preferences over the different computer programmes. Let individual returns from a choice  $x \in \{A, B\}$ , when  $k$  persons are adopting the same programme, be given by

$$u_x(k), \quad x \in \{A, B\}, \quad k \in \{1, \dots, n\}$$

The idea of positive ‘network’ effects is reflected in the following assumption:

$$u_x(k+1) > u(x, k), \forall x, \quad k \in \{1, \dots, n-1\} \quad (8.1)$$

To simplify the exposition, let us also suppose that network effects are significant. So, for every individual  $i$ :

$$u_A(n) > u_B(1); u(B, n) > u(A, 1) \quad (8.2)$$

When individual utility satisfies this assumption it is easy to see that there are two natural Nash equilibria: everyone chooses programme A or programme B.

As there are multiple equilibria, the outcome is sensitive to the expectations that persons have about each other. So a programme may be chosen because everyone expects it to be chosen: this may be for instance because it happens to popular in the recent past. Thus recent trends may be reinforced. Moreover, this suggests that once a software is widely used, it may be difficult for users to change even when a new superior programme becomes available. This raises the possibility of inefficient lock-ins. We take up these issues in the next section. In the discussion so far we have assumed that all individuals have the same preferences over the programmes. Differences in preferences are an important and we will come back to this point later in the chapter.

### 8.2.1 Installed Base, Dynamic Choice and Lock-Ins

One of the implications of above analysis is that if everyone has coordinated on action A, then this action will remain optimal and the outcome will persist even if, (say) due to technological change, a new product B becomes available and this product is superior, i.e.,  $u_B(k) > u_A(k)$ , for all  $k$ . This suggests that in settings with network effects, there can be a lock-in into old, established ways of doing things. We explore the scope of this argument with the help of a simple model.

We consider a model which is a simplified version of Farrell and Saloner [1986]. At

At the start, there is a group of consumers  $n_0$ , who have adopted a product  $A$ , also referred to as the old technology. In period 1, a group of consumers  $n_1$ , can choose to either buy product  $A$  or refrain from buying. In between periods 1 and 2, product  $B$ , also referred to as the new technology, becomes available in the market. In period 2, consumers  $n_2$  choose between buying  $A$  or  $B$  or abstain from buying altogether. We now specify the payoffs from the different actions. The payoff from the old technology (per period, for periods 1 and 2) is given by:

$$\begin{aligned} u_A(k), & \quad \text{where } k \text{ is the network size.} \\ u_A(0) \geq 0, & \quad u_A(k+1) > u_A(k), k \in \{1, \dots, n-1\} \end{aligned}$$

An example satisfying this requirement is:

$$u_A(k) = a + bk, \quad a, b > 0$$

The payoff from the new technology per period is as follows:

$$\begin{aligned} u_B(k), & \quad \text{where } k \text{ is the network size.} \\ u_B(0) \geq 0, & \quad u_B(k+1) > u_B(k), k \in \{1, \dots, n-1\} \end{aligned}$$

The first point to note is that period 1 consumers only know about old technology. Hence they choose action  $A$  since it is better than the outside option. In period 2, technologies  $A$  and  $B$  are both available and consumers choose action  $B$  if:

$$u_B(n_2) > u_A(n_0 + n_1 + n_2) \tag{8.3}$$

Thus consumers in period 2 may choose action  $A$  even if  $u_i(B, k) > u_i(A, k)$  for all  $k$ . For concreteness, suppose old technology has payoffs  $a + bk$  while the new technology has payoffs  $c + dk$ . This inequality tells us that it is possible for consumers to persist with an old technology even if  $c > a$  and  $d > b$  (so long as  $a + b(n_0 + n_1 + n_2) > c + dn_2$ ).

This is the simplest expression of the traditional argument of how a lock-in into old established ways of doing things may arise. While the possibility of such a lock-in seems quite robust, it is not clear whether such an outcome is something good or bad, and needs to be remedied. This leads us to examine the conditions under which technological change is optimal. An exploration of these conditions will also enable us to address the difficult question: Is there a systematic bias against technological change in markets with network effects?

Aggregate social welfare under each choice is as follows:

$$\begin{aligned} W(\text{old}) &= n_0[u_A(n_0 + n_1) + u_A(n_0 + n_1 + n_2)] \\ &\quad + n_1[u_A(n_0 + n_1) + u_A(n_0 + n_1 + n_2)] \\ &\quad + n_2[u_A(n_0 + n_1 + n_2)] \end{aligned}$$

$$\begin{aligned} W(\text{new}) &= n_0[u_A(n_0 + n_1) + u_A(n_0 + n_1)] \\ &\quad + n_1[u_A(n_0 + n_1) + u_A(n_0 + n_1)] \\ &\quad + n_2[u_B(n_2)] \end{aligned}$$

We will say technological change is optimal if it maximizes total consumer surplus across the different generations. Therefore, comparing the two expressions, adopting a new technology is optimal if and only if,

$$\begin{aligned} W(\text{new}) > W(\text{old}) &\iff n_2[u_B(n_2) - u_A(n_0 + n_1 + n_2)] \\ &> (n_0 + n_1)[u_A(n_0 + n_1 + n_2) - u_A(n_0 + n_1)] \end{aligned} \quad (8.4)$$

These computations allow us to move on to the question of whether there is too little or too much technological change in markets with network effects. A comparison of (8.3) and (8.4) yields the following observation: *Private incentives for switching to new technology are greater than what is socially desirable.* The reason for too much technological change is that active period 2 consumers only compare their own payoffs in making a decision on technology and their actions generate externalities on earlier consumers. In particular, choosing the new technology generates a *negative effect* on the payoffs of earlier generation consumers – in terms of the lack of growth of the network of the old technology – which is ignored by period 2 consumers. They therefore overestimate the benefits of the new technology and have excessive incentives to adopt the new technology, from a social point of view.

The possibility of too much technological change naturally raises the issue: are there circumstances under which there could be too little change? We need to extend the simple model above to address this question.

Consider a situation where both period 1 and period 2 consumers can choose between new and old technology and payoffs are such that period 2 consumers find it optimal to buy whichever good period 1 consumers bought. First note that consumers in period 1

choose the old technology if

$$\begin{aligned} u_A(n_0 + n_1) + u_A(n_0 + n_1 + n_2) &> u_B(n_1) + u_B(n_1 + n_2) \\ \iff u_A(n_0 + n_1) - u_B(n_1) &> u_B(n_1 + n_2) - u_A(n_0 + n_1 + n_2) \end{aligned} \quad (8.5)$$

On the other hand, social welfare under the new and the old technologies is, respectively,

$$\begin{aligned} W(\text{old}) = & n_0[u_A(n_0 + n_1) + u_A(n_0 + n_1 + n_2)] \\ & + n_1[u_A(n_0 + n_1) + u_A(n_0 + n_1 + n_2)] \\ & + n_2[u_A(n_0 + n_1 + n_2)] \end{aligned}$$

$$\begin{aligned} W(\text{new}) = & n_0[u_A(n_0) + u_A(n_0)] \\ & + n_1[u_B(n_1) + u_B(n_1 + n_2)] \\ & + n_2[u_B(n_1 + n_2)] \end{aligned}$$

If  $u(n_0) \approx u(n_0 + n_1) \approx u(n_0 + n_1 + n_2)$ , then

$$\begin{aligned} W(\text{new}) > W(\text{old}) \iff & (n_1 + n_2)[u_B(n_1 + n_2) - u_A(n_0 + n_1 + n_2)] \\ & > n_1[u_A(n_0 + n_1) - u_B(n_1)] \end{aligned} \quad (8.6)$$

A comparison of (8.5) and (8.6) reveals that *consumers may persist with the old technology even if new technology is socially desirable, because they do not take into account the effects of their actions on future consumers.*

Thus individual incentives may generate too little or too much technological change relative to what is socially desirable. Our discussion helps identify the nature of externalities that generate these outcomes. Too much technological change or *excessive momentum* comes about when current period consumers ignore the interests of the installed base (the users of the existing technology). This may be termed *backward externality*. By contrast, too little change or *excessive inertia* arises because current consumers ignore the interests of future consumers who could benefit from a growing network of new technology users. This may be termed the *forward externality*. Both forward and negative externalities are present in markets with network effects and that such markets are therefore likely to generate technological change which can be too slow or too fast relative to what is socially desirable. Our analysis also raises the question: which type of externality is more likely to arise and in which markets? An understanding of this issue requires at the very least a model in which both the supply and demand side of the market are active. So far we have only looked at the demand side of the market. In the next section we shall take a first look

at the supply side when we consider some strategies that firms can use in such markets.

### 8.2.2 The Strategies of Firms

Firms use a variety of strategies to promote their products and introduce new technologies; some of these strategies – such as introductory pricing and product pre-announcements – are common in markets with no network effects as well, but they take on particular significance when network effects are important.

*Pre-announcements:* Recall that in the basic model only period 2 consumers can choose between old and new technology. Moreover, period 1 consumers had no choice but to decide in period 1. To see the role of product pre-announcements it is useful to modify the model slightly. Suppose first that the firm introducing the new technology in period 2 can pre-announce the launch. Secondly, suppose that consumers in period 1 can postpone decision and buy in period 2. We now examine incentives of the firm to pre-announce and the implication of such pre-announcements.

Suppose there is a pre-announcement. Consumers in period 1 can either buy the old technology or wait until period 2 and buy the new technology. In making their decision, they compare

$$\begin{aligned} u_A(n_0 + n_1) + u_A(n_0 + n_1 + x) \quad x \in \{0, n_2\} \\ \text{with} \\ u_B(n_1 + n_2) \end{aligned}$$

where we have assumed that period-2 consumers always buy good *B*. Period 1 consumers choose the new technology if

$$u_B(n_1 + n_2) > u_A(n_0 + n_1) + u_A(n_0 + n_1 + x)$$

It is worth noting that if

$$u_B(n_1 + n_2) > u_A(n_0 + n_1 + n_2)$$

but

$$u_B(n_2) < u_A(n_0 + n_1 + n_2)$$

then in the absence of pre-announcements the new technology would not be adopted, while, with a pre-announcement, the new technology can in principle be adopted. Thus *pre-announcements play a crucial role in shaping technological evolution in network markets*.

*Introductory Pricing:* In the discussions above, we have highlighted the role of the installed base; the larger the size of  $n_0$  the more difficult it is to get consumers to switch to a new technology. This suggests that firms have an incentive to build a network rapidly.

This raises the question: can firms induce faster growth of the network through pricing? The essential idea is the following: the firm starts by selling cheap to attract consumers and once the network is established it charges high prices to subsequent consumers and recovers the initial losses if any.

To see the role of this strategy we return to the model where period 1 and period 2 consumers can choose between new and old technologies. We focus on the case (the set of parameters) in which period 1 consumers persist with the old technology. This is the case covered in the analysis above. Recall that this happens if

$$u_A(n_0 + n_1) + u_A(n_0 + n_1 + n_2) > u_B(n_1) + u_B(n_1 + n_2)$$

It is worth noting that this inequality can hold even if

$$W(\text{new}) > W(\text{old})$$

This happens due to the loss in payoff in the transition period:

$$u_B(n_1) \ll u_A(n_0 + n_1)$$

We examine the role of an introductory price strategy in this setting. Can the firm set prices in such a way as to induce period 1 consumers to choose the new technology and is this in the interest of this firm?

Suppose that in period 1, the firm sets the prices as follows:

$$p_1 = [u_B(n_1) + u_B(n_1 + n_2)] - [u_A(n_0 + n_1) + u_A(n_0 + n_1 + n_2)]$$

This is the maximum price that the firm can set which will make consumers in period 1 buy the new technology. It is worth noting that this price 1 is negative. Such a strategy only makes sense if these losses in period 1 are somehow recouped larger profits in period 2.

We next examine the maximum prices that the firm can charge in period 2. Note that in period 2, consumers compare  $u_A(n_0 + n_2)$  and  $u_B(n_1 + n_2)$ . Thus the firm can set a price such that these two payoffs are equal. In other words, the sets:

$$p_2 = u_B(n_1 + n_2) - u_A(n_0 + n_2)$$

Finally, we check if this strategy is attractive for the firm. Note that the above strategy is the best strategy in the class of strategies which induce the consumers to switch to the new technology, while the strategy with no switching generates a payoff of 0. Thus the firm finds it attractive to use this introductory pricing strategy if the combined profits from

the two periods is positive. The combined profits are given by:

$$\begin{aligned} & n_1[u_B(n_1) + u_B(n_1 + n_2) - \{u_A(n_0 + n_1) + u_A(n_0 + n_1 + n_2)\}] \\ & + n_2[u_B(n_1 + n_2) - u_A(n_0 + n_2)] \end{aligned}$$

What are the circumstances under which this expression is positive? From the above discussion recall that adopting the new technology is socially optimal if and only if:

$$\begin{aligned} W(\text{new}) > W(\text{old}) &\iff (n_1 + n_2)[u_B(n_1 + n_2) - u_A(n_0 + n_1 + n_2)] \\ &> n_1[u_A(n_0 + n_1) - u_B(n_1)] \end{aligned}$$

We have thus shown that *introductory pricing strategy is attractive for a firm if and only if it is socially optimal.*

### 8.2.3 Competition among Networks

We consider a simple model with two platforms, A and B, located at points 0 and 1 of the unit interval. Let  $F(x)$  be the fraction of consumers with  $b < x$ ; in our setting, for simplicity,  $F(x) = x$ , i.e., consumers are located uniformly on the unit interval. The consumer located at point  $b$  has ‘intrinsic benefit’  $b$  from platform B, and intrinsic benefit  $1 - b$  from platform A.

There is an advantage to joining a larger network: we will say that the benefits of joining a network with  $d$  consumers is  $kd$ . We assume that consumers can choose at most one of the platforms. The prices of the two platforms are given by  $(p_A, p_B)$ .

Let us solve for the equilibrium prices and network sizes. To begin suppose that the networks are of size  $x_A$  and  $x_B$ , with  $x_A + x_B = 1$ . This assumes that the market is fully covered; full market coverage can be ensured by a suitably high value of the stand-alone value of a platform.

Consider the optimal choice of a consumer: the net utility of choosing platform A is

$$1 - b + kx_A - p_A \tag{8.7}$$

The net utility from platform B is

$$b + kx_B - p_B \tag{8.8}$$

It is optimal to choose A if  $1 - b + kx_A - p_A \geq b + kx_B - p_B$ . In other words, a consumer

will choose platform A if

$$b \leq \frac{1}{2} + k(2x_A - 1) + p_B - p_A. \quad (8.9)$$

where we have substituted  $x_B = 1 - x_A$ .

In an interior equilibrium, the marginal consumer must be indifferent between the two products and expected network size must correspond to the actual networks. Thus, in the uniform distribution case, in equilibrium it must be true that the marginal consumer,  $x_A$ , must be equal to the size of network A and this must correspond to the expected network, i.e.,

$$x_A = \frac{1}{2} + k(2x_A - 1) + p_B - p_A. \quad (8.10)$$

We shall say that network effects are weak (strong) if the marginal returns from an increase in network size are smaller (greater) than 1.

To develop a feel for how the magnitude of network effects matter, let us consider some examples. First suppose that network effects are weak, so  $k < 1/2$ . We can solve for the network size as a function of prices to obtain:

$$x_A = \frac{1}{2(1-k)} [1 - k + p_B - p_A]. \quad (8.11)$$

The profit of platform A may be written as:

$$\Pi_A(p_A, p_B) = p_A \frac{1}{2(1-k)} [1 - k + p_B - p_A]. \quad (8.12)$$

The first order conditions of optimal price for platform A yields us the following condition:

$$\frac{1}{2(1-k)} [1 - k + p_B - 2p_A] = 0. \quad (8.13)$$

It is natural to focus on symmetric equilibrium as the platforms are symmetric in this model. The equilibrium price is given by

$$p_A = p_B = 1 - k. \quad (8.14)$$

We see that prices are falling in the magnitude of network effects. In particular, for  $k = 0$ , with zero network effects, we get a price of 1 that corresponds to the equilibrium price for the baseline Hotelling model. Thus with small network effects, both networks are active and of equal size. This is illustrated in Figure 8.1.

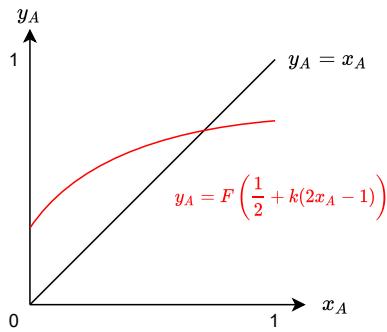

Figure 8.1: Weak Network Effects

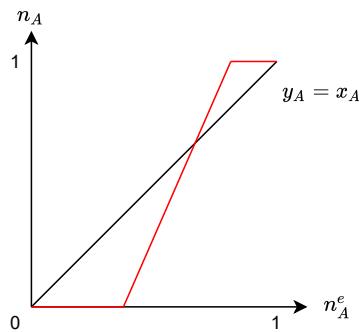

Figure 8.2: Strong Network Effects

Next let us consider the case of strong network effects. Suppose  $k = 1$ . For simplicity suppose that prices are equal  $p_A = p_B$ . The demand for platform A is then given by  $y_A = F(-1/2 + 2x_A)$ . This is shown in Figure 8.2 Notice that there are now three equilibria, one in which all consumers go to platform A, another in which all consumers go to platform B and a third one that is interior. However, the interior equilibrium is unstable as a slight change in network size leads through the strong networks effect away from the interior equilibrium towards one of the single platform outcomes. The equilibrium  $(x_A = 1, x_B = 0)$  is supported by prices  $(p_A = 1, p_B = 0)$ , while the equilibrium  $(x_A = 0, x_B = 1)$ , is supported by prices  $(p_A = 0, p_B = 1)$ . Thus strong network effects push toward a single dominant platform.

These computations suggest that if network effects are modest relative to the diversity of consumer tastes then that can account for coexistence of multiple platforms/standards. A prominent example is operating systems: Apple and Microsoft operating systems have thrived by focusing on different segments of the market: Windows for business and Apple for graphics and education. Another example of a market with multiple platforms is gaming: PlayStation and Nintendo have continued to perform well. PlayStation focuses

on hardware, third party games and traditional gamers while Nintendo are more focused on their own IP games and a wider population of "casual gamers".

Ride hailing is another example in which multiple online platforms compete with traditional taxis. Uber was the first mover in 2009; in the years falling that launch, a number of competitors have emerged. Chief among them are Lyft, Grab, Ola and Didi Chuxing. The first operates solely in the US market (and a small part of Canada), Ola is strong in India, while the latter two operate in the lucrative Southeast Asian and Chinese markets respectively. Uber and Lyft have 65% and 30% share of the ride hailing market in the US. Ola and Uber control respectively one half and 35% of the Indian market, Didi Chuxing controls 90% of the market in China.

By contrast, in the market for internet search, Google is overwhelmingly dominant in many of the large economies, such as USA (88%), India (95%), UK (85%), France (91%), Japan (74%), Brazil (96%), Nigeria (98%) and Germany (97%). Google shares the market equally with Yandex RU in Russia, and it is not allowed to operate in China. The choice of a search engine is driven mainly by a desire for accurate and relevant results. There is little difference in consumer preference in this dimension. A search engine delivers more useful results as it has access to more past searches. Therefore a larger market share in the past will generate more data and this can give rise to tipping in favour of a dominant platform.

Let us summarize what we have learnt in this section. An important aspect of many economic activities is that the returns from choosing an action are increasing in the number of others who adopt the same action. A variety of product markets also share this property.

We have argued that markets with strong network effects exhibit multiple equilibria, which are typically extremal, with one product/technology usually taking over the market. The nature of eventual winner in the market depends on the expectations that consumers have regarding the behaviour of other consumers.

We examined in some detail the effects of the historical factors in shaping the evolution of such markets. Once an economy is in one equilibrium – choosing a certain network technology – it may be difficult to transit to a new superior technology due to the disadvantage of the small network of the new technology. This is known as the installed base effect. Several authors have argued that the installed base effect will typically inhibit technological change. Our analysis explored this contention and identified the different types of externalities inherent in such markets and how they drive technological change. Our analysis of the demand side of the market suggests that this is not necessarily true and that individual incentives for adopting new products can be greater as well as less than what is socially optimal. This motivated an examination of the role of the supply side of the market.

We examined two strategies that firms frequently use in such markets – product pre-

announcements and introductory pricing. We argued that these strategies facilitate a switch to new technology.

Finally, we examined a context in which consumers have different preferences for platforms. The pressure toward a dominant platform depends on the relative size of the network effect. When the network effect is modest, preferences for different platforms lead to coexistence of platforms. By contrast, when these networks are large, one platform takes over the entire market.

### 8.3 Compatibility

Compatibility refers to the ability of a consumer using one platform to reach a seller using another. A well known example of compatibility concerns banks and ATM networks. A depositor with one bank can use that bank's ATM network and can also use the network of other banks depending on the agreements between the banks. The networks are more or less compatible depending on the charges that apply outside own ATM networks. The example on ATM networks offers an instance of compatibility arising from inter-connection. But compatibility may have a more technological aspect to it: for instance, two products are compatible if they can operate together to generate value. A well known example is Blu-Ray discs and DVD's. A DVD can be played on a BluRay player but a BluRay disc cannot be played with a standard DVD player. Thus compatibility may sometimes be one-sided. We study incentives of firms to make their products compatible.

We present a model taken from Katz and Shapiro [1985]. There are  $n$  firms who choose quantities and there are consumers who choose whether to buy or not to buy. Moreover, they care about the size of the network of firms. They are willing to pay more for large networks. Expectations play a major role, as in the earlier model of network externalities.

Let  $y_i^e$  be the size of firm  $i$ 's network as *expected* by consumers. We will assume that consumers have the same expectations. Then a consumer  $r$ 's valuation is given by

$$\begin{aligned} r + v(y_i^e) \\ v(0) = 0, \quad v'(\cdot) > 0 \quad v''(\cdot) < 0 \\ \lim_{y \rightarrow \infty} v'(y) = 0 \end{aligned}$$

A word on the assumptions on  $v$ . As we are studying the role of network effects, it is natural to assume that the returns from a network are increasing in its size. The decreasing rate of increase helps ensure that multiple firms are active in the market. Assume  $r$  is

uniformly distributed on  $[-\infty, A]$ , where  $A > 0$ .

In making a choice between two products (networks)  $i$  and  $j$ , a consumer compares the net payoffs from them:

$$r + v(y_i^e) - p_i$$

as against

$$r + v(y_j^e) - p_j$$

All consumers are identical with regard to their preference: so it follows that if one consumer favours  $i$  over  $j$  then so will all consumers. For two distinct networks  $i$  and  $j$  to be active it must be the case that they are equally attractive for everyone:

$$r + v(y_i^e) - p_i = r + v(y_j^e) - p_j \iff p_i - v(y_i^e) = p_j - v(y_j^e)$$

Let us define  $p_i - v(y_i^e) = \phi$  be the hedonic price of a product. The above condition says that for two firms to be active, their hedonic prices should be the same. We can use this to compute the aggregate demand. All consumers with high enough  $r$  will buy:

$$r \geq p_i - v(y_i^e) = \phi$$

$$\text{Demand} = A - \phi = A - [p_i - v(y_i^e)]$$

In equilibrium, quantity sold by firm  $i$  is equal to this number as well. Let  $x_i$  be the sales of firm  $i$  and let  $z = \sum_i x_i$  be the aggregate sales.

$$z = A - [p_i - v(y_i^e)] \iff p_i = A + v(y_i^e) - z$$

Thus a higher  $y_i^e$  leads to a higher  $p_i$ . A lower  $z$  leads to a higher  $p_i$ . Observe that if there were no network effects,  $v(y_i^e) = 0$  and  $p_i = A - z$ , as in the standard Cournot model.

For simplicity in the computations, we assume that firms have zero production costs. We next turn to compatibility. Two products are said to be compatible if consumers buying one of the the products can enjoy the benefits of the networks of either of them. This compatibility my require technical modifications or add-on features so we assume that it is costly to make products compatible. In particular, firm  $i$  incurs a cost  $F_i > 0$  in making its product compatible with firm  $j$ . Given these assumptions, the payoffs to firm  $i$  are as follows:

- Pay-off under *full compatibility*:  $\pi_i = x_i(A - z + v(z)) - F_i$
- Pay-off under *incompatibility*:  $\pi_i = x_i(A - z + v(y_i^e))$

Notice that taking expectations and output of other firms as given, we can work out an equilibrium as in the standard Cournot model. Thus given expectations  $y$  about network sizes of different firms, there is a unique equilibrium in the market. In this equilibrium the quantities are given by:

$$x_i^* = \frac{A + nv(y_i^e) - \sum_{j \neq i} v(y_j^e)}{n + 1}$$

Thus expectations of consumers concerning the network size translate into cost advantages/disadvantages for the firms sponsoring the different networks. To see this, note that if

$v(y_i^e) = 0, \forall i$  we get  $x_i^* = \frac{A}{n+1}$ , which is the standard Cournot equilibrium output. Moreover for every set of expectations there is a corresponding equilibrium. We will focus on Fulfilled Expectations equilibrium.

**Fulfilled Expectations Equilibrium:** In such an equilibrium, the expected network size is equal to the actual network size. Thus

$$y_i^e = x_i, \quad \forall i.$$

Standard computations allow us to say that the equilibrium profits are given by  $x_i^2$ , while the consumers surplus is given by  $z^2/2$ . This is somewhat surprising, since it suggests that firms extract all the surplus generated by the network effects. We elaborate on this briefly here. Note that  $r = A - z$ . Hence

$$CS = \int_{A-z}^A (\rho + z - A) d\rho$$

Consumer ' $r$ ' expects

$$r + v(y_i^e) - p_i = r + v(y_i^e) - A - v(y_i^e) + z = r - A + z$$

We are now ready to study the equilibrium outcomes under different levels of compatibility in the market.

### 8.3.1 Compatibility and Equilibrium

*Full Compatibility Case:* This is the situation when all firms are compatible with each other. Letting  $z^e = \sum_{i=1}^n x_i$  and  $y_i^e = z^e$ , the equilibrium quantity of firm  $i$  is given by

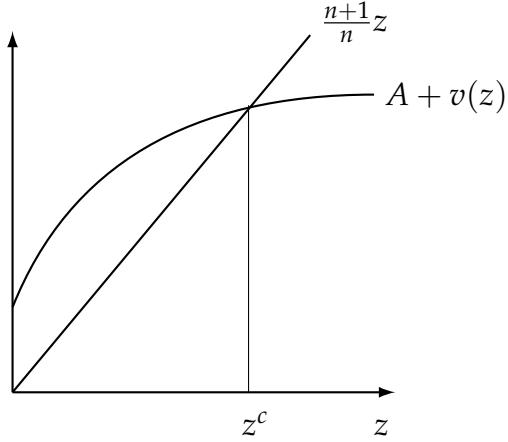

Figure 8.3: Equilibrium in the Full Compatibility Case.

$$x_i^* = \frac{[A + v(z^e)]}{n+1}, \forall i = 1, \dots, n \quad (8.15)$$

The aggregate output is implicitly defined by the following equation:

$$z^c = \frac{n}{n+1}(A + v(z^c))$$

Given our assumptions on the function  $v(\cdot)$ , it is possible to check that the equilibrium is unique.

*Complete Incompatibility Case:* In this case different types of equilibria are possible:

- Symmetric:  $x_i = x, \forall i = 1 \dots n$
- Natural Oligopoly:  $x_i = x, \forall i = 1 \dots k, x_i = 0, i = k+1 \dots n$ .
- Asymmetric Outcomes: different outputs for active firms

For simplicity, we will only take up the symmetric outcomes case in this discussion. The profits are given by  $x_i(A + v(y_i^e - x_i - \sum_{j \neq i} x_j))$ . Taking derivatives, the first order conditions are

$$x_i = A + v(y_i^e) - \sum_{j=1}^n x_j$$

Rewriting

$$2x_i = A + v(y_i^e) - \sum_{j \neq i} x_j$$

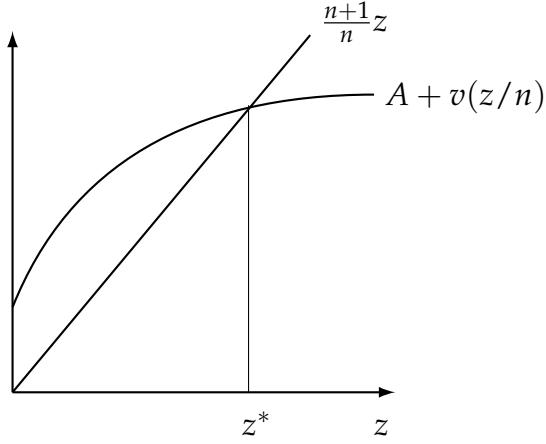

Figure 8.4: Equilibrium in the Complete Incompatibility Case.

The aggregate output in a symmetric equilibrium is implicitly defined

$$z \frac{n+1}{n} = A + v\left(\frac{z}{n}\right) \quad (8.16)$$

Putting together the cases with full compatibility and incompatibility yields us the following result.

**Proposition 8.1.** *Under full compatibility, there exists a unique symmetric equilibrium in which  $x_i^* = z^c/n$  and aggregate output/sales  $z^c$  are implicitly defined by:*

$$z^c = \frac{n}{n+1}(A + v(z^c/n)) \quad (8.17)$$

*Under incompatibility, there exists a unique symmetric equilibrium in which  $x_i = z^*/n$  and aggregate output/sales  $z^*$  are implicitly defined by:*

$$\frac{n+1}{n}z^* = A + v(z^*/n) \quad (8.18)$$

We now take up the effects of compatibility on total output. It is easy to show that aggregate output is higher under full compatibility as compared to partial compatibility. Recall that the first order conditions for individual firms that

$$x_i = A + v(y_i^e) - z \quad (8.19)$$

Adding up for all firms and re-arranging gives

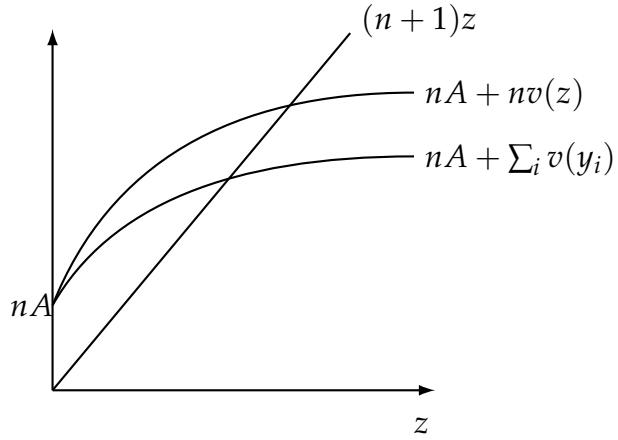

Figure 8.5: Total output under compatibility and under incompatibility.

$$(n+1)z = nA + \sum_{i=1}^n v(y_i^e) \quad (8.20)$$

If there is complete compatibility, then  $y_i^e = z, \forall i \in N$ . If there is incomplete compatibility, then  $y_i^e < z$ , for some  $i$ . Thus the curve  $nA + nv(z)$  lies above  $nA + \sum_i v(y_i^e)$ .

We next turn to the effects of compatibility on individual firms' output. Here matters are considerably more complicated. We will establish the following result.

**Proposition 8.2.** *Suppose two groups of firms make their products mutually compatible. If in the pre-compatibility phase total output is less than  $A$  then in any post-compatibility equilibrium, (i) the average output of firms in the compatibility group will increase, (ii) the output of any firm not in the merging coalitions will fall, and (iii) total industry output will rise.*

Let us go through the arguments underlying this result. Suppose there are  $J$  groups of firms, each of which is compatible within itself but incompatible with every other group. In the pre-compatibility phase, first-order condition for individual firms (assuming that all firms behave symmetrically within a group) satisfy:

$$x^j = A - z + v(m^j x^j) \quad (8.21)$$

where  $m^j$  is the number of firms in group  $j = 1, 2, \dots, J$ . Let  $\tilde{x}^j$  and  $\tilde{z}$  be the individual firm output and total output after compatibility, for groups 1 and 2.

We now construct an argument by contradiction. Suppose that aggregate output  $\tilde{z} < z$ . Then for groups  $j \geq 3$ , output satisfies  $\tilde{x}^j = A - \tilde{z} + v(m^j \tilde{x}^j)$ . However,  $A - \tilde{z} + v(m^j \tilde{x}^j)$  lies above  $A - z + v(m^j x^j)$ , and so the equilibrium output  $\tilde{x}^j > x^j$ . Similarly, we may argue that  $\tilde{x}^j < x^j$  if  $\tilde{z} > z$  and  $\tilde{x}^j = x^j$  if  $\tilde{z} = z$ .

Next consider the two groups  $j = 1, 2$  which make products compatible. For these firms in  $j = 1, 2$ :

$$A - z + v(m^1 \tilde{x}^1 + m^2 \tilde{x}^2) > A - z + v(m^j x^j) \quad (8.22)$$

Thus if  $\tilde{z} < z$  then  $\tilde{x}^j > x^j, \forall j = 1, 2$ . But this means that if  $\tilde{z} < z$ , then all firms produce more in the post compatibility world. This is a contradiction. Thus  $\tilde{z} > z$ . Next, from the above arguments, the claims about the output of the firms in groups  $j \geq 3$  and firms in groups 1 and 2 follow. ■

It is important to emphasize what the result establishes and what it does not do. It shows that aggregate output by firms in these two groups must increase:  $m^1 \tilde{x}^1 + m^2 \tilde{x}^2 > m^1 x^1 + m^2 x^2$ . This does not imply that every firm in the combining groups increases output! It may be well be that one group loses output while another group gains output. This will be important when we examine the incentives to achieve compatibility.

### 8.3.2 Incentives for compatibility

There are different ways in which products can be made compatible. We will start with the case of mutual compatibility. In this case, all the firms involved must agree to make their products compatible.

We consider a two firm setting to illustrate some of the issues that come up.

- The equilibrium under incompatible products is given by:

$$x^1 = A - z + v(x^1)$$

$$x^2 = A - z + v(x^2)$$

- A symmetric equilibrium under compatibility is given by:

$$\tilde{x}_1 = \tilde{x}_2 = x^c = A - \tilde{z} + v(\tilde{z}) \iff \frac{3}{2}z^c = A + v(z^c)$$

Let us start with the case where the firms are in a symmetric situation in a pre-compatibility setting:

$$\frac{3}{2}z^I = A + v\left(\frac{z^I}{2}\right)$$

Clearly  $z^I < \tilde{z}^c$  and profits  $\pi^I = (x^I)^2 < (x^c)^2 = \pi^c$ .

This suggests that the profits of both firms increase after moving to compatibility and the increase in profits is equal. So if one firm wants compatibility so does the other firm. If  $F_i = F$  is the cost of compatibility then firms choose compatibility if  $F \leq \pi^c - \pi^I$ .

The social welfare is given by  $W = \sum \pi + CS$ . Typically,  $CS$  is an increasing function of aggregate output and so firms will underestimate the value of moving to compatible product.

There is another issue: if the costs of compatibility are different,  $F_i \neq F_j$ , then incentives for compatibility are different and transfers may be needed to facilitate compatibility. We then have to check the condition

$$\sum_i F_i \leq \sum_i (\pi_i^c - \pi_i^I)$$

Let us now take up the case in which the firms are in an asymmetric equilibrium in the pre-compatibility setting. Suppose  $x_1^I > x_2^I$  in the initial equilibrium. Then note that the change in profits due to compatibility will be quite different for the two firms. Recall that under incompatibility the profits are given by

$$\begin{aligned}\pi_1^I &= (x_1^I)^2 \\ \pi_2^I &= (x_2^I)^2\end{aligned}$$

While the profits under compatibility are given by  $\pi_1^c = \pi_2^c = (z^c)^2 / 4$ . Thus it follows that  $(\pi_1^c - \pi_1^I) < (\pi_2^c - \pi_2^I)$ . This implies that the larger firm under incompatibility will have lower incentives to switch to compatibility. This is consistent with empirical observations: dominant firms are generally averse to compatibility.

In the model we have so far assumed that compatibility is attainable, at some cost, between different products. This is a good starting point, but there are sometimes technological constraints to how far products can be made to work together. For instance, consider the case of digital technology and analog technology. More generally, there may be a trade-off between performance and compatibility.

One consideration suggested by the computations above is that low costs of compatibility will facilitate the emergence of a common standard. In the context of multi-sided platforms this suggests the following general point. If a side of the market can join many platforms at little cost then that would make multiple standards attractive. It has been suggested that the modest costs of providing video games for multiple standards have led to increased distribution of games across multiple game systems (such as PlayStation, Nintendo, and Xbox) and a less-concentrated game system market (Corts and Lederman

[2009].

In the model, we have assumed competition between the firms is in terms of quantity choice. This moderates the effect of competition and firms can earn positive profits even when they choose a compatible product. If firms compete in prices then there would be a greater need to differentiate themselves from each other. The ability of firms to differentiate themselves on some dimension is important in the choice of compatibility. Film producers provide a highly differentiated good. Consequently, film producers were quick to settle on the VHS standard. More recently, this was also a factor in the emergence of BluRay as a single standard. By contrast, if content providers cannot differentiate themselves then they must differentiate by choosing separate standards, which leads to the adoption of multiple standards (Ellison and Fudenberg [2003]).

Let us summarize what we have learnt in this section. Network effects depend on compatibility of products. If two software programmes are distinct but files in one programme can be read and understood equally well on the other programme, then the two software programmes can be said to be perfectly compatible and essentially constituting a single network. However, if files in one programme cannot be read at all on the other programme then the two programmes are incompatible. We examined the effects of compatibility on market outcomes – outputs, consumers surplus and profits – and then examined the incentives of firms to make their products compatible.

Our analysis suggests that compatibility usually increases value and thus the size of surplus. Compatibility usually also increases aggregate output of firms. However, the impact on the profits of firms is unclear. It maybe that some firms lose out while others gain. In general, larger firms will be less interested in choosing compatibility than small firms. Finally, the firm's incentives for making products compatible are lower than what is socially desirable.

## 8.4 Standards

We now examine the choices of firms with regard to compatibility more systematically. For expositional simplicity, we will focus on the case in which two firms are compatible if and only if they have the same standard and produce the same product. We first introduce a typology of compatibility choices and then we connect the incentives to our discussion of the Katz-Shapiro model (in the section above). The present section draws heavily on BelleFlamme and Peitz [2015].

Suppose there are two firms denoted by 1 and 2. They choose between two possible versions of their product, A and B. The two versions are incompatible, so the firms can be

compatible only if they choose the same version. For easy reference we present the payoffs in Table below.

	2	<i>A</i>	<i>B</i>
1			
<i>A</i>	$(\pi_1^{A,A}, \pi_2^{A,A})$	$(\pi_1^{A,B}, \pi_2^{A,B})$	
<i>B</i>	$(\pi_1^{B,A}, \pi_2^{B,A})$	$(\pi_1^{B,B}, \pi_2^{B,B})$	

The form of competition will depend on the compatibility choices. There are therefore four cases to consider.

1. Firms choose the same product version. Let us refer to this as straightforward standardization. There is straightforward standardization on version A if there is a unique Nash equilibrium in which both firms choose A. This occurs when  $\pi_1^{A,A} > \pi_1^{B,A}$  and  $\pi_2^{A,A} > \pi_2^{A,B}$  and either  $\pi_1^{A,B} > \pi_1^{B,B}$  or  $\pi_2^{B,A} > \pi_2^{B,B}$ .
2. Firms agree that standardization is best but disagree about which version A or B is better. This is the situation referred to as the Battle of the Sexes. Now both  $(A, A)$  and  $(B, B)$  are Nash equilibria:  $\pi_1^{A,A} > \pi_1^{B,A}$  and  $\pi_2^{A,A} > \pi_2^{A,B}$  and  $\pi_1^{B,B} > \pi_1^{B,A}$  and  $\pi_2^{B,B} > \pi_2^{A,B}$ . But firms rank the equilibria differently:  $\pi_1^{A,A} > \pi_1^{B,B}$  and  $\pi_2^{B,B} > \pi_2^{A,A}$ .
3. The firms strictly prefer to compete for the market to become the defacto standard: this leads to a standards war. For instance, if firm 1 wants version A, while firm 2 wants version B, then  $(A, B)$  is the only Nash equilibrium of the game, with  $\pi_1^{A,B} > \pi_1^{B,B}$  and  $\pi_2^{A,B} > \pi_2^{A,A}$  and either  $\pi_1^{A,A} > \pi_1^{B,A}$  or  $\pi_2^{B,B} > \pi_2^{B,A}$ .
4. Firms have contrasting strategies: firm 2 prefers incompatibility, while firm 1 (the Pesky Little Brother) prefers to be compatible. In this setting, there is no Nash equilibrium in pure strategies, because  $\pi_1^{A,A} > \pi_1^{B,A}$  and  $\pi_1^{B,B} > \pi_1^{A,B}$ ,  $\pi_2^{A,B} > \pi_2^{A,A}$  and  $\pi_2^{B,A} > \pi_2^{B,B}$ .

It is helpful to briefly discuss a well known instance of standards war at the start of the twenty-first century. This was about the new generation of DVD: Blu-ray and HD DVD. Both technologies used blue-light lasers that increased disc capacity. The two formats were incompatible. Each standard was backed by powerful collection of hardware firms: Blu-ray was backed by Sony, Panasonic, Philips, Pioneer, Dell and Apple. HD DVD was backed by Toshiba, NEC, Microsoft and Intel. The main content providers were the film producers and even here some of them were producing exclusively Blu-ray, while one of them was

producing exclusively on HD DVD. It seemed as though each of the two standards had a good chance to prevail. However, early in February 2008, Toshiba announced that it would stop the production of HD DVD players and recorders. This brought the standard war to an end. The tipping point apparently arrived when Warner Brothers, following a number of other film producers, decided that they would produce exclusively on Blu-ray.

We will now explore more systematically the economic circumstances under which these different outcomes arise. The discussion will focus on two variables – the size of the installed base of the different firms and the relative advantage/disadvantage of firms vis-a-vis the different technologies. We extend the Katz-Shapiro model of compatibility to incorporate these two variables. Each firm has an installed base of users,  $\beta_i$ ,  $i = 1, 2$ . The firms compete for new consumers; let  $q_i^e$  denote the number of expected new consumers for firm  $i$ . Thus the expected size of the network of firm  $i$  will be  $n_i^e = q_i^e + \beta_i$ . Suppose that  $\gamma \in \{0, 1\}$  is the level of compatibility. The expected network benefit to adopting product  $i$  is then given by

$$g_i = v[(\beta_i + q_i^e) + \gamma(\beta_j + q_j^e)] \quad (8.23)$$

#### 8.4.1 Fulfilled Expectations Equilibrium

As in the analysis above, we will study equilibrium in which consumer expectations are fulfilled. Building on the methods of analysis above, and assuming that there is a unit measure of consumers with initial valuations between 0 and 1, we can then write the inverse demand for product  $i$  as:

$$p_i = 1 + v(\beta_i + \gamma\beta_j) - (1 - v)q_i - (1 - \gamma v)q_j \quad (8.24)$$

The firms seek to maximize their profits  $\pi_i = (p_i - c_i)q_i$ , where  $c_i \geq 0$  is the per unit cost of production. It is straightforward to check that the (fulfilled expectations) equilibrium quantities and profits are:

$$q_i^* = \frac{2(1 - v)[1 - c_i + v(\beta_i + \gamma\beta_j)] - (1 - \gamma v)[1 - c_j + v(\beta_j + \gamma\beta_i)]}{4(1 - v)^2 - (1 - \gamma v)^2} \quad (8.25)$$

$$\pi_i^* = (1 - v)(q_i^*)^2 \quad (8.26)$$

These expressions bring out interesting implications of compatibility: one, setting  $\gamma = 1$  raises the equilibrium quantities, and two, setting  $\gamma = 1$  mitigates installed base advan-

tages and cost advantages. To develop these implications more fully we further simplify the model: suppose that costs take on two values  $c > 0$  and 0. Firm 1 has an advantage in product A and hence its cost is 0 for product A and  $c$  for product B. Firm B has an advantage in product B. Also, for simplicity, set  $v = 1/4$ . Finally, suppose that firm 1 has installed base  $\beta_1 = \beta > 0$ , while firm 2 has no installed base,  $\beta_2 = 0$ . With these assumptions in hand, we now write out the payoffs of the firm under standardization. As products are compatible they have the same network benefit, given by  $\frac{1}{4}[\beta + q_1 + q_2]$ . The inverse demand function is given by

$$p_1 = p_2 = \frac{1}{4}(4 + \beta - 3(q_1 + q_2)) \quad (8.27)$$

The payoffs of the firms will be different due to differences in the cost of production. Let us consider standardization on product A. In that case, the payoffs of firms 1 and 2 are as follows:

$$\pi_1 = \frac{1}{4}[4 + \beta - 3(q_1 + q_2)]q_1; \quad \pi_2 = \frac{1}{4}[4 + \beta - 3(q_1 + q_2)]q_2 - cq_2 \quad (8.28)$$

Taking first order conditions and solving for equilibrium we get:

$$q_1^* = \frac{1}{9}[4 + \beta + 4c] \quad q_2^* = \frac{1}{9}[4 + \beta - 8c] \quad (8.29)$$

$$\pi_1^* = \frac{1}{108}[4 + \beta + 4c]^2 = \pi_1^{AA} \quad \pi_2^* = \frac{1}{108}[4 + \beta - 8c]^2 = \pi_2^{AA} \quad (8.30)$$

Similar computations yield the follow equilibrium quantities and profits for the equilibrium with standardization on product B.

$$q_1^* = \frac{1}{9}[4 + \beta - 8c] \quad q_2^* = \frac{1}{9}[4 + \beta + 4c] \quad (8.31)$$

$$\pi_1^* = \frac{1}{108}[4 + \beta - 8c]^2 = \pi_1^{BB} \quad \pi_2^* = \frac{1}{108}[4 + \beta + 4c]^2 = \pi_2^{BB} \quad (8.32)$$

In the 2nd sentence, perhaps "recall that firm 2 suffers from ..." rather than "due to incompatibility", since firm 2 was assumed to suffer from a smaller user base even in the previous analysis (where the standards were compatible)

Consider next the incompatibility situations. We start with the case where the firms pick their less preferred product, thereby incurring the cost  $c$ . Recall that firm 2 suffers from a smaller user base. Firm 1 has user base  $\beta + q_1$ , while firm 2 has user base  $q_2$ . Firm 1 and firm 2 payoffs can then be written as:

$$\pi_1 = \frac{1}{4}[4 + \beta - 3q_1 - 4q_2]q_1 - cq_1; \quad \pi_2 = \frac{1}{4}[4 - 3q_2 - 4q_1]q_2 - cq_2 \quad (8.33)$$

Taking first order conditions and solving for equilibrium, we get:

$$q_1^* = \frac{1}{10}[4(1 - c) + 3\beta] = q_1^{BA} \quad q_2^* = \frac{1}{10}[4(1 - c) - 2\beta] = q_2^{BA} \quad (8.34)$$

$$\pi_1^* = \frac{3}{400}[4(1 - c) + 3\beta]^2 = \pi_1^{BA} \quad \pi_2^* = \frac{3}{400}[4(1 - c) - 2\beta]^2 = \pi_2^{BA} \quad (8.35)$$

Finally, we can compute the equilibrium for the case AB, by noting that all costs are then 0. This yields:

$$q_1^* = \frac{1}{10}[4 + 3\beta] = q_1^{AB} \quad q_2^* = \frac{1}{10}[4 - 2\beta] = q_2^{AB} \quad (8.36)$$

$$\pi_1^* = \frac{3}{400}[4 + 3\beta]^2 = \pi_1^{AB} \quad \pi_2^* = \frac{3}{400}[4 - 2\beta]^2 = \pi_2^{AB} \quad (8.37)$$

These computations are summarized in the following matrix.

	2	
1	A	B
A	$\frac{[4+\beta+4c]^2}{108}, \frac{[4+\beta-8c]^2}{108}$	$\frac{3[4+3\beta]^2}{400}, \frac{3[4-2\beta]^2}{400}$
B	$\frac{3[4(1-c)+3\beta]^2}{400}, \frac{3[4(1-c)-2\beta]^2}{400}$	$\frac{[4+\beta-8c]^2}{108}, \frac{[4+\beta+4c]^2}{108}$

Table 2

### 8.4.2 Describing Equilibrium Outcomes

Let us now explain the different equilibria that can arise as a function of the two key parameters,  $c$  and  $\beta$ . Both firms choosing product A is an equilibrium if  $\pi_1^{AA} \geq \pi_1^{BA}$  and  $\pi_2^{AA} \geq \pi_2^{BA}$ . Substituting these payoffs from Table 2, we get

$$(1) \pi_1^{AA} \geq \pi_1^{BA} \leftrightarrow \beta \leq \frac{4}{17} + \frac{76}{17}c. \quad (8.38)$$

$$(2) \pi_2^{AA} \geq \pi_2^{BA} \leftrightarrow \beta \geq -\frac{1}{7} + \frac{20}{7}c. \quad (8.39)$$

Similarly, both firms choosing product B is an equilibrium if  $\pi_1^{BB} \geq \pi_1^{AB}$  and  $\pi_2^{BB} \geq \pi_2^{AB}$ . Substituting these payoffs from Table 2, we get

$$(3) \quad \pi_1^{BB} \geq \pi_1^{AB} \leftrightarrow \beta \leq \frac{4}{17} - \frac{80}{17}c. \quad (8.40)$$

$$(4) \quad \pi_2^{BB} \geq \pi_2^{BA} \leftrightarrow \beta \geq -\frac{1}{7} - \frac{19}{7}c. \quad (8.41)$$

Similarly, for AB to be an equilibrium  $\pi_2^{AB} \geq \pi_2^{AA}$  and  $\pi_1^{AB} \geq \pi_1^{BB}$ : this means that  $\beta \leq -\frac{1}{7} + \frac{20}{7}c$  and/or  $\beta \geq \frac{4}{17} - \frac{80}{17}c$ .

Finally, for BA to be an equilibrium, it must be the case that  $\pi_1^{BA} \geq \pi_1^{AA}$  and that  $\pi_2^{BA} \geq \pi_2^{BB}$ . However, observe that  $\pi_2^{BA} \geq \pi_2^{BB}$  is always violated, as  $\beta \geq 0$ . So BA can never be an equilibrium. This is intuitive: as firm 2 prefers to choose its preferred technology (B) and this incentive is reinforced if that also gives access to the installed base of firm 1.

To get an overall picture we plot the three inequalities (1)-(3) in Figure 8.6.

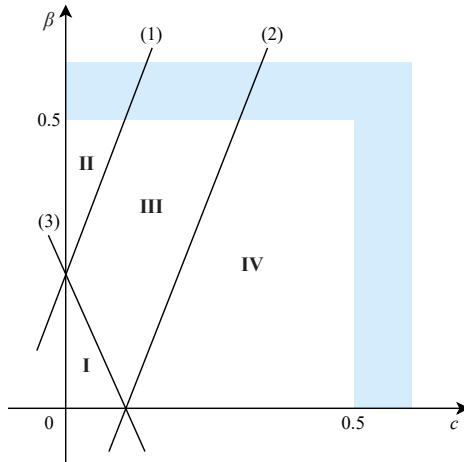

Figure 8.6: Installed base size and technology costs

In area I, the two standarization outcomes AA and BB are both equilibria. This happens because the costs are very modest so both firms are open to moving to the other technology and the installed base is sufficiently small so that the lead firm 1 is not entirely averse to having firm 2 choosing a compatible product (in return for sharing a network of new users).

In area II, the benefits from installed base are large and the costs of choosing product A is not large, so firm 1 has a strong incentive to choose product A. However, firm 1 does not wish to share its network with firm 2, so there is no pure strategy equilibrium.

In area III, straightforward standarization on product AA is the unique outcome. The costs of product A are modest so firm 2 is keen to adopt product A. Firm 1 finds costs of switching to product B larger than the potential costs of sharing its installed base with firm

2.

In area IV, the costs of switching products are large and so both firms stick to their preferred products. This leads to a standards war, the outcome AB.

Let us summarize what we have learnt in this section. Pre-market standardization is more likely to emerge if one, when installed base effects and costs of different technologies are both small or, two, when the installed base advantage makes switching technology worthwhile for new entrants. By contrast, a standards war is more likely to arise when installed base effects are relatively modest relative to cost differences across technologies for the firms.

## 8.5 Multi-sided Platforms

So far we have studied a very simple setting in which there is one group and the returns from choosing an action depend on how many others from that group choose the same action. We now turn to richer settings with multiple groups. Consider the Windows Operating system: more users make it more attractive for software developers, and more software programmes make the operating system more attractive for users. In this example, there are positive effects across the two groups of users and software developers. On the other hand in a newspaper an increase in number of readers makes it more attractive to advertisers, but more advertising probably makes the newspaper less attractive to the reader. The effects take on different signs across groups: readers dislike a paper with more advertisements, but advertisers like a paper with more readers.

The issues we studied in the simple setting with one group remain pertinent – the emergence of a dominant platform and the risks of lock-in into a platform that is inefficient. But the setting with multiple groups also raises new questions, such as how should a platform price the access to its services? We now study this pricing problem.

Let us start with one platform serving two sides,  $A$  and  $B$ . Demand on one side  $D_i$ , depends positively on the size of the other side  $j$ .

$$\begin{aligned} D_A(p_A, E(D_B)) &= V + \beta_{AB}E[D_B] - p_A \\ D_B(p_B, E(D_A)) &= V + \beta_{BA}E[D_A] - p_B. \end{aligned} \tag{8.42}$$

where  $\beta_{AB}$  and  $\beta_{BA}$  reflect the magnitude of the cross side demand effects, and  $E(D_B)$  and  $E(D_A)$  reflect the expected demands on the other side.

The profits of the platform can be written as follows as sum of profits from the two sides

of the market:

$$\Pi(p_A, p_B) = D_A(p_A, E(D_B))p_A + D_B(p_B, E(D_A))p_B. \quad (8.43)$$

To make progress, we consider that expectations are met in equilibrium. In other words, the expected demand is equal to the true demand.

$$\begin{aligned} E[D_A(p_A, E(D_B))] &= V + \beta_{AB}E[D_B] - p_A \\ E[D_B(p_B, E(D_A))] &= V + \beta_{BA}E[D_A] - p_B. \end{aligned} \quad (8.44)$$

Given the prices,  $(p_A, p_B)$ , we therefore have a demand system of two equations in two unknowns,  $D_A$  and  $D_B$ .

We can solve these two equations and obtain ‘consistent’ demands:

$$\begin{aligned} D_A(p_A, p_B) &= \frac{V(1 + \beta_{AB}) - \beta_{AB}p_B - p_A}{1 - \beta_{AB}\beta_{BA}} \\ D_B(p_A, p_B) &= \frac{V(1 + \beta_{BA}) - \beta_{BA}p_A - p_B}{1 - \beta_{AB}\beta_{BA}} \end{aligned} \quad (8.45)$$

Observe that an increase in  $p_A$  lowers demand of side A and, due to cross-side positive externalities, also lowers demand for side B.

If we substitute these demands in the profit expression we obtain:

$$\Pi(p_A, p_B) = p_A \frac{V(1 + \beta_{AB}) - \beta_{AB}p_B - p_A}{1 - \beta_{AB}\beta_{BA}} + p_B \frac{V(1 + \beta_{BA}) - \beta_{BA}p_A - p_B}{1 - \beta_{AB}\beta_{BA}} \quad (8.46)$$

Equipped with this expression, we can compute optimal prices. To develop a sense of the problem it is helpful to start with the benchmark case  $\beta_{AB} = \beta_{BA} = 0$ . It is easy to see that the optimal price will be  $V/2$ , as in the monopoly pricing of independent markets. Next let us consider the case of cross group externalities.

Solving for optimal prices, we arrive at

$$\begin{aligned} p_A &= \frac{V(-1 + \beta_{BA})}{-2 + \beta_{AB} + \beta_{BA}} \\ p_B &= \frac{V(-1 + \beta_{AB})}{-2 + \beta_{AB} + \beta_{BA}} \end{aligned} \quad (8.47)$$

To develop an appreciation for the effects of cross effects: suppose that  $\beta_{AB}, \beta_{BA} > 0$  and  $\beta_{AB} + \beta_{BA} = 1$ . Substituting these assumptions in the profit function and solving for optimal prices yields us:

$$\begin{aligned} p_A &= \frac{V}{2} + V\left(\frac{1}{2} - \beta_{BA}\right) \\ p_B &= V(1 - \beta_{AB}) \end{aligned} \tag{8.48}$$

Let us examine the effects of the cross group externality term. Suppose  $\beta_{AB} > 1/2$  and so  $\beta_{BA} = 1 - \beta_{AB} < 1/2$ . Consumers on side A gain more from side B, than vice versa. It then follows that the optimal price is higher for side A as compared to side B. This is intuitive: an increase in demand of group B raises the demand of group A more than the converse, so the firm sets a higher price for group A and a lower price for group B. This intuition is also reflected in the price elasticity for the two groups. The price elasticity expressions for the two groups may be written as follows:

$$\epsilon_{D_A, p_B} = \frac{\beta_{AB}}{1 - \beta_{AB}\beta_{BA}} \frac{p_B}{D_A} \tag{8.49}$$

$$\epsilon_{D_B, p_A} = \frac{\beta_{BA}}{1 - \beta_{AB}\beta_{BA}} \frac{p_A}{D_B}. \tag{8.50}$$

We see that if  $\beta_{AB} > 1/2$  then the cross price elasticity for side A (with respect to price B) is higher. This means that the platform can set fairly asymmetric prices to exploit cross side network effects. A question at the end of the chapter examines this point.

We present examples of well known platform and their pricing policies. In these examples, a general presumption is that if other aspects of the demand is the same for both sides, the side that creates larger positive cross effects is offered a relatively lower price to access the platform. Let us summarize what we have learnt in this section. We study the optimal pricing by a platform that serves multiple consumer segments. The key insight was that over and above the standard considerations as reflected in the price elasticity of demand, cross effects on demand give rise to discrimination in pricing across different sides of the market: in particular, the side of the market that exerts a larger positive effect on the demand of the other side faces a relative lower price to access the platform.

INDUSTRY	PLATFORMS	PREMIUM/SUBSIDY
Employment	Naukri, Zhaopin, LinkedIn	Employers/Workers
Retail	Amazon, Alibaba	Sellers/Buyers
Lodging	Tujia, AirBnB	Sellers/Consumers
Ride-Hail	Uber, Lyft	Drivers/Passengers
Payments	Visa, MasterCard	Sellers/Consumers
Operating Systems	Windows, Mac	Programmers / Users
Newspapers	Guardian, NYT	Advertisers/Readers

Table 8.1: Two sided platforms: pricing strategies

### 8.5.1 Openness

Openness pertains to how many sides of a market a firm should pursue. A prominent example is the different choices of Apple and Microsoft. Apple produces both its computer hardware and its computer operating system, whereas Microsoft controls only the operating system and counts on independent manufacturers to supply (most of) the hardware. In this market, Microsoft manages a three-sided market between consumers, software providers, and hardware providers, whereas Apple manages a two-sided market between consumers and software providers. So we may say that Microsoft is more open as it manages a three sided market, while Apple manages a two sided market.

A firm may change its strategy on openness as its market evolves. This is because a entrant firm faces a chicken and egg problem: – to establish a large demand on one side of the market, a firm should establish itself on the other side of the market – that can in principle be addressed by providing one side of the market itself. An example of this sequence of strategies is Amazon that first established itself as an on-line book retailer before introducing its “marketplace” where sellers set prices and interact with consumers. Thus there is a sense in which it may be better to think of two-sided “strategies” rather than two-sided “markets”, because the number of sides is to some extent endogenous. Another instance of this is the Palm line of computers. The Palm personal digital assistant was launched as a one-sided network product. It produced its own hardware, operating system, and applications software. Palm eventually allowed independent software developers into the system, but only after the product was fairly well established. At this point, Palm devices ran its own operating system, and Palm licensed very few non-Palm devices to use it. That strategy changed again and the company split into operating system company and a hardware company. The hardware firm introduced a Palm device that ran a Windows operating system, while the operating system sought out to attract hardware production from independent suppliers.

## 8.6 Chains of Intermediation

Intermediaries are a prominent feature of the modern economy: they are a defining feature of banking, retail, and information services. A central theme in the chapter has been the dynamics of competition between different intermediaries and platforms. This section presents an experimental examination of this competition. In particular, inspired by examples like Amazon, we study a setting where traders need connections to be able to trade. Intermediaries lower costs of exchange or reduce frictions between buyers and sellers. In line with the earlier discussions on two sided network effects intermediation has a reinforcing aspect: the more actors use an intermediary, the more attractive it becomes for other actors to use. The earlier sections have highlighted how these network pressures may give rise to highly visible globally dominant intermediaries. This section explores the dynamics of competition among the intermediaries from an experimental perspective. The goal is to better understand the mechanisms underlying the emergence of such dominant intermediaries. The experiment is taken from Choi, Goyal, and Moisan [2020].

We consider a setting in which trades between two actors can be realized if they have a direct link or if they are indirectly linked through a chain of intermediaries. These links are costly to maintain. For concreteness, consider a network with  $n$  actors in which all pairs are linked (the complete network). In this setting, every bilateral exchange involves direct trading: there is no intermediation. However, there are  $n(n - 1)/2$  links formed. By contrast, consider the hub-spoke network: in this setting all the exchanges involving pairs of spokes – i.e.,  $(n - 1)(n - 2)/2$  pairs – entail intermediation (and possibly large rents for the hub). This is accompanied by a large saving in costs of links, as the hub-spoke network contains only  $n - 1$  links. A network may be sparse and connected without concentration of intermediation power. An instance of such a network is a cycle containing all actors: in this setting, there are only  $n$  links and as everyone is symmetrically located, every actor will earn an equal payoff. So the cycle reconciles efficiency and equity. The experiment helps us understand when the cycle and the hub-spoke structure will emerge.

We will consider a network formation model that builds on the work of Goyal and Vega-Redondo [2007], Kleinberg et al. [2008] and Galeotti and Goyal [2014]. Individuals choose to form links with each other and then use the network constructed to engage in exchange. If an actor maintains links with many others, she incurs large linking costs but she will be able to appropriate a fair share of the surplus generated by the exchanges. If on the other hand she maintains few links then her linking costs will be modest, but she will either not undertake many exchanges (as she has no path connecting her to several traders) or she will conduct her exchange with the help of intermediaries. Over and above this, this

environment gives rise to an intermediation incentive: an actor may wish to strategically form links with others with a view to extracting rents by acting as an intermediary for trades between other actors.

### 8.6.1 Model

We start by presenting the theoretical model. There are  $N = \{1, \dots, n\}$ , where  $n \geq 3$  players. Players propose links with others: a link is realized only if it is reciprocated. Formally, the strategy of a player  $i$  is a vector of link proposals  $s_i = [s_{ij}]_{j \in N \setminus \{i\}}$ , with  $s_{ij} \in \{0, 1\}$  for any  $j \in N \setminus \{i\}$ . The strategy set of player  $i$  is denoted by  $S_i$ . A link between agents  $i$  and  $j$  is formed if both propose a link to each other, i.e.,  $g_{ij} = s_{ij}s_{ji}$ . A strategy profile  $s = (s_1, s_2, \dots, s_n)$  induces an undirected network  $g(s)$ .<sup>1</sup> There exists a path between  $i$  and  $j$  in a network  $g$  if either  $g_{ij} = 1$ , or if there is a distinct set of players  $i_1, \dots, i_n$  such that  $g_{ii_1} = g_{i_1i_2} = g_{i_2i_3} = \dots = g_{i_nj} = 1$ . All players with whom  $i$  has a path defines the component of  $i$  in  $g$ , which is denoted by  $C_i(g)$ .

Suppose that players are traders who can exchange goods and that this exchange creates a surplus of  $V$ . This exchange can be carried out only if these traders have a link or if there is a path between them. There is a fixed cost  $k$  per individual for every link that is established. On the other hand, any proposal that is not reciprocated carries no cost. In the case where two traders have a link, it is natural that they split the surplus equally, each earning  $V/2$ . If they are linked indirectly, then the allocation of the surplus depends on the nature of competition between the intermediary agents. One idea is to view these paths as being perfect substitutes. Another possibility is that the paths offer differentiated trading mechanisms.

**Criticality Pricing:** Suppose that paths between traders are perfect substitutes. A trader is said to be *critical* for a pair of traders A and B if she lies on all paths between these traders. Trade between A and B occurs if there is a path between them. The surplus is divided equally between the traders and all critical intermediaries. This may be justified using Bertrand pricing by intermediate nodes: then the surplus is divided among the critical traders. For a theoretical analysis and experimental evidence on this outcome see Choi, Galeotti, and Goyal [2017].

Denote by  $T(j, k; g)$  the set of players who are critical for  $j$  and  $k$  in network  $g$  and let  $t(j, k; g) = |T(j, k; g)|$ . Following Goyal and Vega-Redondo [2007], for every strategy profile  $s = (s_1, s_2, \dots, s_n)$  the net payoffs to player  $i$  are given by:

---

<sup>1</sup>With a slight abuse of notation, for simplicity, we will write  $g$  instead of  $g(s)$ .

$$\Pi_i^{crit}(s) = \underbrace{\sum_{j \in C_i(g)} \frac{V}{t(i, j; g) + 2}}_{\text{Access Benefits}} + \underbrace{\sum_{j, k \in N \setminus \{i\}} V \frac{I_{i \in T(j, k; g)}}{t(j, k; g) + 2} - \eta_i(g)k}_{\text{Brokerage Rents}} \quad (8.51)$$

where  $I_{i \in T(j, k)} \in \{0, 1\}$  stands for the indicator function specifying whether  $i$  is critical for  $j$  and  $k$ . We shall refer to it as the model of criticality-based pricing, which relies on two distinct sources of benefits: access benefits and brokerage rents.

**Betweenness Pricing:** We next turn to betweenness pricing that is taken from Kleinberg, Suri, Tardos, and Wexler [2008]. Let  $n_{jk} = (d(j, k; g) - 1)$  denote the number of intermediaries on a shortest path between  $j$  and  $k$  in network  $g$ . Trade surplus between  $j$  and  $k$  is equally distributed among the source and destination  $j$  and  $k$ , and among the intermediaries on the shortest path. In the case of multiple shortest paths, one of them is randomly chosen. Therefore, the (ex-ante) expected return for any trader  $i$  is in proportion to the shortest paths between  $j$  and  $k$  that  $i$  lies on. Formally, we write  $b_{jk}^i(g) \in [0, 1]$  to denote *betweenness* of player  $i$  between  $j$  and  $k$ . Formally,

$$b_{jk}^i(g) = \frac{\# \text{ shortest paths between } j \text{ and } k \text{ on which } i \text{ lies}}{\# \text{ shortest paths between } j \text{ and } k}$$

Given a strategy profile  $s = (s_1, s_2, \dots, s_n)$ , the net payoffs to player  $i$  are given by:

$$\Pi_i^{btwn}(s) = \underbrace{\sum_{j \in C_i(g)} \frac{V}{n_{ij} + 2}}_{\text{Access Benefits}} + \underbrace{\sum_{j, k \in N \setminus \{i\}} V \frac{b_{jk}^i}{n_{jk} + 2} - \eta_i(g)k}_{\text{Brokerage Rents}} \quad (8.52)$$

We will study pairwise stable networks. Simple computations yield the following result on network formation with criticality-based pricing.

**Proposition 8.3.** *Suppose payoffs are given by (8.51). There always exists a pairwise stable network. Pairwise stable networks include the empty network if  $k > \frac{V}{2}$ , the star network if  $\frac{V}{6} < k < \frac{Vn}{3} - \frac{V}{6}$ , and the cycle network if  $k < \sum_{i=1}^{n-2} \frac{Vi}{2(2+i)}$ . The complete network is not stable for  $n \geq 4$ .*

A general observation is that pairwise stable networks cover a wide range of structures that include the star and the cycle. So incentives in this model sustain networks with very small diameter as well as very large diameter. This also means that stability is compatible with efficiency and equality.

We next state a result on pairwise stable networks with betweenness-based pricing.

**Proposition 8.4.** *Suppose payoffs are given by (8.52). There always exists a pairwise stable network. Pairwise stable networks include the empty network if  $k > \frac{V}{2}$ , the complete network if  $k < \frac{V}{6}$ ,*

and the star network if  $\frac{V}{6} < k < \frac{Vn}{3} - \frac{V}{6}$ . For a given value for  $k$  and  $V$ , the cycle is not pairwise stable for large  $n$ .

Pairwise stability of the empty network follows from noting that two isolated individuals hope to earn  $V/2$  on forming a link. The conditions on the pairwise stability of the star network arise from two incentive constraints: spokes must not wish to form a link (this yields the constraint  $V/6 < c$ ) and the central hub must wish to form a link with a spoke (this yields the constraint  $c < Vn/3 - V/6$ ). In the complete network, no player can benefit by removing a link as long as  $k < \frac{V}{6}$ . In the cycle network, the gain in benefits (access benefits and brokerage rents) for adding a link between two players sitting at opposite points of the cycle increases with  $n$ . As a result, if  $n$  is sufficiently large, such a move becomes profitable for both players. Finally observe that for any values of  $k > 0$  and  $n \geq 3$ , at least one of empty, star, and complete network is pairwise stable.

Turning to efficiency, observe that the intermediation rents cancel out when we sum across individuals. A network is said to be efficient if it maximizes the sum of trade surplus realized less the costs of links. Goyal and Vega-Redondo [2007] prove that an efficient network is either the empty network or a minimally connected network. The total payoffs in the latter case are  $\frac{Vn(n-1)}{2} - 2(n-1)k$  and they are equal to 0 in the case of an empty network. So it follows that an efficient network is minimally connected if  $k < \frac{Vn}{4}$ , and empty otherwise. A prominent example of minimally connected network is the star network.

Finally, payoff inequality significantly varies across different stable network structures. The outcome is equal in the empty network and in a cycle network. By contrast, in the star network (under both criticality and betweenness), the hub and spoke earn respectively:

$$V(n-1) \left[ \frac{1}{2} + \frac{n-2}{6} \right] - (n-1)k \quad V \left[ \frac{1}{2} + \frac{n-2}{3} \right] - k \quad (8.53)$$

The ratio of the two payoffs grows without bound, in  $n$ , highlighting large inequalities in large groups.

As is common in network formation games there exist multiple stable networks with quite different properties. For instance, there exists  $n$  different star networks, each corresponding to a different player being hub. In addition, under criticality pricing the cycle network is also stable. Finally, the empty network is stable along side the star network for a wide set of parameters. Thus while the forces of efficiency and equity point to the cycle and the star, individuals face multiple challenges to arriving on such networks and it is far from clear what networks will arise. The scope of the theory is therefore quite unclear. We present an experiment with human subjects to delineate the scope of the theory, in particular the ways in which pricing rules shape incentives to form links and thereby determine

the architecture of the intermediation network.

### 8.6.2 Experiment

We will set the value of trade between any two traders is  $V = 10$ . The cost of a link is  $k = 80$ . With these parameters, the star network is efficient. It is however very unequal: in the star network the hub and spokes earn respectively 8745 and 252. In the cycle network every player earns 335. The ratio of maximum to median payoffs is 35 therefore; the cycle network by contrast is almost equally efficient and is perfectly equal. This tension between inequality and efficiency is a key element in the experiment.

The analysis of pairwise stable networks, efficiency and inequality suggests the following hypothesis.

**Hypothesis** *Under both pricing treatments subjects create networks that are efficient. Under criticality pricing, networks are equal and spread out with significant average distances. Under betweenness pricing, networks are unequal with small average distance.*

**Design:** In a round, at any moment, the subject is shown the entire network of reciprocated links. In addition, every subject is shown all outstanding link proposals – made and received – that involve them. Every subject is also provided full information on the payoffs of everyone (this is done by mentioning the numeric value of the payoffs for every subject next to their player ID. However, subjects are *not* shown unreciprocated links among other pairs. The principal motivation for this design choice was to keep the information options available to a subject manageable.

The experiment consists of a group playing 6 rounds of the linking game; each round lasts six minutes. At any instant a subject can make or remove a proposal to another subject by simply double-clicking on the corresponding node in the computer screen. Any reciprocated proposal leads to the formation of a link. At any point in time, a subject is shown the amount of access benefits, brokerage rents, overall cost of linking, and net payoffs. Finally, subjects are also provided with information about the net payoffs of every other player (given within the corresponding node of the network).

The experiment considered 4 groups of 100 subjects (per pricing rule). A session lasted 90 minutes, and subjects earned on average about 16.4 euros (including a 5 euros show-up fee).

### Findings

We begin by presenting snap shots of the typical dynamics under the two pricing rules. Figures 8.7a and 8.7b show the snap shots of the criticality treatment at minute 3 and minute

6, respectively. Network structures are sparse and connected and fairly dispersed. There is no single player who occupies a dominant network position and extracts large brokerage rents. Figures 8.7c and 8.7d show that the dynamics in the betweenness treatment are quite different. At minute 3, one subject (represented in red) starts to emerge as a hub, and becomes a dominant hub at the end of the game. As a result, she earns substantial brokerage rents.

These snap shots bring out three points: first, under both pricing protocols, subjects create sparse and connected networks; two, the pricing protocol leads to the emergence of equal and dispersed networks under criticality and to unequal and small distance networks under betweenness pricing; third, there is little inequality in the criticality treatment while the hub in the betweenness treatment earns large brokerage rents and, as a result, there is great payoff inequality in the betweenness treatment. Let us examine the data more systematically.

First, consider efficiency. At any second, the level of efficiency is measured by the ratio of the total payoffs of an observed network, relative to the star network, i.e., the first-best pairwise stable and efficient network. Figure 8.8 plots the time series for efficiency levels. We note that subjects create networks that attain high levels of efficiency: for group sizes of 100, it is around 0.7 under criticality pricing, while it starts very low but then increases rapidly to reach over 0.4 under betweenness pricing.

The level of efficiency depends on the connectivity of subjects (the realization of trade between subjects) and the total number of links created by subjects. Connectivity of subjects is very high and similar across treatments: on average 98.7% under criticality pricing, and 98.1% for betweenness pricing. As connectivity is high and comparable, the differences in efficiency across treatments must be due to variations in the number of links. Figures 8.9a and 8.9d show that there is a large difference in the number of links.

We now turn to the effects of pricing on network structure. Figure 8.9 summarizes the findings.

In the criticality treatment, the average degree lies between 2 and 3. In the betweenness treatment, the average degree is higher: falling from 5 to 4 for  $N = 100$ . Keeping in mind that there are 100 subjects, this tells us that subjects create sparse networks. This is consistent with our Hypothesis. Figures 8.9b and 8.9e show that link inequality is modest and remains stable under criticality pricing, while it is large under betweenness pricing.

Turning to distance, Figures 8.9c and 8.9f show that average distance is above 4 in the criticality treatment and below 3 in the betweenness treatment. To put this in perspective, we note that the average size of the largest component under the criticality pricing 99.3 and under betweenness pricing it was 99.1. We summarize these observations as follows:

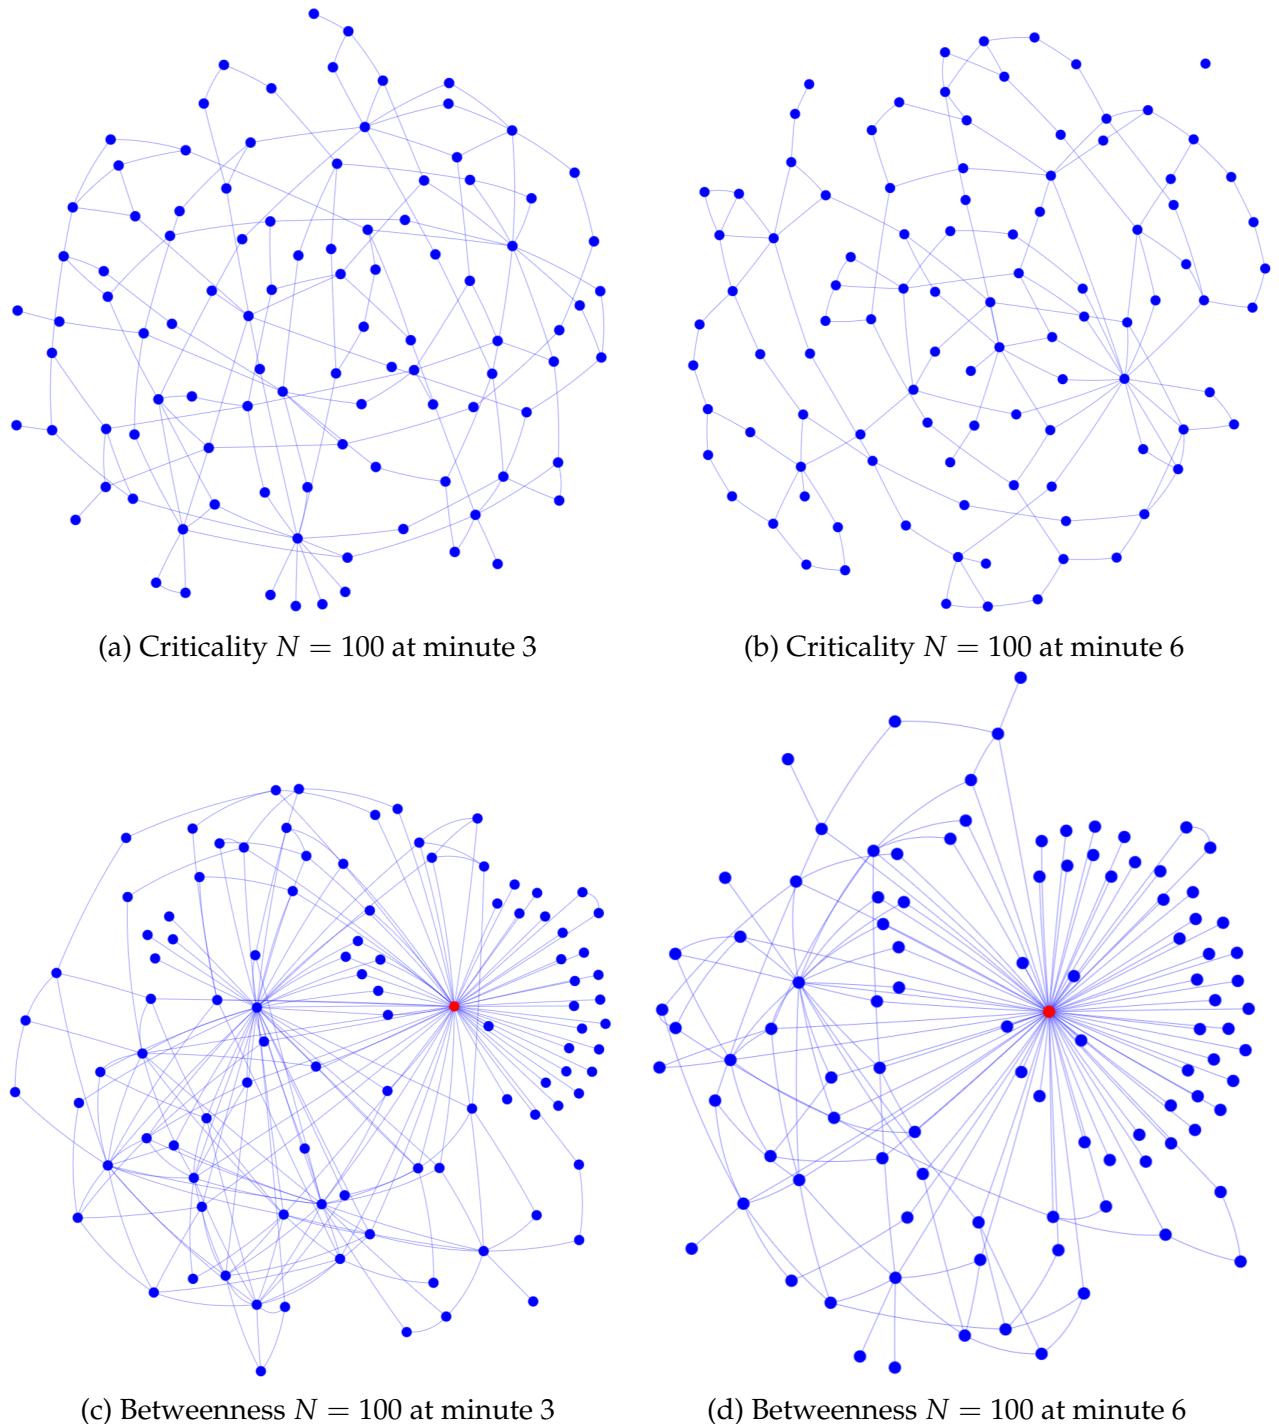

Figure 8.7: Snap shots. Source: Choi, Goyal, and Moisan [2020].

Figure 8.10 presents time series of the ratio of maximum payoff divided by the median payoff. We see that payoff inequality is modest (between 2 and 3) under criticality pricing, while it is very large (around 34 to 35) under betweenss pricing.

To summarize, subjects create networks that are sparse. The efficiency is very high

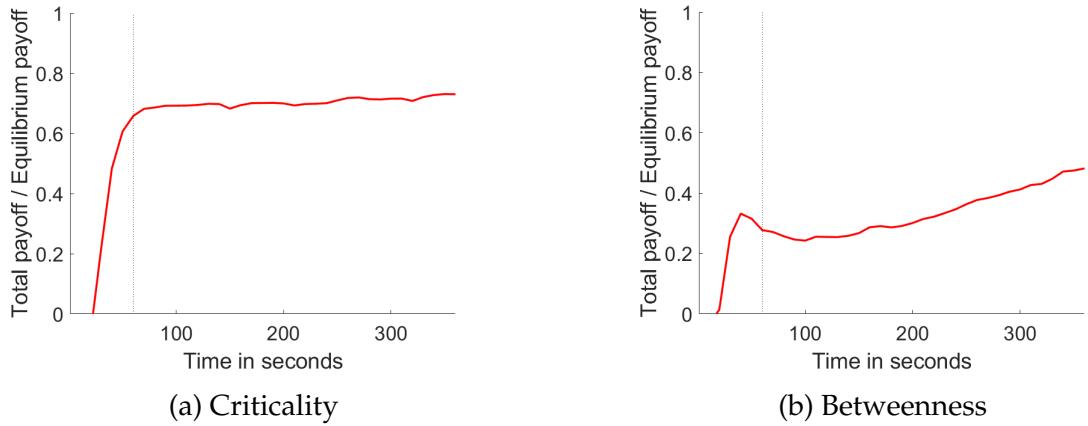

Figure 8.8: Efficiency. Source: Choi, Goyal, and Moisan [2020].

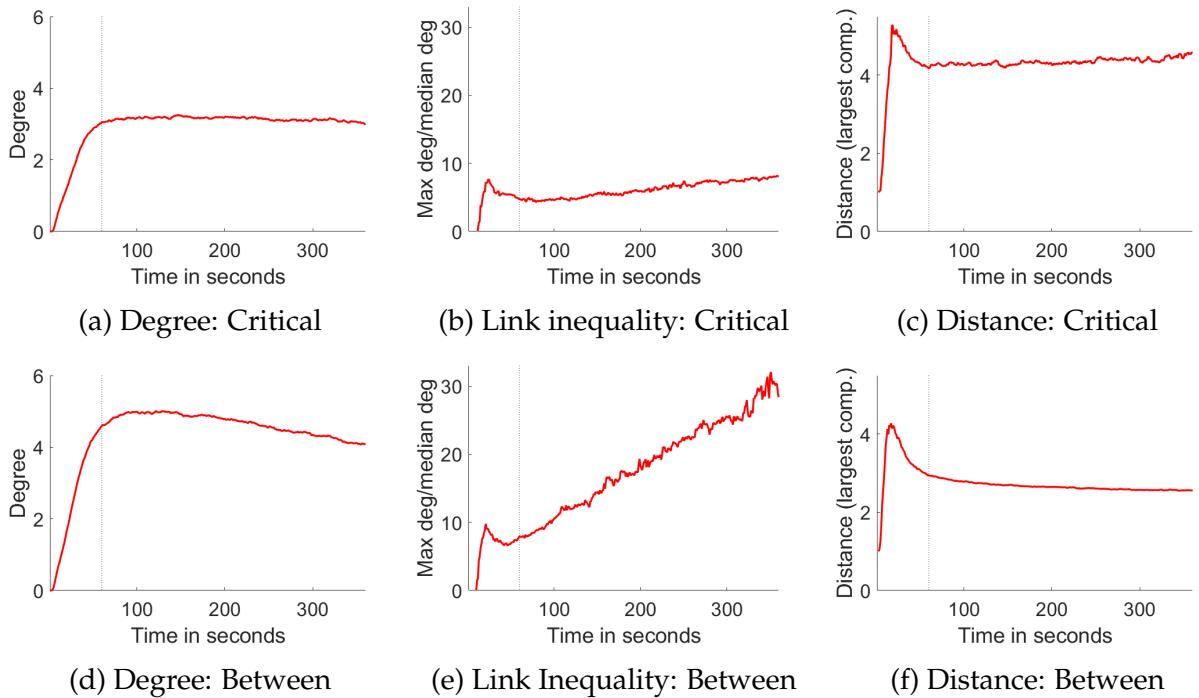

Figure 8.9: Network Structure. Source: Choi, Goyal, and Moisan [2020].

under criticality pricing and moderate under betweenness pricing. Pricing has powerful effects on network structure. We turn to the ways in which pricing shapes incentives to form links.

### Pricing Rules and Linking Incentives

We start by examining the number of link proposals made by the different types of subjects (measured in terms of how many link proposals they have received): the most popular in-

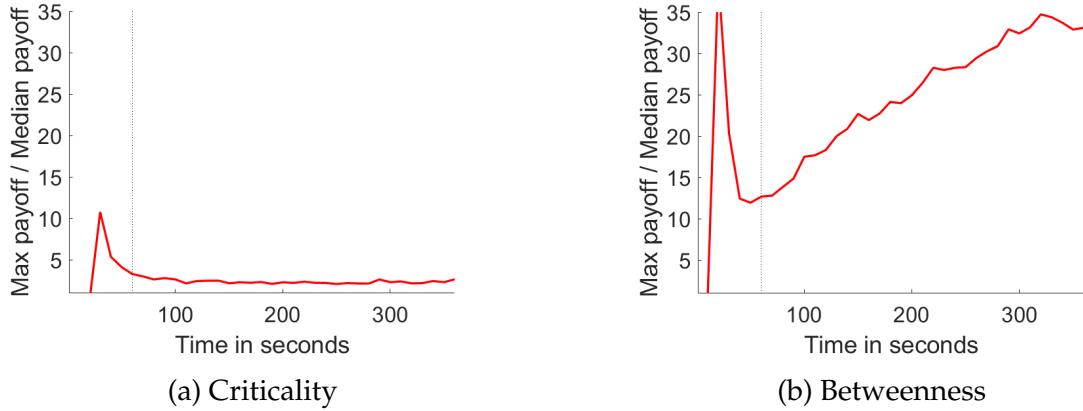

Figure 8.10: Payoff Inequality. Source: Choi, Goyal, and Moisan [2020].

dividual, the 2nd most popular individual, and the other individuals. Figure 8.11 plots the time series of the average fraction of the number of link proposals made by each type to the total number of link proposals. We see that there major differences in the link proposals made by the two most popular individuals. Under criticality pricing, most subjects form two links and no one forms a very large number of links, thus keeping the average degree close to 2. By contrast, under betweenness pricing, a number of individuals compete for the hub position by making a large number of link proposals. Notably, the number of link proposals by the most popular individual is growing over time. In addition, the second most popular subject also proposes a large number of links. These proposals are reciprocated and, as a result, there is a high fraction of subjects that have three or more links. This pushes up the average degree.

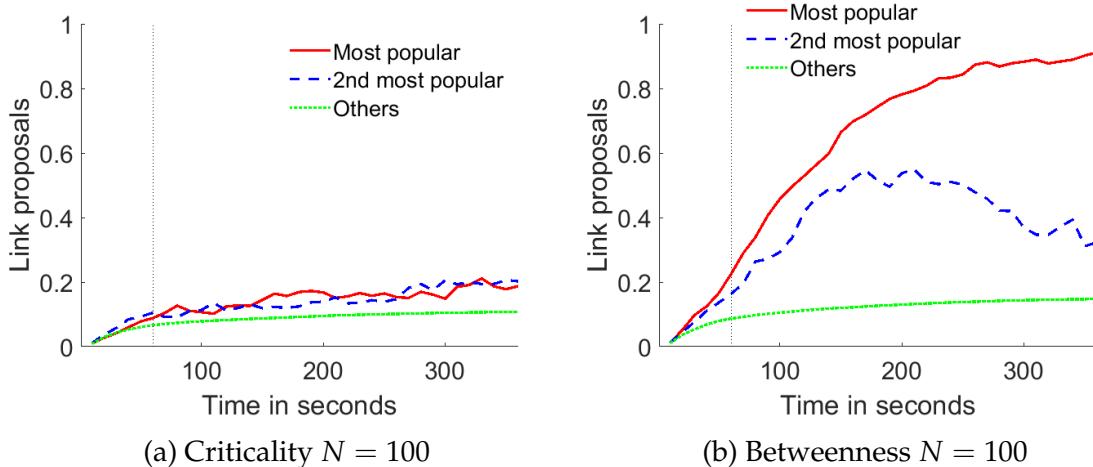

Figure 8.11: Link proposals

The different link proposals under the two pricing rules arise out of the possibility of

generating intermediation rents – under criticality pricing, there is very little incentive to propose once individuals are in a cycle, as there are no brokerage rents to be earned. By contrast, under betweenness, additional links create shorter paths and generate brokerage rents. Other individuals respond positively to the proposals as this enables them to access traders at shorter length. However, as the network evolves and average distance goes down, the returns to links with multiple hubs declines. Table 8.2 presents the relationship between number of links and payoffs in comparison with the equilibrium payoffs.

It shows that under criticality pricing, subjects with 2 links earn more than those with either 1 link or 3 links ( $p < 0.01$  from two-sample t-tests with the group level average data, comparing payoffs with 2 links and payoffs with either 1 or 3 links, for any group size). In contrast, subjects with 1 link earn the most under betweenness pricing ( $p < 0.01$  from two-sample t-tests with the group level average data, comparing payoffs with 1 link and payoffs with either 2 or 3 links, for any group size). Moreover, the difference in payoffs grows over time as the network evolves and average distances gradually come down. The rate at which links come down is however slow and this accounts for the relatively low level of efficiency even at the end of six minutes.

	Criticality $N = 100$	Betweenness $N = 100$
1 link	235	202
2 links	311	131
3 links	231	70
Equilibrium	335	252

Notes: equilibrium payoffs are based on the cycle network under Criticality, and the star network (spokes' payoffs) under Betweenness.

Table 8.2: Payoffs associated with forming 1, 2, or 3 links: Last 2.5 minutes

Let us summarize what we have learnt in this section. We have examined the effects of pricing rules on the formation of intermediation networks and the rise of market dominance. The theory is permissive with different networks being stable. However when we combine stability with the requirement of efficiency and equity pricing protocols the theory predicts different networks under different pricing protocols. The experiments offer support to these theoretical predictions. In particular, we find that subjects create spread out and sparse networks that are close to cycles under criticality pricing. These networks lead to fairly equal payoffs. By contrast, under betweenness pricing, subjects create sparse but very unequal networks that give rise to extreme market dominance. There is great payoff inequality across subjects in such networks.

## 8.7 Reading Notes

The literature on markets with network goods goes back a long way. For a seminal discussion of pricing and multiple equilibrium in such markets see Rohlfs [1974]. The analysis of inertia, excess momentum, and lock-ins originated with Farrell and Saloner [1985] and Arthur [1989]. David [1985] offers an influential discussion of lock-ins using the example of QWERTY keyboard. More generally the issue of technological change has been extensively studied in the context of network externalities; see e.g., de Bijl and Goyal [1995]. The analysis of the compatibility problem draws on the seminal work of Farrell and Saloner [1986], Katz and Shapiro [1985] and Katz and Shapiro [1986]. For surveys of the early literature on markets with network effects, see Besen and Farrell [1994] and Katz and Shapiro [1994] and for a non-technical introduction to firm strategies in markets with network effects, see Shapiro and Varian [1995].

The literature on indirect network effects can be traced back to the early work of Chou and Shy [1990], Church and Gandal [1992] and Church and Gandal [1993]. Within this literature, two issues have received a great deal of attention: optimal pricing strategies and emergence of a dominant platforms. For optimal pricing, see Armstrong [2006], Caillaud and Jullien [2003], Rochet and Tirole [2003] and Rochet and Tirole [2006]. For research on dominant platform see Rochet and Tirole [2002] and Ellison and Fudenberg [2003]. For an early empirical analysis of network effects, see Rysman [2004] and Rysman [2007]. Rysman [2009] provides a survey of the literature on two sided markets.

The experiment on trading and network formation is part of a large literature on intermediation. Influential early work examines pricing by intermediaries, their ability to reduce frictions, and thereby extract surpluses, see Rubinstein and Wolinsky [1987], Choi, Galeotti, and Goyal [2017], and Manea [2018]. Condorelli and Galeotti [2016] provide a survey of this work. For experiments on trading in networks and on intermediation, see Gale and Kariv [2009], Charness, Corominas-Bosch, and Frechette [2007] and Choi, Galeotti, and Goyal [2017]. The exposition in this chapter draws heavily on the theoretical models presented in Goyal and Vega-Redondo [2007] and Kleinberg et al. [2008]. The criticality based pricing rule is taken from Goyal and Vega-Redondo [2007], while the betweenness based pricing rule is taken from Kleinberg, Suri, Tardos, and Wexler [2008]. The exposition here draws on the recent experimental paper, Choi et al. [2020].

In addition to these papers, in writing this chapter, I have also drawn on the industrial organization textbook of BelleFlamme and Peitz [2015] and on the lecture notes of Jonathan Levin at Stanford and Andrea Galeotti at LBS.

## 8.8 Questions

1. Markets with positive adoption externalities are prone to dominance by single firms. Discuss.
2. Markets with demand side externalities may exhibit too little or too much technological change. Discuss.
3. (BelleFlamme and Peitz [2015]). Consider the Hotelling model with linear transport costs where two firms, 1 and 2, are located at the ends of the unit interval. Assume that the unit mass of consumers are uniformly distributed on this unit interval. Suppose that the products offered exhibit network effects. Let choice of consumer  $x \in [0, 1]$  be given by  $a_x \in \{1, 2\}$ . A consumer located at point  $x \in [0, 1]$  has utility

$$\begin{aligned} r - tx - p_1 + vn_1^e, & \text{ if } a_x = 1 \\ r - t(1-x) - p_2 + vn_2^e, & \text{ if } a_x = 2 \end{aligned}$$

where  $n_i^e$  is the expected number of consumers buying product  $i \in \{1, 2\}$ . Let us assume that  $r$  is sufficiently large so that the market is covered, i.e.,  $n_1^e = 1 - n_2^e$ . Both firms produce at zero marginal costs.

We consider a two stage game: in stage 1, both firms simultaneously announce prices and, in stage 2, observing these prices, the consumers choose whether to buy product 1 or 2. We will consider sub-game perfect equilibrium of the two stage game. In particular, we will study the fulfilled expectations equilibrium in stage 2 and then given that stage 2 equilibrium, we will work backward and solve for equilibrium in firm prices (in stage 1).

- Show that if  $t > v$  then there is a unique fulfilled expectations equilibrium in stage 2 for any pair of prices. Assuming that  $t > v$  solve for the equilibrium in the first stage game of pricing. Discuss the effects of network effects,  $v$  on this equilibrium.
  - Show that if  $t < v$  then there could exist multiple fulfilled expectations equilibrium in the stage 2 for some pairs of prices.
4. (BelleFlamme and Peitz [2015]). Consider a monopoly platform that serves two groups of users. Each group  $i = a, b$ , comprises a unit mass of users. The platform charges membership fees  $M_a$  and  $M_b$  for two types of the users. The marginal costs of serving

users are set equal to zero. A user of group  $i$  enjoys utility

$$U_i = \alpha_i + \gamma_i n_j - M_i, \quad (8.54)$$

where  $\alpha_i$  is the standalone or intrinsic value of being on the platform,  $\gamma_i$  is the marginal benefit of an additional user on the other side of the market, and  $n_j$  is the number of users on side  $j$ . We shall assume that  $\alpha_i$  is drawn from a uniform distribution on interval  $[0, v]$  and we assume that  $\gamma_a, \gamma_b > 0$ .

- Derive the demand on a side of market as a function of firm prices and number of users on the other side
  - Solve for the system of demand equations derived in previous part to express the number of users as a function of prices  $M_a, M_b$ .
  - Now consider an asymmetric externality setting: set  $\gamma_a = \gamma$  (with  $0 < \gamma < 1$ ) and  $\gamma_b = 0$  and to simplify matters also assume that  $v_a = v_b = 1$ . Solve for the optimal prices of the monopolist.
5. Consider a  $n$  player network formation game. Link formation is two-sided. Every pair of players who have a path between them create a total surplus of 1. Suppose that the surplus is shared equally with critical traders necessary for the trade between a pair of traders.
- (a) Consider a game with 5 players and write down all the critical players in a cycle and the star network.
  - (b) Recall the payoffs as given in expression 8.51. Discuss the incentives to create links.
  - (c) Show that a star and a cycle containing all players are both pairwise stable (under suitable costs of linking).
6. Carry out the computations and establish the following result from section 8.6 under criticality based pricing: Pairwise stable networks include the empty network if  $k > \frac{V}{2}$ , the star network if  $\frac{V}{6} < k < \frac{Vn}{3} - \frac{V}{6}$ , and the cycle network if  $k < \sum_{i=1}^{n-2} \frac{Vi}{2(2+i)}$ . The complete network is not stable for  $n \geq 4$ .
7. Consider a  $n$  player network formation game. Link formation is two-sided. Every pair of players who have a path between them create a total surplus of 1. Suppose that the surplus is independent of the length of the path. The payoffs are shared with players who lie on the shortest paths between the two traders in the exchange.

- (a) Consider a game with 6 players numbered 1 to 6 who are located on a cycle network. Write down the payoffs of a player under betweenness pricing (using the payoffs expression as in 8.52).
- (b) Consider a game with 5 players numbered 1 to 6 who are located on a star network (with player 1 as the hub). Write down the payoffs of the players under betweenness pricing.
- (c) Show that a star is pairwise stable and also efficient (under suitable costs of linking).
- (d) Show that for fixed costs of linking as number of players gets large the cycle is not pairwise stable.
8. The star is pairwise stable and efficient under both criticality pricing and betweenness pricing. However, in the experiments, subjects only create the star under betweenness pricing.
- Discuss the circumstances under which criticality based pricing and betweenness based pricing are respectively reasonable.
  - Discuss the economic forces driving the emergence of high diameter low centrality networks under criticality pricing and the small diameter hubs-poke like networks under betweenness pricing.

# Chapter 9: Financial Contagion

## 9.1 Introduction

The Financial Crisis of 2007-2008 drew attention to the great interconnectedness of the global financial system. The collapse of a large American bank, Lehman Brothers, set off a financial contagion that spread across America and in due course had profound effects on financial markets across the world. This contagion poses a number of questions: What is the nature of interconnectedness among financial institutions? How do these interconnections transmit shocks? Do more connections amplify or dampen shocks to individual institutions? Does the structure of the network matter? If so, what are the structural features of networks that are relevant for setting policy? The aim of this chapter is to develop a theoretical framework that can help us address these questions.

The next section sets the stage by describing some empirical features of the financial sector. The sector consists of banks and institutions that span a wide range of activities: mortgages, insurance, supply credit, and short term bank liquidity. The diversity of activities makes the network of financial linkages potentially very complex. Moreover, the linkages between banks are private knowledge to these institutions. This makes the network opaque to participants (and also to outsiders such as regulators) and this means that it may be difficult for individual entities to work out the implications of any shock.

Section 9.3 lays out the basic features of inter-linkages of obligations between banks and relations to outside players. We will argue that the valuation/net worth of a bank will depend on the valuations of other banks, which in turn depend on the valuation of the bank in question. This circularity in valuations is a fundamental feature of financial networks. Thus the health of a financial system will depend on the fundamentals and the network structure but beliefs/expectations about valuations will also have an important role.

Section 9.4 presents a simple model of liquidity shocks. The model presents a detailed description of the motivation for the formation of links. The analysis of this model highlights a fundamental trade-off in financial networks: linkages reduce the exposure of in-

dividual banks to idiosyncratic shocks but at the same time they open a path toward the spread of defaults across institutions.

Section 9.5 presents a general model in which linkages can represent cross ownerships as well as borrowing and lending between banks. The study of this model shows that both the nature of the link as well as the architecture of the network play a role in shaping financial contagion. A key insight concerns the relation between the size of shocks and the nature of optimal networks. This provides a foundation for the widely commented upon ‘robust yet fragile’ nature of financial networks.

Section 9.6 takes up the issue of network complexity and opacity. The effects of a shock on a bank on other banks depend on the connections that the originator bank has and the structure of the network. However, this structure is often very poorly understood by the participants in the network and by outsiders such as policy makers and regulators. We present a model to examine the implications of network opacity on behaviour of banks. The model helps us understand how network complexity and risk aversion of banks can give rise to very large fire sales as a reaction to a shock on a single bank.

Section 10.4 presents a model that studies the forces that lead to core-periphery networks. The conventional view is that institutions establish links with one another as a way of diversifying different types of risk and facilitating intermediation. The model focuses on the intermediation element. In this model, banks choose borrowing and lending links strategically in a way that tilts the division of surplus along an intermediation chain in their favor. This strategic behaviour pushes investment banks toward forming many links with each other and occupying a core position in the network. The resulting network exhibits higher systemic risk as compared to the network that maximizes aggregate surplus.

## 9.2 The Financial Sector: Some Background

This section lays out the broad features of interdependence between financial institutions. We discuss, one, globalization in trade of goods and movement of capital; two, growth in market concentration in the financial sector; three, correlations in portfolios held by leading financial institutions; four, the core-periphery network connecting financial institutions; and five, the large costs of default and bankruptcy. Finally, we discuss case studies of financial contagion. This section draws on Jackson [2019], Jackson and Pernoud [2020] and Glasserman and Young [2016].

*Globalization:* World trade grew from just under 20 percent of world GDP at the end of the Second World War to over 60 percent by 2015. This growth in trade was supported

and mirrored by growth in financial interconnectedness. To get a sense of the changes in financial interconnectedness let us consider a much more recent period. In 2000, 17 percent of equities and 18 percent of bonds around the world were held by foreigners; by 2016, the corresponding numbers were 27 percent for equities and 31 percent for bonds. Similarly, in 2016, more than USD 132 trillion out of a total world investment of just over USD 300 trillion comes from foreigners. This international connectedness is accompanied by a great measure of linkage within the financial sector. Take for example the United States: Duarte and Eisenbach [2018] estimate that 23% of the assets of bank holding companies and 48% of their liabilities come from within the US financial system.

*Consolidation:* The financial sector has grown enormously but market concentration has grown too. To get an impression of these trends consider the situation in the United States: In 1980 there were 14000 commercial banks with total assets of USD 2 trillion. In 2018, there were only 4700 banks but they held total assets of USD 16.5 trillion. We see that the number of banks has dropped to a third of what it was while the assets have increased by a factor of eight. Thus in 1990 the five largest banks in the United States held 10% of total assets, in 2007 they held 35%, and in 2015 they held 45% of all financial assets. The concentration can be seen at the global level: in 2016, the ten largest banks in the world held assets worth USD 26 trillion dollars. To put that in perspective, the combined GDP of US and Chinese in that year was USD 29 trillion, and the world GDP was USD 75 trillion.

*Complexity:* An important feature of the financial sector over time is a great expansion in the range of instruments available. Consider the case of mortgages. A hundred years ago, a mortgage was typically issued by a bank and often it was the sole intermediary between that borrower and the bank's depositors. The bank performed a number of functions: it took in deposits, it assessed the worthiness and monitored the loan and the payments of the borrower.

Over time, the number of parties involved in mortgages has grown: a mortgage may now be issued through a broker who provides the sales and marketing expertise. The brokers work with a multitude of firms who do the actual issuing of the mortgages. They specialize in documenting the circumstances of the borrower and property involved and then often resell the mortgages. Mortgages are typically purchased and held en masse by entities that collect the payments and then resell these payments in different tranches (packages of mortgages grouped by risks and maturities) in the form of mortgage-backed securities. The securities are in turn bought by banks (and other investment companies) who then package them together in portfolios either to pay interest to their depositors or offer them as investment funds to private investors. Along the way, various parties insure

and hedge their risks via a variety of derivatives and insurance contracts that are sold by entirely different firms.

*Core-Periphery Structures:* The interbank lending networks have a core-periphery structure: a core of very large national/international banks and a periphery of smaller (but often still large) regional banks. The core banks are highly interconnected with each other, whereas the rest of the network is usually very sparse, a regional bank interacts with a few of the core banks. These empirical studies motivate the study of the economic forces that give rise to core-periphery networks.

*Correlations:* The financial crisis of 2008 was a situation in which many financial institutions were heavily exposed to the same mortgage and subprime mortgage markets, and had extensive exposures to each other at the same time. Since then, several studies have examined this sort of correlation explicitly. For instance, German banks are more likely to lend to banks with portfolios similar to their own: going from the 25th to 75th percentile of similarity in portfolios between two banks increases their lending to each other by 31 percent. There is also a similar pattern when we look at the extensive margin in terms of the probability that two banks lend to each other (for a discussion of these and other relationships among financial institutions, see Elliott, Georg, and Hazell [2020a]).

*Bankruptcy Costs:* The costs of default or bankruptcy are very large, James [1991]. Consider the Lehman Brothers default. There were initially USD 1.2 trillion of claims made by creditors. The courts ultimately allowed only USD 362 billion of claims. These creditors received 28 percent of their claims. This is probably an extreme example but it does help to bring out the fact that bankruptcy costs can be very large. More generally, bankruptcy recovery rates are on average under 60%, suggesting that over 40% of the value of a company is lost in the process. These bankruptcy costs are due to legal costs and the drop in asset values. The magnitude of these bankruptcy costs is therefore a first order factor in understanding the economic costs of contagion.

### 9.2.1 The anatomy of a crisis

We discuss the collapse of Lehman Brothers. Here we draw on Wiggins, Piontek, and Metrick [2019] and Wiggins and Metrick [2019]. At the time of its collapse on September 15, 2008, Lehman was the fourth largest financial institution in United States. It sought Chapter 11 protection initiating the largest bankruptcy in American history. At the point of bankruptcy, Lehman had USD 639 billion in assets and USD 613 billion in liabilities.

Lehman's collapse turned out to be a seminal event in the financial crisis that began in the American subprime mortgage industry in 2007, spread to the credit markets, and then burned through the world's financial markets. Estimates of the cost to the American economy based on lost output range from a few trillion dollars to over USD 10 trillion. The global costs were even greater. These large losses arose despite the unprecedented efforts of several major American Institutions (like the American Federal Reserve, the U.S. Treasury, the Federal Deposit Insurance Corporation (FDIC)), and the central banks of many of the world's largest economies. What were the pathways that led from the collapse of one institution to a global economic crisis whose consequences are still being felt more than a decade later?

Let us begin with the immediate cause of Lehman's demise: this was exposure to the American (sub-prime) mortgage and real estate markets. When these markets began to slow down in 2007, they sparked a retraction in the "shadow banking system" for short-term loans as concerns about unknown exposures to securitized sub-prime mortgages spread to other types of assets. Lehman, like many of the largest investment banks, relied on these short-term markets to raise billions of dollars each day. In 2008, Lehman had assets of USD 680 billion, supported by a mere USD 22.5 billion of equity. Thus a 5% fall in real estate value could wipe out all of its capital. When the other institutions refused to roll over their loans, Lehman was doomed.

Turning now to the spread of the default, it is important to set out the broader economic context. Through the late 1990's and in the years, 2000-2005, there were two large scale forces at work: on the one hand, there was a funding glut due to large surpluses from oil rich countries and, on the other hand, there was a US government had a policy to encourage home ownership. This was accompanied by generous funding through two federal government agencies, Fannie Mae and Freddie Mac. This led them to support mortgages worth USD 5 trillion. Housing and mortgages was felt to be a very safe market. Private banks borrowed and lent heavily in the housing market. By 2005, loans were increasingly being made to individuals and households with little creditworthiness. Lehman had underwritten very large mortgage loans and it had borrowed vast amounts of money to fund these loans. Many other major institutions had invested large amounts in Lehman.

By 2005-2006, as borrowers defaulted on the housing loans, there were foreclosures which in turn led to housing sales and to lower housing prices. By early 2007, several home mortgage lenders filed for bankruptcy protection, and on July 31, 2007, Bear Stearns halted all redemptions and liquidated two of its mortgage funds. By August 2007, lenders were becoming increasingly reluctant to lend as they feared that the borrowers were holding sub-prime mortgages that could become illiquid and be marked down to market.

Although sub-prime mortgages constituted only a small fraction of the portfolios of most structured credit vehicles, cautious lenders pulled back from even those that likely had no exposure to sub-prime mortgages. The resulting pressure in turn transmitted to major banks that had sponsored or provided funding guarantees to vehicles. Bernanke [2010], page 3.

Beginning in early 2008, Lehman faced increasing questions regarding the value of its real estate assets and increased difficulty in trying to sell its assets. Lehman was increasingly forced to deliver non-real-estate assets to secure funding. By March 2008, after the near collapse of Bear Stearns, there was a fear that Lehman would fall. This in indeed what happened. It filed for bankruptcy on September 15, 2008.

In the next few months, 22 Lehman affiliates around the world were taken into bankruptcy and had their accounts frozen. The fire sales of assets and the unwinding of Lehman's large stock of derivatives quickly escalated. As Lehman's counter-parties began to take account of their exposures they recorded very large potential losses. In September 2008 alone a number of major international banks had to be saved by their respective governments: Bradford and Bingley in the U.K., Fortis in the Netherlands, Glitnir in Iceland, and the entire financial sector had to be taken over by the government in Ireland. Although Lehman was the only major international financial institution to collapse, worldwide fifteen to eighteen major institutions were saved from collapse through very large government support.

Another important aspect of the Lehman Brothers' collapse relate to the role of regulatory agencies.

So the agencies were concerned. They gathered information. They monitored. But no agency regulated.

..The SEC knew that Lehman was reporting sums in its reported liquidity pool that the SEC did not believe were in fact liquid; the SEC knew that Lehman was exceeding its risk control limits; and the SEC should have known that Lehman was manipulating its balance sheet to make its leverage appear better than it was. Yet even in the face of actual knowledge of critical shortcomings, and after Bear Stearns' near collapse in March 2008 following a liquidity crisis, the SEC did not take decisive action.

Statement by Anton R. Valukas Examiner, Lehman Brothers Bankruptcy before the Committee on Financial Services United States House of Representatives regarding "Public Policy Issues Raised by the Report of the Lehman Bankruptcy Examiner," April 20, 2010

The Lehman collapse and its aftermath illustrates the many ways in which financial contagion can occur. A direct loss imposed on the Reserve Primary Fund, fears on the quality of all money funds (a form of information contagion), a run on funding as creditors pulled back lending, and potential fire sales. Network opacity heightened these pressures: a major concern throughout the evolving crisis was that “there was no way to know who would be owed how much and when payments would have to be made — information that would be critically important to analyze the possible impact of a Lehman bankruptcy on derivatives counter-parties and the financial markets” (Government [2009], page 329).

Let us summarize a few key points from the discussion of this case. Financial networks contain very large banks and financial institutions. The linkages between these institutions spread across a wide range of activities: mortgages, insurance, supply credit, and short term bank liquidity. The wide range of activities makes the network of financial linkages as a whole potentially very complex. Moreover, the linkages between banks are private knowledge to these institutions. This makes the network very opaque and also means that it is often very difficult to work out the implications of any shock.

### 9.3 Building Blocks of Financial Networks

A financial network consists of nodes that are financial institutions and links that represent different types of obligations between them. We start by describing these two elements of the network. The exposition draws on Glasserman and Young [2016].

It is helpful to start with the financial institutions; for simplicity they will be referred to as banks in what follows. Figure 9.1 presents a stylized balance sheet of a bank. Let a bank be denoted by  $i$ . The bank has two types of assets – outside and in-network. Outside assets are claims on non-financial entities, such as mortgages and commercial loans. In-network assets are claims on other banks; they include interbank loans and exposures through derivatives. We denote by  $\bar{p}_{ki}$  the obligation of bank  $k$  to bank  $i$ . The bank’s liabilities include obligations to non-financial institutions such as depositors and obligations  $\bar{p}_{ij}$  to other banks  $j$ . The difference between the bank’s assets and liabilities yields the bank’s net worth  $e_i$ .

A key function of the bank is to facilitate payments between sellers, buyers and other banks. These payments are central to the large value payment systems such as CHAPS in the UK, FEDWIRE in the United States and TARGET2 in Europe. Another key function is the allocation of capital by intermediating between lenders and borrowers/investors. This function calls for a sequence of relationships between depositors and investors and borrowers. In carrying out this function, the bank invests the outside liabilities  $b_i$  in outside

$c_i$ Outside assets	$b_i$ Outside liabilities
$\sum_k \bar{p}_{ki}$ In-network assets	$\sum_j \bar{p}_{ij}$ In-network liabilities
	$e_i$ Net worth

Figure 9.1: Balance Sheet of a Bank

assets  $c_i$ . This gives rise to liquidity exposures for the bank: to mediate between lenders who prefer to lend for short maturities and borrowers who prefer to borrow for longer maturities, the bank is led to engage in interbank borrowing and lending. This motivation for interbank links will be central to our study of financial contagion in the next section.

A third important function is to mediate between parties that have different appetite for risk-taking: the bank provides risk transfer from agents seeking to reduce risk to others willing to bear greater risk. Banks also help corporations manage their exposures to exchange rates, interest rates, and commodity prices through derivatives and other contracts; the banks hedge this risk by trading with other banks.

Let us now discuss briefly how the network can act a mechanism for the transmission of shocks from one bank to another. Suppose the outside assets of bank  $i$  fall, say, due to a fall in value of real estate. A drop in  $c_i$  is initially absorbed by the bank's net worth  $e_i$ . But if the shock is sufficiently large, the net worth is wiped out, the bank is unable to fully repay its liabilities, and it defaults. Its actual payment  $p_{ij}$  to bank  $j$  will be less than its promised payment  $\bar{p}_{ij}$ . If the payment shortfall is sufficiently large, the assets of bank  $j$  may not cover its liabilities and it may also default. This in turn could lead to defaults by creditors of bank  $j$ . In this way, an asset shock to bank  $i$  can spread through linkages from one bank to another.

The Figure 9.1 also suggests another important route through which bank balance sheets may interact: common exposures to outside assets. If a bank declares a fall in its mortgage assets, this reveals information to other banks that hold similar assets. This could give rise to "information contagion." This form of contagion is amplified if the banks in question also have debt linkages.

So far, we have considered the 'downward' flow of a shock from an originating bank to its creditors. However, financial linkages often feed back: so bank  $i$  may borrow from bank  $j$ , which may in turn borrow from bank  $i$ . Thus a shock on bank  $i$  may feed back on itself via a cycle of linkages. Let us consider a numerical example to appreciate the role of such

financial cycles.

The example is based on the network presented in Figure 9.2. The number on each directed edge represents a payment obligation, and each node's net worth is shown in bold. So bank C is owed 160 by mortgage holders and it owes 50 to a set of depositors. Additionally, C is owed 100 by bank B and it owes 100 to each of banks A and D. The difference between bank C's assets ( $160 + 100$ ) and its liabilities ( $50 + 100 + 100$ ) leave it with a net worth of 10.

Suppose that the economy is hit by a shock that causes some households to default on their payments to bank C: instead of the promised 160, they pay only 40. Then C defaults because its assets total  $100 + 40 = 140$  whereas it owes 50 to the outside sector and 200 to other banks. Suppose that C's remaining assets are paid pro rata to C's creditors. Let us consider the spillover effects of this default.

Suppose to start that the value of C's assets is 140, then pro rata rule implies that C pays  $(140/250) \times 100 = 56$  to D, 56 to A, and 28 to the outside depositors. Now D has assets worth  $204 + 56 = 260$  and debts totalling 300, so D is in default. The pro-rata rule implies that D pays 130 to A and 130 to its outside depositors. At this stage A's assets have interim value  $120 + 130 + 56 = 306$ , whereas its nominal obligations come to 360. Thus, A defaults and the pro rata rule implies that it pays one-half of its assets to B, namely 153, and an equal amount to outside depositors.

At this juncture, B's assets are worth  $153 + 30 = 183$ , whereas its obligations total 200. Therefore, B defaults and the pro-rata rule implies that it pays 91.5 to C and 91.5 to outside depositors. Therefore the value of 140 we used for C's assets was incorrect.

That value reflected the initial outside shock of 40, but it assumed full repayment of 100 from bank B. In fact, B is able to pay at most 91.5, so C's assets are worth at most 131.5 and the cycle must be repeated.

### 9.3.1 Keeping accounts

We now present a general approach to compute the correct profile of payments between banks. The approach is taken from a paper by Eisenberg and Noe [2001]. We start with a network of obligations: the goal is to study how shocks to particular institutions or assets propagate through the network.

Following the discussion above, the model has four key ingredients: (1) a set of  $n$  nodes  $N = \{1, 2, \dots, n\}$  representing different financial entities such as banks, broker-dealers, and insurance companies (2) an  $n \times n$  liabilities matrix  $\bar{P} = [\bar{p}_{ij}]$ , where  $\bar{p}_{ij} \geq 0$ , represents the payment due from node i to node j at the end of the current period and  $p_{ii} = 0$  for

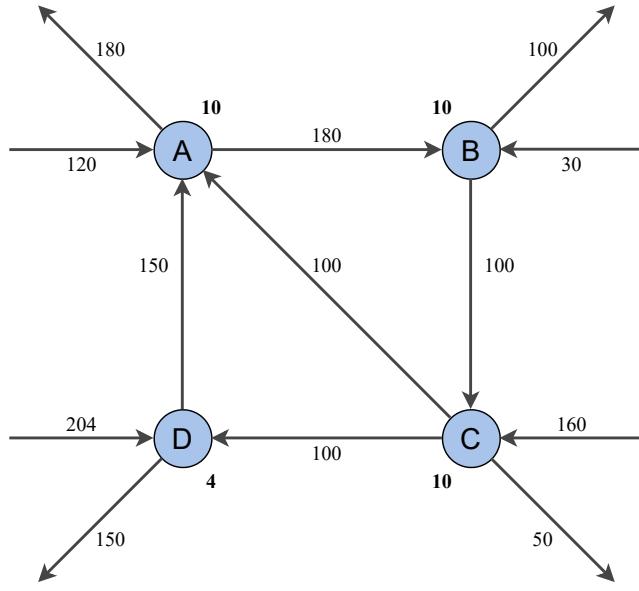

Figure 9.2: Financial Network Showing Payments

every  $i$ ; (3) a vector  $c = (c_1, c_2, \dots, c_n)$  where  $c_i \geq 0$ , represents the total payments due from nonfinancial entities to node  $i$ ; and (4) a vector  $b = (b_1, b_2, \dots, b_n)$  where  $b_i \geq 0$  represents the total payments due from node  $i$  to nonfinancial entities. The numbers  $c_i$  and  $b_i$  will be called  $i$ 's outside assets and outside liabilities, respectively.

The asset side of node  $i$ 's balance sheet is given by  $c_i + \sum_{j \neq i} \bar{p}_{ji}$  while the liability side is given by  $\bar{p}_i = b_i + \sum_{j \neq i} \bar{p}_{ij}$ . The node's net worth is

$$e_i = c_i + \sum_{j \neq i} \bar{p}_{ji} - \bar{p}_i \quad (9.1)$$

Let us assume that, initially, the net worth of every node is strictly positive.

Consider a shock given by an  $n$ -vector  $x = (x_1, x_2, \dots, x_n)$  where  $0 \leq x_i \leq c_i$  for  $1 \leq i \leq n$ . The direct effect of the shock  $x$  is to reduce the net worth of each node  $i$  to the value

$$e_i(x) = c_i - x_i + \sum_{j \neq i} \bar{p}_{ji} - \bar{p}_i \quad (9.2)$$

If the net worth  $e_i(x)$  is negative, node  $i$  defaults. We shall assume that all debt obligations have equal priority and that in case of default, the assets are distributed to the creditors in proportion to the nominal amounts they are owed. (The equity holders are wiped out, since their claim is on the firm's net worth, provided the latter is positive.) The problem is to determine a consistent set of payments conditional on the initial shock. Recall

that we encountered this problem in our illustration of a default cascade that was based on Figure 9.3 above.

To this end, let us define the relative liabilities matrix  $A = (a_{ij})$  to be the  $n \times n$  matrix with entries

$$a_{ij} = \bar{p}_{ij}/\bar{p}_i \quad \text{if } \bar{p}_i > 0 \quad (9.3)$$

$$a_{ij} = 0 \quad \text{if } \bar{p}_i = 0. \quad (9.4)$$

The term  $a_{ij}$  represents the proportion that  $i$ 's obligations to node  $j$  represent of its total liabilities to all other nodes and to the external sector. Suppose that the outside assets suffer a shock,  $x$ . We shall say that node  $i$  suffers a direct default if  $x_i > c_i + \sum_{j \neq i} \bar{p}_{ji} - \bar{p}_i$ . The pro-rata allocation rule implies that  $i$ 's payments are proportional to the various claims against  $i$ 's assets. The complication is that the value of  $i$ 's assets depends on the payments made by others to  $i$ . Thus  $i$ 's payment to  $j$  (conditional on  $x$ ) satisfies

$$p_{ij}(x) \leq a_{ij}(c_i - x_i + \sum_{k \neq i} p_{ki}(x)) \quad (9.5)$$

where  $\sum_{k \neq i} p_{ki}(x)$  is the sum of payments to  $i$  from the other nodes in the system. In particular, the payment  $p_{ki}(x)$  will be less than  $\bar{p}_{ki}$ , if node  $k$  is also in default. We shall say that the payments  $p_{ij}(x)$  are consistent if, for all  $i$  and  $j$

$$p_{ij}(x) = \bar{p}_{ij} \wedge a_{ij}(c_i - x_i + \sum_{k \neq i} p_{ki}(x)) \quad (9.6)$$

We note that the symbol  $a \wedge b$  indicates the largest number smaller than  $a$  and  $b$ .

This condition can be expressed in a more compact form as follows. Let  $p_i(x)$  denote the total payment from  $i$  to all other nodes in the financial system plus its payments to the outside sector. Let  $p(x) = (p_1(x), p_2(x), \dots, p_n(x))$  be the corresponding payments vector. These payments are consistent if they are feasible. In other words, for every  $i$ ,

$$p_i(x) = \bar{p}_i \wedge (c_i - x_i + \sum_j a_{ji} p_j(x)). \quad (9.7)$$

Any vector  $p(x) \in R_+^n$  satisfying (9.7) is called a clearing vector. We will show that there exists a clearing vector, for any shock realization  $x$ .

For a given shock realization  $x$ , let  $p = p(x)$  and define the mapping  $\phi : R_+^n \rightarrow R_+^n$  as follows:

$$\forall i, \phi_i(p) = \bar{p}_i \wedge (c_i - x_i + \sum_j p_j a_{ji}) \quad (9.8)$$

Starting with  $p_0 = \bar{p}$  let

$$p_1 = \phi(p_0), p_2 = \phi(p_1), \dots \quad (9.9)$$

Observe that this algorithm yields a monotone decreasing sequence  $p_0 \geq p_1 \geq p_2 \dots$ . Since the sequence is bounded below by the zero vector, it must converge. Let the limit  $p' = p'(x)$ . Since  $\phi$  is continuous,  $p'$  satisfies (9.7), hence it is a clearing vector.

We will now show that the net equity of the clearing vector is unique. This step of the argument requires some additional mathematical notation.

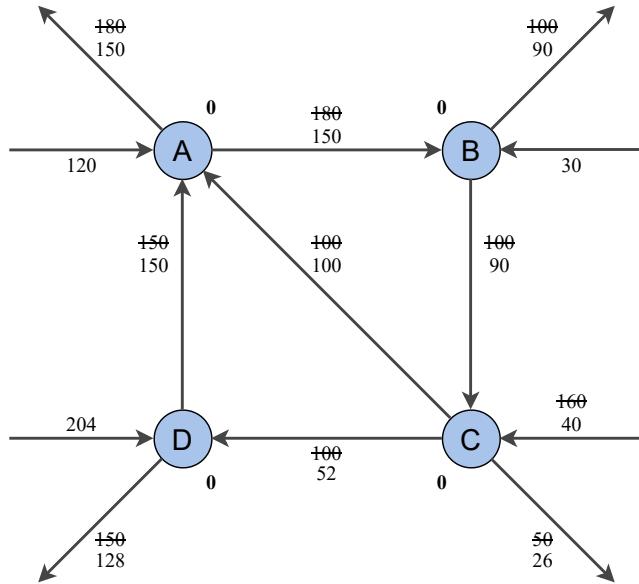

Figure 9.3: Eisenberg-Noe Method

We start with a partially ordered set  $\{\mathcal{L}, \geq\}$

For  $S \subseteq \mathcal{L}$  let  $\wedge S$  denote the greatest lower bound, i.e.,  $\hat{s} \in \mathcal{L}$  such that (i)  $\hat{s} \leq s$  for all  $s \in S$  and (ii)  $\hat{s} \geq s'$  for all other lower bounds  $s' \in \mathcal{L}$ . Similarly, let  $\vee S$  denote the least upper bound, i.e.,  $\tilde{s} \in \mathcal{L}$  such that (i)  $\tilde{s} \geq s$  for all  $s \in S$ , and (ii)  $\tilde{s} \leq s'$  for all other upper bounds  $s' \in \mathcal{L}$ .  $(\mathcal{L}, \geq)$  is a complete lattice if and only if for every  $S \subseteq \mathcal{L}$  (i)  $\wedge S \in \mathcal{L}$ , and (ii)  $\vee S \in \mathcal{L}$ .

In our setting, note that  $\mathcal{L} := \prod_i [0, \bar{p}_i]$  and (ii) a partial order  $\geq$  is given by:

$$p \geq p' \text{ if and only if } p_i \geq p'_i \text{ for all } i. \quad (9.10)$$

Thus for  $S \subseteq \prod_i [0, \bar{p}_i]$ ,

$$(\wedge S)_i = \min_{s_i: s \in S} s_i \quad (9.11)$$

$$(\vee S)_i = \max_{s_i: s \in S} s_i \quad (9.12)$$

It is straightforward to check that for any  $S \subseteq \mathcal{L}$  (i)  $\wedge S \in \mathcal{L}$  and (ii)  $\vee S \in \mathcal{L}$ . Thus  $(\mathcal{L}, \geq)$  is a complete lattice. Moreover, the mapping  $\Phi(p) : \mathcal{L} \rightarrow \mathcal{L}$  is order preserving: if  $p \geq p'$  then  $\Phi(p) \geq \Phi(p')$  because all organizations are repaid more given  $p$ . Functions  $\Phi$  with this property are called isotone.

The Tarski fixed point theorem (Tarski [1955]) tells us that if a partially ordered set  $(\mathcal{L}, \geq)$  is a complete lattice and  $\Phi : \mathcal{L} \rightarrow \mathcal{L}$  is isotone, then letting  $\mathcal{P}$  be the set of fixed points of  $\Phi$ ,  $\mathcal{P}$  is non-empty and  $(\mathcal{P}, \geq)$  is a lattice.

Equipped with this result, we can show that the net equity is unique. Suppose that there are two clearing vectors,  $p$  and  $p'$ . These two clearing vectors constitute fixed points of  $\Phi$ . As the set of fixed points is a lattice it follows that: (i)  $\hat{p} := p \wedge p'$  is a fixed point and (ii)  $\tilde{p} := p \vee p'$  is also a fixed point.

Moreover, note that  $\tilde{p}_i \geq \hat{p}_i$  for all  $i$ , and  $\tilde{p}_i > \hat{p}_i$  for some  $i$ . Thus more banks fail and all banks have weakly lower equity value under  $\hat{p}_i$  and this means that total equity must be strictly smaller. The total equity under  $\hat{p}$  is given by

$$\sum_i \sum_j [\Pi_{ij} \hat{p}_j + e_i - \hat{p}_i] = \sum_i e_i \quad (9.13)$$

It is easy to see that the sum of net equity under  $\tilde{p}$  is also equal to  $\sum_i e_i$ . This is a contradiction that completes the argument for uniqueness of net equity. ■

Let us summarize what we have learnt in this section. We have described the basic features of inter-linkages of obligations between banks and relations to outside players. The valuation/net worth of a bank will depend on the valuations of other banks, which in turn depend on the valuation of the bank in question. This circularity in valuations is a fundamental feature of financial networks and shows that the health of a financial system will depend on the fundamentals but beliefs/expectations will also have an important role.

## 9.4 Liquidity Shocks and Financial Contagion

Our discussions in section 9.2 draw attention to the role of interconnections between banks in spreading the collapse of Lehman Brothers. This section presents a simple model of liquidity shocks and how financial linkages can help overcome them. But we will also see how these linkages create a pathway through which shocks on a single bank or financial institution can spread to other banks. Our discussion will draw attention to the role of the network structure in shaping this trade-off.

The model is taken from Allen and Gale [2000]. Depositors have different timing for liquidity. Longer term investments yield larger returns. The uncertainty in liquidity timing and the differential returns between short and long term investments creates the potential for a mismatch between liquidity demand and investment returns. Banks can make deposits in each other to tide over liquidity shocks. The linkages give rise to networks that have different levels of robustness to the shocks.

This is a 3 period model, where the time periods are denoted by  $t = 0, 1, 2$ . There is a single consumption good. This good can be invested for future use. Consumer is either of type 1 or type 2. Type 1 values only period 1 consumption, while type 2 values only period 2 consumption. Type is revealed at period  $t = 1$ . All consumers are ex-ante identical, so there is probability  $\omega$  that consumer needs liquidity in period  $t = 1$  and probability  $1 - \omega$  that they need liquidity in period  $t = 2$ . There are two assets: short asset, which invested for one period yields 1, and long asset which yields  $r < 1$  after one period and  $R > 1$  after two periods. There are four regions A, B, C and D. In each region, there is a continuum of consumers. Regions are identical in their composition of different types of consumers.

Let  $c_1$  be the consumption for a period 1 consumer and  $c_2$  the consumption of period 2 consumer. Utility of consumers depends on consumption in periods 1 and 2 and is given by  $U(c_1, c_2) = u(c_1)$  if type 1 and  $U(c_1, c_2) = u(c_2)$  for type 2. The utility function  $u(\cdot)$  is increasing and strictly concave (risk-aversion). There are two states of nature:  $S_1$  and  $S_2$ . In state  $S_1$ , regions A and C have a large fraction of period 1 consumers,  $\omega_H$ , and regions B and D have a low fraction of type 1,  $\omega_L$ . The opposite is true in state  $S_2$ . The two states are equally likely. Thus aggregate demand for liquidity is constant across states and is given by  $2\omega_H + 2\omega_L$ .

We now turn to the optimal consumption paths for consumers. First note that all consumers in all regions are identical. As consumer preferences are concave a utilitarian planner that seeks to maximize sum of utilities must assign the same ex-ante utility to all individuals in all regions. As all banks are identical, they too must make same investments. Let bank allocate (per capita)  $x$  to the long asset and (per capita)  $y$  to short asset. The planner

chooses  $x$  and  $y$  such as  $x + y \leq 1$  with a view to maximizing the expected utility of consumers. As the planner's choice can be implemented in a competitive equilibrium among the banks, we shall assume that the banks do likewise.

We note an important implication of the structure of uncertainty: in both states 1 and 2, total consumption must be equal. In other words, there is no aggregate uncertainty. So the optimal plan is to allocate returns of  $x$  to cover type 2 consumers and allocate returns of  $y$  to cover type 1 consumers. Define:

$$\gamma = (\omega_H + \omega_L)/2, \quad \gamma c_1 = y, \quad (1 - \gamma)c_2 = Rx \quad (9.14)$$

Planner maximizes  $\gamma u(c_1) + (1 - \gamma)u(c_2)$ . Let us substitute for  $c_1$  and  $c_2$  from equation above. It follows that in the social optimum, the marginal utilities must be equal:

$$u'(c_1) = Ru'(c_2) \quad (9.15)$$

Since  $R > 1$ ,  $c_1 < c_2$ . Type 2 consumers therefore have no incentive to pretend to be type 1 consumers and withdraw their deposits in period 1.

Observe that this optimal investment strategy provides us with the rationale for interbank deposits. A bank in region A cannot implement this strategy on its own, i.e., in isolation, as it will not be able to meet the liquidity demands of its depositors in State 1. On the other hand, a bank in region A and another in region B can exchange deposits and depending on the state can then liquidate their deposits and thereby meet the high liquidity needs. We now describe three inter-bank deposit networks each of which allow for the optimal allocation to be feasible: complete, cycle, and two disconnected pairs.

#### 9.4.1 The role of networks

The *complete* network is one in which each region holds deposits in all other regions. The size of the deposit is  $z = (\omega_H - \gamma)/2$  (see Figure 9.4). A representative bank in a region will invest  $(x, y)$ , as in the social optimum (note that deposits cancel each other and so the allocation remains feasible at time  $t = 0$ ). In period  $t = 1$ , with probability  $1/2$  we are in state  $S_1$ : region A, has high demand for liquidity and it liquidates all its deposits in other regions. Region C does likewise. Region B and D will however retain their deposits. So the net inflow of liquidity into region A is given by  $(\omega_H - \gamma)c_1$  and this is exactly what is required to cover the liquidity demand in state  $S_1$ .

$$(\omega_H - \gamma)c_1 + \gamma c_1 = \omega_H c_1 \quad (9.16)$$

Simplifying, we get  $\gamma c_1 = y$ , the first best allocation requirement. So deposits of regions B and D remain in place and in period  $t = 2$  they are liquidated to pay  $1 - \omega_L$  period 2 consumers the promised  $c_2$ .

The *cycle network* is one in which each region holds deposits in only one other region. The size of the deposit is given by  $z = (\omega_H - \gamma)$  (see Figure 9.4). The representative bank in a region will invest  $(x, y)$ , as in the social optimum. In period  $t = 1$ , with probability one half we are in state  $S_1$ : region A has high demand for liquidity and it liquidates all its deposits in region B. Region C will do likewise in region D. Regions B and D retain their deposits. The net inflow of liquidity into region A is given by  $(\omega_H - \gamma)c_1$ : this is exactly what is required to cover the liquidity demand in state  $S_1$ .

$$\omega_H c_1 = \gamma c_1 + (\omega_H - \gamma)c_1. \quad (9.17)$$

Similarly, for regions C. Deposits of regions B and D remain in place and in period  $t = 2$  they will be liquidated to pay  $1 - \omega_L$  period 2 consumers the promised  $c_2$ . The liquidity balance for region A in period  $t = 2$  is  $[(1 - \omega_H) + (\omega_H - \gamma)]c_2 = Rx$ , and this simplifies to  $(1 - \gamma)c_2 = Rx$ , which is prescribed by the social optimum.

The *disconnected network* is one in which pairs of regions hold deposits in each other. The size of the deposit is  $z = (\omega_H - \gamma)$  (see Figure 9.4). The representative bank in a region will invest  $(x, y)$ , as in the social optimum. In period  $t = 1$ , with probability one half we are in state  $S_1$ : region A has high demand for liquidity and it liquidates all its deposits in other region B. Region B will retain deposits in region A. Region C liquidates its deposits in D while D retains them in C. So the net inflow of liquidity into region A is given by  $(\omega_H - \gamma)c_1$  and this is exactly what is required to cover the liquidity demand in state  $S_1$ .

$$\gamma c_1 + (\omega_H - \gamma)c_1 = \omega_H c_1 \quad (9.18)$$

Simplifying this equation we get  $\gamma c_1 = y$ , the first best allocation requirement. Similarly, for regions C. So deposits of regions B and D remain in place and in period  $t = 2$  they will be liquidated to pay  $\omega_H$  period 2 consumers the promised  $c_2$ .

We have shown how interbank deposits help the system attain the first best allocation (something that is unattainable under autarchy). Now we show how these linkages can act as a conduit for the spread of shocks and lead to the breakdown of the system as a whole. To study financial contagion in its simple form, let us suppose that there is an *unanticipated* shock to the system that leads to excess aggregate liquidity. We will show how the shock can spread across from one region and lead to the breakdown of the whole system.

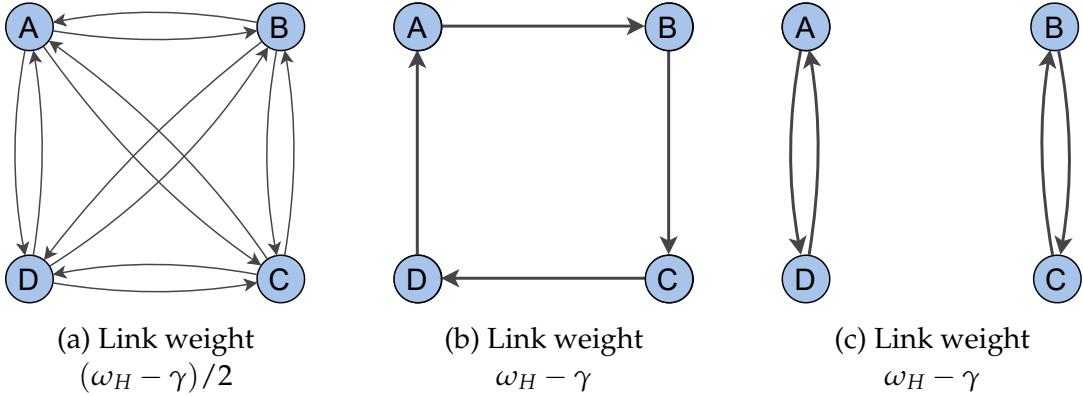

Figure 9.4: Inter-bank Networks: (a) Complete (b) Cycle (c) Disconnected Pairs

#### 9.4.2 Shocks and Robustness

Let there be a new state  $S$  in addition to states  $S_1$  and  $S_2$ . This state has  $\gamma + \epsilon$  type 1 individuals for region A (with  $\epsilon > 0$ ) and  $\gamma$  type 1 consumers in all regions. In other words, there is excess aggregate liquidity demand in state  $S$ .

Suppose we arrive at state  $S$ : The bank in region A cannot pay off its type 1 consumers by using its own deposits  $y$ : this is because from the first best allocation  $\gamma c_1 = y$ . What can such a bank do? It can liquidate its deposits in other regions and/or it can liquidate its long assets. What is the optimal order in which to liquidate assets?

Observe that the cost of liquidating its own short assets is 1: they yield 1 now and upon reinvestment will also yield 1 in the next period. Liquidation of deposit in another bank leads to current payoff of  $c_1$  and a loss of  $c_2$  in the next period. Finally, if it liquidates its own long asset then it gives up  $R$  in return for  $r$ . To study the spread of shocks, we will suppose that

$$\frac{R}{r} > \frac{c_2}{c_1}, \quad (9.19)$$

This condition implies a pecking order for liquidation, starting with own short assets, then deposits in other banks and finally own long assets. We now study how liquidation of Bank in region A plays out in the different networks.

Let us start with the cycle. Recall, that each bank holds  $(x, y)$  initial allocation and promises to pay  $c_1$  to type 1 consumers and  $c_2$  to type 2 consumers. To make this feasible, a bank in each region holds  $[\omega_H - \gamma]$  deposits in one other region (so banks in region A hold deposits in region B, B in region C, C in D and D in A and so forth). Next consider the effects of the state  $S$  as mediated through the network. As D holds deposits in region A, the focus is on the effects on D and via D on other regions.

At date 1, a bank is said to be *solvent* if it can meet demands from consumers and other banks from its short assets and deposits on other banks, *insolvent* if it needs to liquidate some of its long term assets *bankrupt* if even the long term assets do not suffice to cover all demands in period 1.

The value of a deposit in bank in region A, at date 1, is  $c_1$  if the bank is not bankrupt and it is  $q^A$  if it is bankrupt. Define  $q^A$  as the value under bankruptcy. This liquidation value equates the value of assets,  $y + rx + zq^B$ , and liabilities,  $(1 + z)q^A$ , and is given by:

$$q^A = \frac{y + rx + zq^B}{1 + z} \quad (9.20)$$

If bank in region B is not bankrupt then  $q^B = c_1$  and we can compute  $q^A$  directly; if not then we must work out  $q^B$ , which may depend on the value of  $q^C$  and so forth. If a bank cannot cover its liquidity needs from its short assets and deposits, it liquidates some of its long assets. This is possible without a *run* so long as type 2 consumers are assured of a return of  $c_1$ . In other words, a bank must keep at least  $[1 - \omega_H]c_1/R$  units in long asset. This yields a *buffer* that is given by

$$b(\omega) = r \left[ x - \frac{(1 - \omega_H)c_1}{R} \right]. \quad (9.21)$$

Bankruptcy occurs when extra liquidity required by Region A exceeds the buffer:

$$\epsilon c_1 > b(\omega). \quad (9.22)$$

Bankruptcy in region A in turn means that the assets of bank in region A are worth  $q^A < c_1$  at date 1. Deposits of region D in region A now entail a loss  $(c_1 - q^A)z$ . This creates liquidity shortage in region D. What is the magnitude of shortage and its ‘systemic’ implications? Observe that  $q^A$  is increasing in the value of deposits of banks in region B. So maximum value of assets of bank in region A is given by

$$\bar{q}^A = \frac{y + rx + zc_1}{1 + z} \quad (9.23)$$

This in turn means that minimum loss to bank in region D is  $z(c_1 - \bar{q}^A)$ . Bank in region D will be bankrupt if this loss exceeds the buffer  $b(\gamma)$ .

$$z[c_1 - q^A] > b(\gamma). \quad (9.24)$$

**Proposition 9.1.** Suppose that (9.19), (9.22) and (9.24) hold. Then state S leads to bankruptcy in

*region A which spreads through the network and leads to bankruptcy in all regions.*

We have developed all the arguments underlying the proposition except for the observation that bankruptcy in region D implies an even greater loss in region C deposits. This is because  $q^D < q^A$ :  $q^A$  is computed under the assumption that  $q^B = c_1$ , while  $q^D$  is computed under the assumption that  $q^A < c_1$ . So if region D bankrupts then the losses are even greater for region C, which will lead to bankruptcy in that region and subsequently also in region B.

The network structure can determine the possibility of financial contagion. To illustrate this point, let us now take up the complete network. Recall that the deposits are  $[\omega_H - \gamma]/2$  in each region. In state  $S$ , bank in region A face a liquidity demand of  $[\gamma + \epsilon]c_1$  and short term assets yield  $y$ : so there is a deficit of liquidity. Under condition (9.22) this leads to bankruptcy in region A. The value of the deposit in region A is

$$\tilde{q}^A = \frac{y + rx + \frac{3}{2}zc_1}{1 + \frac{3}{2}z} \quad (9.25)$$

By definition,  $\tilde{q}^A < c_1$ , so there is a loss in each of the other regions. The size of this loss is

$$\frac{z}{2} [c_1 - \tilde{q}^A]. \quad (9.26)$$

This loss may be smaller than the loss in the cycle network, since the size of each link is smaller,  $z/2 < z$ . Thus moving from a cycle to the denser complete network can avert financial contagion. This suggests that adding linkages reduces contagion.

We now turn to the disconnected network to illustrate that the effects of additional links on financial contagion are non-monotonic. Recall that in the disconnected network, Banks A and D and B and C respectively hold deposits in each other. The deposit size is  $z = [\omega_H - \gamma]$ . Bankruptcy in region A now leads to bankruptcy in region B but there is no contagion as there are no links across to banks C and D. The connectivity of the network offers some risk-insurance and liquidity smoothing but also contains the contagion.

Let us summarize what we have learnt with this model. Resilience issues arise out of a tension between benefits of links and the potential spillovers. The push towards efficient risk sharing necessitates connections between banks and they create the potential for systemic contagion and widespread collapse. We have examined a very specific type of linkage and we have looked at very simple networks with four banks/regions. In the next section, we will take up more general networks and other types of connections to further elaborate on the role of financial linkages in shaping contagion.

## 9.5 Financial Shocks and Optimal Networks

The discussion in section 9.2 suggests that the linkages between banks can have different basis ranging from debt to equity to common exposure to the same assets. In this section we develop a general theoretical model to allow us to explore these relationships more formally. The analysis will reveal that it is both the content of the relationship as well as the topology of the network that will matter for financial contagion. The framework presented builds on the work of Cabrales, Gottardi, and Vega-Redondo [2017], Elliott, Golub, and Jackson [2014], Glasserman and Young [2015], Acemoglu, Ozdaglar, and Tahbaz-Salehi [2015b], and Acemoglu, Ozdaglar, and Tahbaz-Salehi [2015a]. The exposition draws on Cabrales, Gottardi, and Vega-Redondo [2016].

Let there be  $N$  banks. Each bank has liabilities and assets. The liabilities are to external investors and given by  $\ell$ . The assets are claims to returns on  $N$  projects. The return on a project  $i$  is given by  $R - s_i$ , with  $s_i \in [0, R]$ . The banks have financial linkages with each other. It is important to observe that the value of the assets of bank  $i$ ,  $v_i$ , is contingent on the value of bank  $v_j$ , as they both depend on the vector  $r$  which describes the realizations of the returns of the  $N$  projects (so for each bank  $i$ , let  $r_i = R - s_i$  if a shock hits the return of project  $i$ , and  $r_i = R$  otherwise). We will write this relationship as follows (keeping in mind that  $v_i$  is contingent on the value of  $v_j$ ):

$$v = f(A; r) \quad (9.27)$$

where  $f : R_+^{N \times N} \times R_+^N \rightarrow R^N$  and  $A$  is a  $N \times N$  non-negative matrix with entry  $a_{ij}$ . The matrix  $A$  describes the pattern of the linkages among the banks. The function  $f(., .)$ , captures the effect of linkages on bank's value. If the value  $v_i$  of the assets of firm  $i$  is lower than the value  $\ell$  of its liabilities, the firm defaults. The default of a bank lowers the value of other banks and may trigger further defaults. Thus linkages bring out correlations between the status of banks.

We now turn to interpretations of the nature of linkages.

**Links as equity exchange:** There are different types of links that banks maintain with each other. Cabrales, Gottardi, and Vega-Redondo [2017] propose the following interpretation. A bank  $i$  initially controls its own project  $i$ . The bank exchanges claims to the returns to projects with other banks who constitute its immediate neighbors. The pattern of exchanges at each round is described by the matrix  $B$ , where the elements of row  $i$  describe  $i$ 's trades with its immediate neighbors. After  $K$  rounds of exchange we arrive at the linkage matrix  $A = B^K$  and  $f(A; r) = Ar$ . This means that at the end of the exchanges, firm  $i$

has access to returns given by  $\sum_j a_{ij}r_j$ .

In a similar spirit, Elliott, Golub, and Jackson [2014] propose that banks start with full ownership of returns to a project and then exchange equity with each other. Letting  $c_{ji}$  denote the fraction of the outstanding equity of firm  $i$  sold to firm  $j$ , and  $c_{ii}$  the fraction that returns owned by external investors, we get  $c_{ii} = 1 - \sum_{j \neq i} c_{ji}$ . This leads a bank to own direct and indirect shares in the returns to different projects that are given by a linear combination of the returns of the underlying projects with weights given by the matrix

$$A = \hat{C}(1 - C)^{-1} \quad (9.28)$$

where  $\hat{C}$  is the diagonal matrix with entry  $\hat{c}_{ii}$ , and  $C$  is the matrix with entry  $c_{ij}$  (and all diagonal terms set equal to 0). Mutual ownership here reflects equity. This means that a bank that has a share in another firm also must bear any losses due to insolvency of that bank. Letting  $\beta$  be the loss due to insolvency, we arrive at the following formulation of a bank's valuation:

$$v = f(A; r) = A(r - \beta 1_{v_i < \ell}), \quad (9.29)$$

where  $1_{v_i < \ell}$  denotes the vector of indicator functions taking value 1 if  $v_i < \ell$ , and 0 otherwise, for  $i = 1, \dots, N$ . Observe that  $v$  is determined as a fixed point of the function defined above. This is because the level of  $v$  determines whether a bank is solvent or not: if a bank is insolvent then it has to pay the additional default cost and this affects its valuation. We illustrate this fixed point feature of valuations with the help of an example: Suppose  $N = 2$  and let the matrix of cross ownerships be given by:

$$A = \begin{bmatrix} 0.7 & 0.3 \\ 0.3 & 0.7 \end{bmatrix} \quad (9.30)$$

In this example, let  $R = 1$  and suppose  $s_i$  takes on values 0 or 0.5; let  $\ell = 0.8$ , and  $\beta = 0.5$ . First consider the case when project 1 yields 1 while project 2 yields 0.5. Then firm 2 defaults, but also firm 1 – due to the fraction of default costs it must bear. By contrast, if both projects yield 1, then there are two possible valuations: one, where both firms are solvent and the other where both firms default. In other words, the belief that a firm may default suffices to generate losses in banks' valuation and this triggers a default even when the returns on the underlying projects are adequate to cover liabilities.

This example is extremely simple but it helps to bring out the self-fulfilling nature of

default cascades. Moreover, they are generated by network interdependencies interacting with beliefs. When there are costs associated with bankruptcy, these cascades are not just transfers that fail, but the failures trigger real economic costs, and therefore the multiplicity can have large economic consequences. This multiplicity is a fundamental feature of this environment and is a consequence of the default cost: note that if there are no default costs, then we are back in the setting of the previous section: the clearing vector and the valuations are then unique.

**Links as borrowing and lending relations:** Financial linkages between banks often represent borrowing and lending; Glasserman and Young [2015] and Acemoglu, Ozdaglar, and Tahbaz-Salehi [2015b] study debt linkages. Under the debt interpretation,  $a_{ij}$  denotes the payments from bank  $i$  to bank  $j$ . The total liabilities of bank  $i$  are then given by  $\ell_i + \sum_j a_{ij}$ . As in the other interpretations, firm  $i$  has access to the returns from project  $i$ , therefore the book value of its assets is  $r_i + \sum_{j \neq i} a_{ji}$ . The firm remains solvent if the actual value of the assets can cover the liabilities. In other words, the actual payments made by firm  $i$  to firm  $j$  will thus depend on the value of the assets of its debtors. Thus the obligations  $A$  create an interdependence between the valuations of the banks. The actual valuation  $v_i$  of bank  $i$  will thus depend on the realizations of projects  $r = (r_1, \dots, r_N)$  and the rules on how the banks settle claims in case of inadequate returns.

Suppose that all claims have equal seniority. Then we can use the methods developed in section 9.3 to solve for clearing vectors and bank valuations. For any vector of realized returns  $r$ , the final repayment from a bank  $i$  is obtained as a solution to the following system:

$$p_i(r) \left( \sum_{j \neq i} a_{ij} + \ell_i \right) = \left( \sum_{j \neq i} a_{ij} + \ell_i \right) \left( \sum_{j \neq i} p_j(r) a_{ji} + r_i \right) \quad (9.31)$$

The actual payments made by firm  $i$  to firm  $j$  are then

$$p_{ij}(r) = p_i(r) a_{ij} \quad (9.32)$$

where  $p_i(r) \in [0, 1]$  and  $p_i(r) = 1$  if firm  $i$  does not default. Firm  $i$  defaults if actual value of assets is less than the value of liabilities:

$$\sum_{j \neq i} p_j(r) + r_i < \sum_{j \neq i} a_{ij} + \ell_i \quad (9.33)$$

In this setting, we know that there is a unique solution of payments,  $p(r)$  (generically). The value of the firms' assets net of their internal liabilities is therefore given by

$$v = f(A; r) = r + (A^T - A)p(r). \quad (9.34)$$

### 9.5.1 The spread of defaults

We are now ready to consider the issue of financial contagion – the process whereby shocks affecting one bank are transmitted by financial linkages and lead to defaults by other banks. The interest will be on the role of the network of financial linkages in transmitting the initial shock. To develop some basic intuitions it is convenient to restrict attention to regular networks where each bank is equally exposed and the pattern of exposure is also the same, i.e., the matrix  $A$  is symmetric. We will consider the impact of a shock on bank 1.

We will study the minimum shock on bank 1 needed to ensure that a certain number of banks default. In particular, we will derive this minimal shock  $s(k)$  for  $k$  defaults as a function of the architecture of the network. Let  $r_j$  be the vector with elements  $(R - s(k), R, \dots, R)$  such that  $f(A; r_k)$  has  $k$  components less or equal to  $\ell$  (at least one of them equal) and the other  $N - k$  strictly greater than  $\ell$ . In other words, a shock of size  $s(k) + \epsilon$  for  $\epsilon > 0$  small will lead to the default of  $k$  banks. We will study how the values of  $s(1), \dots, s(N)$  vary with the network of linkages as reflected in the matrix  $A$ . It is instructive to focus attention on two very stylized networks: the complete network where all bank is equally linked to all other banks, and the (one directional) ring network, where every bank is linked to one other bank.

*Cross-ownership Linkages:* Consider the interpretation that financial linkages involve cross ownerships and sharing the returns of the projects. Under this interpretation, let us define the complete network as one in which every bank owns share  $c/N - 1$  of every other bank. The residual  $1 - c$  of a bank is owned by outside investors. Applying the formula  $A = \hat{C}(I - C)^{-1}$ , this yields us

$$A^C = \begin{bmatrix} \alpha & \frac{1-\alpha}{N-1} & \dots & \frac{1-\alpha}{N-1} \\ \frac{1-\alpha}{N-1} & \alpha & \dots & \frac{1-\alpha}{N-1} \\ \dots & \dots & \dots & \dots \\ \frac{1-\alpha}{N-1} & \frac{1-\alpha}{N-1} & \dots & \alpha \end{bmatrix} \quad (9.35)$$

The complete network reflects common exposure of a set of banks to the same set of assets. Let us define the ring networks as one in which every bank  $i \geq 2$  own share  $c$  of bank  $i - 1$  and bank  $n$  own share  $c$  of bank 1. We represent this as

$$A^R = \begin{bmatrix} \alpha & \frac{(1-\alpha)^2}{1-\alpha^{N-1}} & \cdots & \frac{(1-\alpha)^2}{1-\alpha^{N-1}}\alpha^{N-2} \\ \frac{(1-\alpha)^2}{1-\alpha^{N-1}}\alpha^{N-2} & \alpha & \cdots & \frac{(1-\alpha)^2}{1-\alpha^{N-1}}\alpha^{N-3} \\ \cdots & \cdots & \cdots & \cdots \\ \frac{(1-\alpha)^2}{1-\alpha^{N-1}} & \frac{(1-\alpha)^2}{1-\alpha^{N-1}}\alpha & \cdots & \alpha \end{bmatrix} \quad (9.36)$$

In the ring networks, the distance reflects the difference in exposure to a set of assets.

Figure 9.5 presents the complete and the ring network. We will assume that every bank  $i$  is more exposed to the returns of its own project  $i$  then to the returns of the each of the other projects. It can be verified that the condition  $\alpha > (1 - \alpha)^2 / (1 - \alpha^{N-1})$  ensures this property for both the complete and the ring network.

Let  $s^C(1)$  and  $s^R(1)$  denote the minimal size of the shock leading to the default of one bank under the complete and the ring network, respectively. This minimum shock is the same for both networks and is given by the following equation:

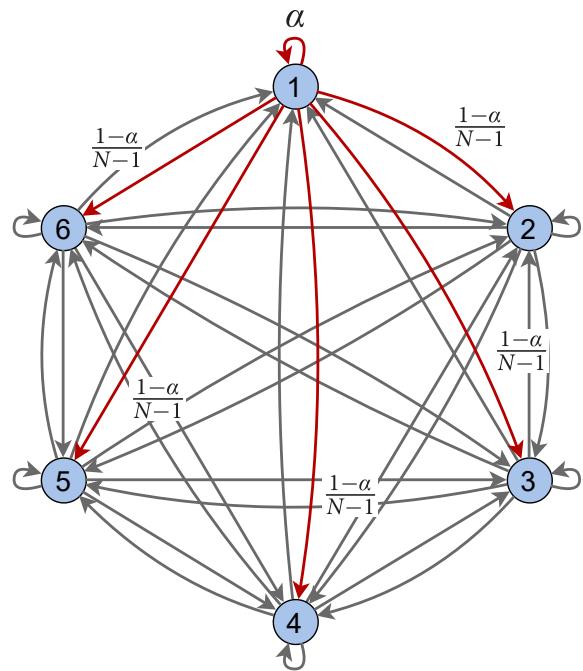

$$\alpha(R - s(1)) + (1 - \alpha)R = \ell. \quad (9.37)$$

This yields us the insight that  $s^C(1) = s^R(1) > (R - \ell) / \alpha$ : thus linkages to other banks allows a bank to remain solvent for larger shocks than an isolated bank. Turning to larger number of defaults, consider the complete network. Observe that every bank (other than 1) faces an identical asset and liability situation. Hence either there is zero default, one default or all banks default. In other words, the minimum shock needed for two or more defaults is the same,  $s^C(2) = \dots = s^C(N)$ . This shock is given as a solution to the following equation:

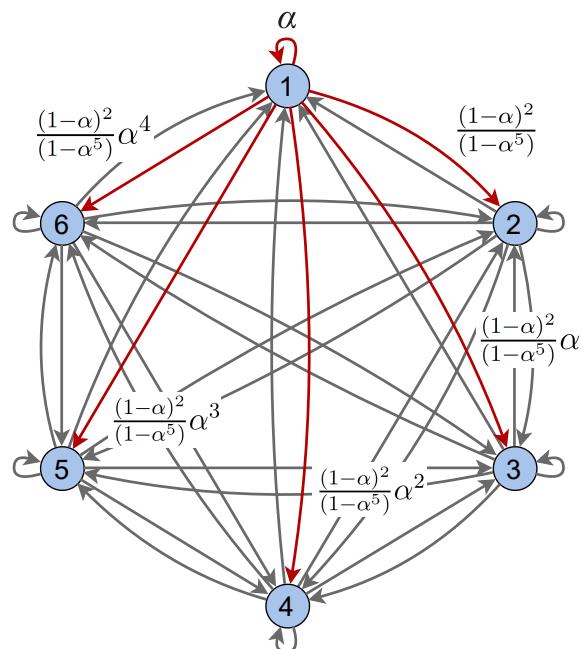

$$\frac{1 - \alpha}{N - 1} [(R - \beta - s^C(N))] + \left[1 - \frac{1 - \alpha}{N - 1}\right] R = \ell \quad (9.38)$$

This suggests that the shock must be large enough to cause the second (and thus  $N^{th}$ ) bank to fail to recapture enough shares to cover its liabilities after the insolvency caused by the first shock. This equation considers the threshold from the point of view of bank  $i \neq 1$ . Suppose only bank 1 has gone bankrupt and all others are solvent: what is the largest shock that could be sustained such that this bank can cover its liabilities. Any shock greater than this would lead to the bank (and hence all other banks) going bankrupt.

Observe that in the ring network, the off-diagonal terms in  $A^R$  decrease with distance from the diagonal. This naturally suggests a higher threshold in the number of defaults. The exact thresholds for different  $k$  may be obtained as a solution to the following equation:

(a) Complete

(b) Ring

Figure 9.5: Networks with Cross-Ownership

$$\left[ \sum_{i=0}^{j-3} \right] \frac{(1-\alpha)^2}{1-\alpha^{N-1}} (R - \beta) + \frac{(1-\alpha)^2}{1-\alpha^{N-1}} \alpha^{j-2} (R - s^R(j) - \beta) + \left[ \sum_{i=j-1}^{N-2} \right] \frac{(1-\alpha)^2}{1-\alpha^{N-1}} R + \alpha R = \ell \quad (9.39)$$

As the off diagonal elements are falling in the number  $N$ , one immediate implication is that the threshold values on minimal shocks are all increasing in the number of banks/projects. In other words, other things being the same, a larger system permits greater diffusion of exposure and this makes it more difficult for a shock on one firm from leading to contagion.

Let us next compare the thresholds in the complete and the ring network. It is simpler to take up the case for large and small default costs separately. First consider small  $\beta$ . An inspection of the matrices  $A^C$  and  $A^R$  reveals that the largest (smallest) off-diagonal term in the ring network is larger (smaller) than the common off-diagonal term in the complete network. This suggests that generalized default of all banks will be more difficult in the ring network as compared to the complete network, but that localized defaults by a small set of banks will be easier in the ring network as compared to the complete network. Turning next to large costs of default. When default costs are large, a default of a single bank leads to default by all banks. The key to understanding this result is to note that when  $\beta$  is small, the size of the shock that needs to be absorbed is roughly equal to size of the shock hitting firm 1,  $s_1$ . By contrast, when  $\beta > 0$  is large the size of the shock is larger and grows on average as more banks default. There is an amplification created by the default costs. This yields us the desired conclusion: the default of a single bank leads to the default of all banks. Indeed it is possible to show that, when default costs are large, generalized default of all banks is easier in a ring than in the complete network. This last step is the subject of a question at the end of the chapter.

We summarize our discussion in the following result.

**Proposition 9.2.** *Shock thresholds for default are rising in the number of banks/projects,  $N$ . If default costs,  $\beta$ , are small then  $s^R(2) < s^C(N) < s^R(N)$ . If default costs,  $\beta$ , are large then either all or none of the firms default,  $s^m(N) \leq s^m(1)$ , for  $m \in \{C, R\}$ . The threshold for all firms defaulting is lower in the ring network,  $s^R(N) < s^C(N)$ .*

This result sets the stage for the derivation of optimal networks in a given environment. Given that there is a uniform cost for bank default, the welfare loss due to contagion is proportional to the number of banks that default.

An inspection of Proposition 9.2 gives us an insight into how levels of shock can translate into relative effectiveness of different networks in containing contagion.

**Proposition 9.3.** (i). If shock  $s \leq s^R(2)$  or  $s > s^R(N)$  then the ring and the complete networks are equivalent. (ii). If  $s^R(2) < s \leq s^C(N)$  then the complete network dominates the ring network. (iii). If  $s^C(N) < s \leq s^R(N)$  then the ring network dominates the complete network.

So far we have focused only on the density of connections in the network. But other aspects of the network can in principle play an important role. To see this let us take up the possibility of segmenting the system of  $N$  firms into disjoint components. Fragmentation of the network into separate components can be an effective instrument for limiting contagion and can dominate complete and ring networks. For concreteness consider situations like (iii) in the Proposition above. In this situation, the network that consists of disjointed and complete components will typically dominate a single ring structure.

In the discussion so far, we have focused on the role of the network topology and the nature of the linkage (equity versus debt). In practice, the details of the network connections are often not easily available. It is therefore worth noting that a higher level statistic is important: the level of integration of a bank with other banks. In the equity model this is captured by  $1 - \alpha$  while in the debt context this is captured by the value of  $a$ . An inspection of equations 9.37, 9.39 and 9.38 reveals that the threshold for one default is increasing in  $1 - \alpha$ , while the threshold for  $j > 1$ ,  $s(j)$  decreases with  $1 - \alpha$ . This contrasting effect on a single and multiple default nicely brings out the trade-off involved in financial linkages.

*Debt Linkages:* We now study the role of financial networks when the linkages represent debt relations. Let us start by noting that the complete and ring network can be constructed in a straightforward way: in the complete network, set  $a_{ij} = a_{ji} = a/(N - 1)$ , where  $a > 0$ , for all  $i, j$ . In the ring network, set  $a_{i,i+1} = a$  for all  $i$  and  $a_{ij} = 0$ , otherwise. We will also set  $\beta = 0$ . Let us start by noting that the effect of size of system,  $N$ , remains unchanged: The minimal size of shock needed for all default of all banks grows with  $N$ . This is true because as  $N$  grows, the magnitude of a shock on directly linked banks becomes smaller and this makes them less likely to default. However, for a given  $N$ , the effects of networks are quite different when links denotes debt.

Observe that when linkages represent debt, changes in the number of linked banks has no effect on the individual threshold for default so long as aggregate liabilities remain unchanged. This is because an individual bank retains full right to the returns to its project and so the threshold. Hence when linkages represent debt, their presence does not provide any insurance to a bank against idiosyncratic shocks. A second major difference pertains to the relative attractiveness of the complete and the ring network. When debt to external creditors (outside the network) is senior to debt within the network, the threshold shock needed get all banks to default is the same in the complete and the ring structure. However, for the ring we have the  $s^R(1) < s^R(j) < s^R(N)$  for  $1 < j < N$ , for shocks of intermediate

size between  $s^R(1) = R - \ell$  and  $s^R(N)$ . In this range of shock values therefore there are multiple failures in the ring and only a single failure in the complete structure. Thus when linkages represent debt, the complete network always dominates the ring network.

Let us summarize what we have learnt. We have developed a model of financial linkages between banks; the linkages may reflect cross ownerships or debt contracts. To bring out the main points in a transparent way, we have focused on two simple networks that are symmetric – the complete network and the ring network. Our analysis helps bring out the following insights. One, the ways in which defaults or financial distress spreads from one bank to another will depend both on the nature of the bilateral ties as well as the topology of the network. Two, the architecture of the optimal networks will depend on the nature of risks faced by individual banks: when shocks are small greater linkages between institutions may be best, but when the shocks are large it may be better to fragment the network into separate components.

## 9.6 Incomplete Network Information and Fire Sales

Our discussion in section 9.2 points to two features of financial linkages: the first relates to the content of the link, it can be very varied, reflecting the diversity of financial instruments; and the second is that actors in the market have very limited knowledge of the network. The complexity of the network reflects both these aspects. This complexity comes together with limited information about the network. These factors are important in the decision making of managers as they can potentially magnify the uncertainty in the market. Federal Reserve Chairman Ben Bernanke captures this concern as follows:

Our financial system is extremely complex and interconnected, and Bear Stearns participated extensively in a range of critical markets. The sudden failure of Bear Stearns likely would have led to a chaotic unwinding of positions in those markets and could have severely shaken confidence. The company's failure could also have cast doubt on the financial positions of some of Bear Stearns' thousands of counterparties and perhaps of companies with similar businesses . . . . Moreover, the adverse impact of a default would not have been confined to the financial system but would have been felt broadly in the real economy through its effects on asset values and credit availability. *Testimony to the Senate on April 3, 2008 following the Fed's Bear Stearns intervention*

The role of domino effects in elevating complexity and uncertainty was also highlighted

by Haldane [2013], when he wrote that at times of stress “knowing your ultimate counter-party’s risk becomes like solving a high-dimension Sudoku puzzle.”

In the previous section, we presented a model that illustrated amplification mechanisms created by connections that could lead to contagion and systemic collapse. One assumption in that model was that the network of exposures is fully known and understood by the banks. This section presents a model of financial crises that builds upon the idea that complexity, a dormant factor during normal times, becomes acutely relevant and self-reinforcing during crises.

The model is taken from Caballero and Simsek [2013]. Banks face liquidity shocks and to adjust to them they maintain linkages with other banks. The new element is complexity: this is reflected in the incomplete knowledge of how far a bank is from the centre of the shock. The model has three periods, labelled  $t = 0, 1, 2$ . To avoid strategic considerations we will assume that there is a continuum of banks, specifically there are  $n$  distinct ‘continua’ of banks and we will denote them by  $\{b_j\}_{j=0}^{n-1}$ . Each of these continua consists of identical banks. We shall refer to a continuum  $b_j$  as bank  $b_j$ . Banks start with a given balance sheet at date 0 (which will be described shortly), but they only consume at date 2. Banks can transfer their date 0 dollars to date 2 by investing in one of two ways. First, banks can keep their dollars in cash, which yields one dollar at the next date per dollar invested. Second, banks can invest in a long term asset. Each unit of the asset yields  $R > 1$  at date 2 (and no dollars at date 1). The asset is supplied at date 0 at a normalized price of one. The return structure captures the standard liquidity and return trade-off, which is prevalent in financial markets.

Each bank initially has  $y$  dollars and  $1 - y$  units of legacy assets. At date 0, the only decision point, banks can trade legacy assets in a secondary market at an endogenous price  $p$ . This price cannot exceed 1 because legacy assets and new assets are identical (and the price of the latter is 1). A key assumption is that the only buyers of legacy assets are the other banks. In the absence of adequate demand this legacy asset sells at an outside valuation of  $p_{scrap} < 1$ . Selling at  $p_{scrap}$  will be referred to as a *fire sale*.

Every bank  $b^i$  has a deposit at bank  $b^{i-1}$  which yields  $z$  in period 1; bank ‘1’ has deposit at bank ‘n’. These are unsecured deposits that reflect large inter-bank exposures. So bank  $i$  is owed  $z$  by bank  $i - 1$  and owes  $z$  in turn to bank  $i + 1$ , at time 1. This creates a ‘cycle’ of exposures (as in 9.6 discussed above).

Banks’ exposures form a financial network. For simplicity, assume that the network is a cycle (see Figure 9.6). The notation,  $b_{j+1} \rightarrow b_j$  means that  $b_{j+1}$  has claims on bank  $b_j$ . As banks are ordered around a cycle, bank  $b_0$  has claims on bank  $b_{n-1}$ . The key idea that financial networks are complex is captured as follows: Bank A may know who it is lending

to or borrowing from but it does not know where its creditor got its money from and to whom its debtor bank lends to. In particular, it will be assumed that banks have only local knowledge:  $i$  knows who bank  $i - 1$  is, but does not know who bank  $i - 1$  lends to, in other words it does not know the identity of bank  $i - 2$ .

Let us define permutations of 'n' banks on a cycle using the mapping  $\sigma : \{0, 1, \dots, n - 1\} \rightarrow \{0, 1, \dots, n - 1\}$ . This permutation assigns bank  $j$  to slot  $i = \sigma(j)$ . Let  $N^i(\sigma)$  be the set of potential permutations for bank  $i$ . Banks do not know the realization,  $\sigma$ . In particular, let  $N_j(\sigma) \subset N$  denote the set of financial networks that bank  $b_j$  deems possible given the actual realization,  $\sigma$ . We refer to the collection  $\{N_j(\sigma)\}_{j,\sigma}$  as an uncertainty model for banks.

At date 0, banks hear that a bank  $b_i$  has had an unexpected shock in period 1. Let  $\theta > 0$  be the size of the shock and it is known to all banks. This shock is senior to the short term claims of its creditor bank.

At this point, banks choose to buy or sell liquidity. The bank's goal is to maximize its equity value at date 2, subject to meeting liquidity need at date 1. Suppose, for simplicity, that bank can either use all cash to buy assets  $B$  or sell all assets to keep cash  $S$ . If a bank buys assets, then a bank facing a shock will get  $z$  and owes  $z$ , which cancel out. So it has a liquidity net need of  $\theta$  and it cannot cover these needs. So the bank sells its legacy assets and keeps cash.

Selling legacy asset is a precautionary move to avert a potential liquidity crises: but the bank may not be able to cover liquidity in spite of that as  $\theta$  may be too large. In that case it is insolvent and pays  $q_1 \leq z$  to creditor bank and its date 2 value is  $q_2 = 0$ . If, on the other hand, it is able to cover the liquidity needs it pays  $q_1 = z$  to depositor bank and its date 2 equity value is  $q_2 \geq 0$ .

The bank makes a choice at date 0: the bank considers the range of possible financial networks,  $N_j(\sigma)$ , and chooses an action that is robust to this uncertainty. We assume that the bank chooses an action which maximizes the minimum payoff it can get across all possible network location permutations. Let  $N^i(\sigma)$  be the set of possible permutations for bank  $i$  given its knowledge of network. Each bank chooses to buy or sell assets to solve:

$$\max_{B,S} \min_{\tilde{\sigma} \in N^i(\sigma)} q_2^i(\tilde{\sigma}). \quad (9.40)$$

Legacy assets are traded at date 0 in a centralized market. The net supply of the legacy asset is:

$$NS = (1 - y) \sum_j \mathbf{1}_{\{A^j=S\}} - \frac{y}{p} \sum_j \mathbf{1}_{\{A^j=B\}}. \quad (9.41)$$

The price  $p = 1$  if  $NS \leq 0$ ,  $p \in (p_{scrap}, 1)$  if  $NS = 0$  and  $p = p_{scrap}$  if  $NS \geq 0$ .  $p_{scrap}$  is the

minimum price for the legacy asset.

An equilibrium consists of bank actions, debt payments, and equity values  $\{A_0^j(\sigma), q_1^j(\sigma), q_2^j(\sigma)\}$  and a price level  $p \in [p_{scrap}, 1]$  for legacy assets such that markets clear and banks solve their optimization problem.

Consider bank actions and payoffs  $\{A_0^j(\sigma), q_1^j(\sigma), q_2^j(\sigma)\}$ . To study this model, it is useful to define the bank's distance from the original distressed bank. The distressed bank  $b_0$  has distance  $d = 0$  from itself. The neighbor of the original distressed bank has distance  $d = 1$ . We will say that there is a *domino effect* of size  $D$  if banks within distance  $d \leq D - 1$  are insolvent and all banks  $d \geq D$  are solvent.

There is a *flight-to-quality* of size  $F$  if banks with distance  $d \leq F - 1$  choose  $S$  and all banks  $d \geq F$  choose  $B$ .

To provide a baseline, we start with the analysis of the perfect information case: all banks know the true network permutation  $\sigma$ . To develop the equilibrium for this setting it is convenient to make the following assumption.

**Assumption (A)**  $ny > \lceil \theta \rceil$ , and  $z + y + (1 - y)p_{scrap} \geq \theta$ .

The first part says that the shock is smaller than the aggregate cash holdings of all banks. This assumption is necessary to make the problem worth studying. Clearly, if this condition is violated then all banks will always go for fire sales after a shock. The second part of the assumption is for notational simplicity only.

### 9.6.1 Complete Network Information

The analysis proceeds in three steps: first, we solve for optimal bank choice given the price and choice of others, second, we solve for equilibrium among banks taking price as given, and finally, we solve for price.

Let us start with a bank at distance  $d$  from the distressed bank: the net liquidity need for bank at distance  $d$  from distressed bank 1 is  $z - q_1(d - 1) + \theta \mathbf{1}_{d=0}$ . The potential liquidity supply upon liquidation of legacy assets is then  $l(p) = p(1 - y) + y$ . If liquidity need is 0 then the bank chooses  $B$ . If liquidity need lies in  $(0, l(p))$  then it can pay off its needs by selling, so optimal action is to sell its legacy assets,  $S$ . Finally, if need is larger than  $l(p)$  then bank is insolvent irrespective of what it does and its equity value is 0. However, its value to debt holders is larger with selling its assets, therefore it chooses  $S$ . Observe that original distressed bank 1 receives its deposit returns from bank  $n$ . Hence the liquidity need is  $\theta > 0$  and bank chooses  $S$ . If  $l(p) \geq \theta$  then the original bank avoids insolvency and the domino effect  $D(p) = 0$ .

If  $l(p) < \theta$ , bank 1 cannot address its liquidity needs. It therefore only transfers  $q_1(0) = z + l(p) - \theta < z$  to bank 2. Now note that due to assumption (A),  $z' \geq 0$ . As there is a shortfall in its payments, Bank 2 too has a positive liquidity need given by  $z - q_1(0) = \theta - l(p) > 0$ . So this bank also chooses  $S$ . Observe that if  $2l(p) \geq \theta$  then Bank 2's available liquidity exceeds need, therefore domino stops at bank 1. If not then Bank 2 is also insolvent and passes on  $q_1(1) = l(p) + q_1(0)$ , and so forth. Eventually, we get the pattern that payment by a distance  $k$  insolvent bank is given by  $q_1(k) = l(p)[k - 1] + q_1(0)$ . The definition of  $D(p)$  says that it is the first integer such that  $\theta \leq l(p)[D(p) + 1]$ . Assumption (A) implies that both the domino effect and the flight-to-quality are contained, i.e.,  $D(p) < n$  and  $F < n$ .

We are now ready to describe the equilibrium in the full information setting.

**Proposition 9.4.** *Suppose assumption (A) holds. Then:*

- (i). Unique equilibrium price is  $p = 1$  (no fire sales)
- (ii). Domino effect of size  $\lceil \theta \rceil - 1$  and a flight to quality of size  $\lceil \theta \rceil$ .
- (iii). Aggregate amount of new asset purchase is  $Y = ny - \lceil \theta \rceil$ .

The main point is to show that price of legacy asset is 1, the rest follows from that fact. Observe that the net demand for asset at price  $p$  is

$$\frac{y(n - D(p) - 1)}{p} - (1 - y)(D(p) + 1) \quad (9.42)$$

By definition  $D(p) + 1 = \left\lceil \frac{\theta}{l(p)} \right\rceil$ , substituting and simplifying and using assumption (A), yields the property that net demand is positive and this implies that the price of asset is 1.

Figure 9.6 illustrates this result. The basic idea is very simple. Banks closest to the distressed bank 0, use their liquidity  $l(p)$  to cover the losses of bank 0. As the shock passes from one bank to the next, the liquidity need decreases by  $l(p)$ . From the definition of  $D(p)$ , it then follows that banks with distance  $d \leq D(p)$ , choose to sell. All but the last of them is insolvent. The last bank with distance  $d = D(p)$  avoids insolvency as it is able to meet its liquidity needs and pays its immediate neighbour in full. It then follows that all the banks at distance  $d > D(p)$  have zero liquidity need and optimally choose to buy long asset. There is therefore a domino effect of size  $D(p)$  and a flight to quality of size  $D(p) + 1$ .

### 9.6.2 Incomplete Network Information

We now study bank choices under incomplete network knowledge and the max-min decision rule. Recall that the local knowledge assumption says that the bank knows the identity

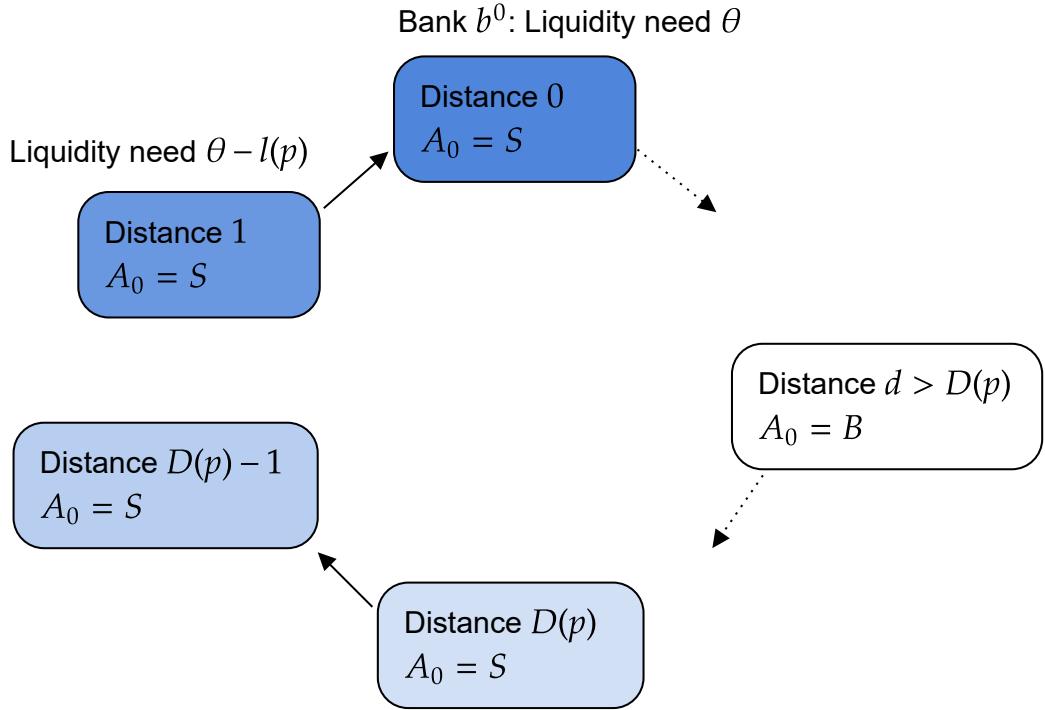

Figure 9.6: Outcomes with Complete Network Information

of the bank who owes it money but only that bank. There are two scenarios for a non-distressed bank  $i$ : one, the distressed bank is the borrower  $i - 1$  and two, the distressed bank is not the borrower bank. In the latter case, the ‘worst’ case scenario is that the distressed bank is bank  $i - 2$ . The optimal choice of bank  $i$  depends on the size of the shock  $\theta$ . If  $\theta \leq 2l(p)$  then  $D(p) \leq 1$  and flight-to-quality size is  $F = D(p) + 1$ . Observe that if  $\theta < 2l(p)$  then it is common knowledge that the distressed bank and its immediate depositor can take care of the liquidity needs. If bank  $i$  is a distressed bank or its depositor then bank  $i$  will know the true state of the world. The distressed bank always chooses  $S$  and the depositor chooses  $S$  or  $B$  depending on whether  $\theta$  is smaller than  $l(p)$  or not. All other banks will choose  $B$ . On the other hand, if  $\theta > 2l(p)$  then  $D(p) \geq 2$  and flight-to-quality size is  $F = n$ . In case  $\theta > 2l$  all banks sell assets.

Equipped with this simple rule of behaviour for banks, we can characterize the equilibrium in the incomplete network knowledge setting.

**Proposition 9.5.** *Consider the economy with incomplete network knowledge and let assumption (A) hold.*

(i) *If  $\theta < 2l(p_{scrap})$  then there is a unique equilibrium with  $p = 1$ ,  $D(p) = \lceil \theta \rceil - 1$  and flight-to-quality size of  $F = \lceil \theta \rceil$ . The aggregate amount of long assets bought is  $Y = ny - \lceil \theta \rceil$ .*

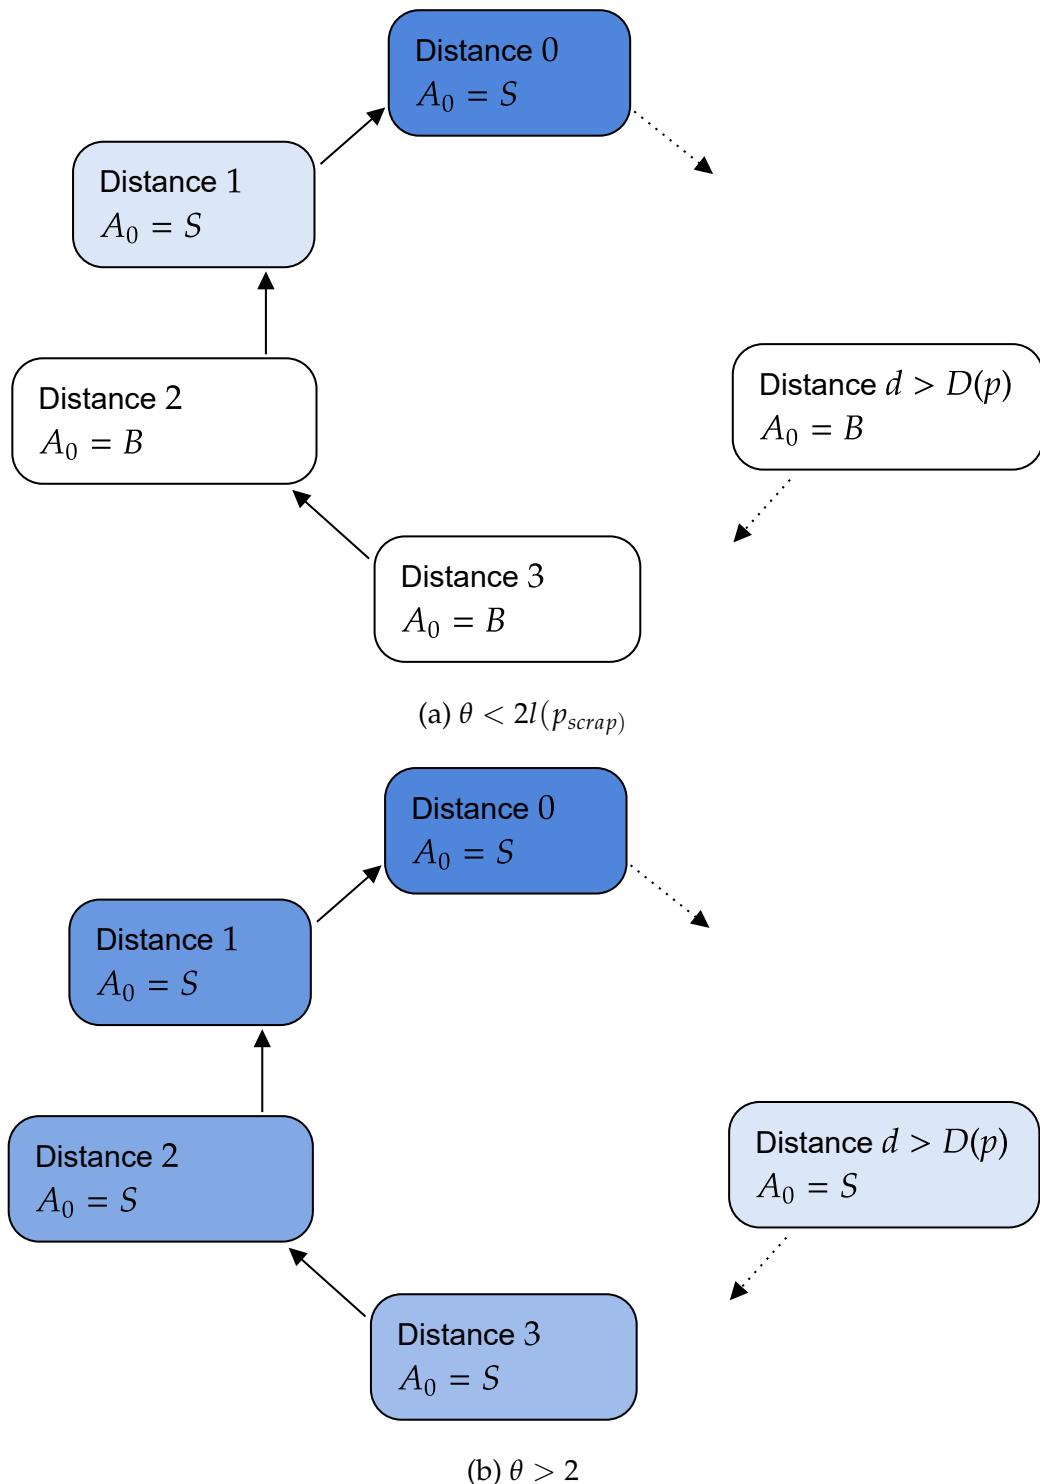

Figure 9.7: Outcomes with Incomplete Network Information

(ii) If  $\theta > 2$  then there is a unique equilibrium with price  $p = p_{scrap}$ ,  $D(p) = \lceil \theta \rceil$ , and flight-to-quality size of  $F = n$ , the total amount of new asset purchases is 0.

(iii). If  $\theta \in (2l(p_{scrap}), 2)$ , then there are two equilibria one corresponding to the fair value  $p = 1$  case and the other to  $p = p_{scrap}$  case.

The main point to note here is the flight-to-quality phenomenon: all banks sell their assets, and so price collapses to scrap value as soon as  $\theta > 2$ .

Figure 9.7 illustrates this result. It plots the equilibrium actions corresponding to the low and high  $\theta$ . In the low  $\theta$  case, the shock is smaller than the available liquidity of original distressed bank and its immediate neighbor. The top part of Figure 5 shows that the equilibrium outcome is the same as the full information case. Note that banks at distance  $d \geq 2$  act as if they are at distance 2. With this small shock, the bank at distance 2 does not suffer any losses from cross exposures and chooses action  $B$ , as do all banks at distance  $d \geq 2$ .

The lower part of 9.7 covers the case of shock  $\theta$  that is larger than the liquidity of two banks. Thus the bank at distance 2 chooses action  $S$  and so do all banks. This leads to a flight to quality of size  $n$ .

Let us summarize what we have learnt in this section. The effects of a shock on a bank on other banks depend on the connections that the originator bank has and the structure of the network. However, this structure is often very poorly understood by the participants in the network and by outsiders such as policy makers and regulators. The study of behaviour with incomplete network knowledge is at a very early stage. The model presented above is very stylized but it helps bring out in a stark manner how complexity and risk aversion can give rise to very large fire sales as a reaction to a shock on a single bank.

## 9.7 The Formation of Financial Networks

In section 9.2 we presented evidence that interbank markets exhibit a core periphery structure. Why do interbank networks have this structure and what are its implications?

We present a model taken from Farboodi [2017] to understand the forces that lead to a core-periphery architecture. There are three periods,  $t = 0, 1, 2$ , and one good, funding. There are two types of agents: banks and households. There are  $K$  banks in all: banks are of two types  $I$  and  $NI$ , banks in group  $I$  have access to investment opportunities and banks in group  $NI$  don't. There are  $k_I$  and  $k_{NI}$  banks of the two types; assume  $k_{NI} \geq k_I$ .

The investment opportunity is a risky asset that is linearly scalable. Every bank  $i \in I$  receives the opportunity to invest in the risky asset with probability  $q$ . The probability is identical and independent across banks.

At  $t = 0$ , banks raise funding from households and create lending and borrowing relationships. A link  $g_{ij}$  means bank  $i$  is committed to lending to bank  $j$ . At  $t = 1$ , investment opportunities are realized and borrowing takes place along a subset of borrowing links created at  $t = 0$ . At  $t = 2$ , the returns from investment are realized. The returns are random: there is a probability  $p$  that investment yields  $R$  and probability  $1 - p$  that investment yields 0. The probability of return is identical and independent across banks. Over and above this investment, every bank has a value  $V_i$ , that reflects the value of the other businesses, assets, and services the bank provides. If the bank fails this value is lost. For simplicity, suppose that  $V_i = V_I$ , for all  $i \in I$ , and  $V_j = V_{NI}$  for all  $j \in NI$ .

A bank can raise funding from two sources. At  $t = 0$  a bank  $j \in NI$  raises resources from a continuum of households  $hh_j$  of measure one. A household is endowed with one unit of funding. Households lend to banks so long as they break even. In addition to households, in period  $t = 1$ , after observing the investment opportunities, a bank can borrow from other banks who created borrowing links with them in period  $t = 0$ .

The financial network is a directed graph, with  $K$  nodes representing the banks and a directed link from  $i$  to  $j$  representing a lending commitment. A bank chooses its links over which he can borrow or lend, to maximize its expected profit net of failure cost. For concreteness, we will focus on an example with 4 banks: two banks of type  $I$ , and two banks of type  $NI$ .

To borrow on the interbank market at date  $t = 1$ , banks need to enter potential agreements at  $t = 0$ . Potential agreements are similar to credit lines, except that they do not have a limit. An agreement established at  $t = 0$  is a promise by the lender to deliver at least one unit to the borrower, if the borrower receives an investment opportunity, or if the borrower has a credit line to another bank that has received an investment opportunity. A bank can create a lending link with another bank only if it can deliver on it: there is thus an opportunity cost to creating a link with a potential borrower. To see this in the simplest setting consider Figure 9.8b. Observe that the network on the left is not feasible: the  $NI$  bank has committed to lending to two  $I$  banks, but it only has one unit of household funds. The network on the right is feasible.

We will assume that there is an exogenously given division of surplus between the investing bank and the banks that directly or indirectly lend to it. In particular, we will assume that when bank  $i$  raises funding from households and lends directly to bank  $j$ , who makes the investment then  $i$  and  $j$  receive a share  $\alpha$  and  $1 - \alpha$  of the surplus. If on the other hand,  $i$  raises the funding, lends to  $j$  who in turn lends to  $k$  who invests, then  $i$ ,  $j$  and  $k$  receive  $\alpha^2$ ,  $\alpha(1 - \alpha)$ , and  $1 - \alpha$ , respectively.

The final return of the project at  $t = 2$  is not contractible. Contracts are bilateral and

take the form of contingent debt. The face value of the debt is such that given the network and the realization of investment opportunities, each bank along the intermediation chain receives its appropriate share, as described above.

A network structure  $G$  is blocked by a coalition  $B$  of banks if there exists another (feasible, individually rational) network structure  $G'$  and a coalition  $B$  such that (i)  $G'$  can be reached from  $G$  by a set of bilateral deviations by banks  $b, b' \in B$  and unilateral deviations by  $b \in B$ . (ii) every bank  $b \in B$  is strictly better off in  $G'$  as compared to  $G$ . A network is said to be *stable* if it is not blocked by any coalition of banks.

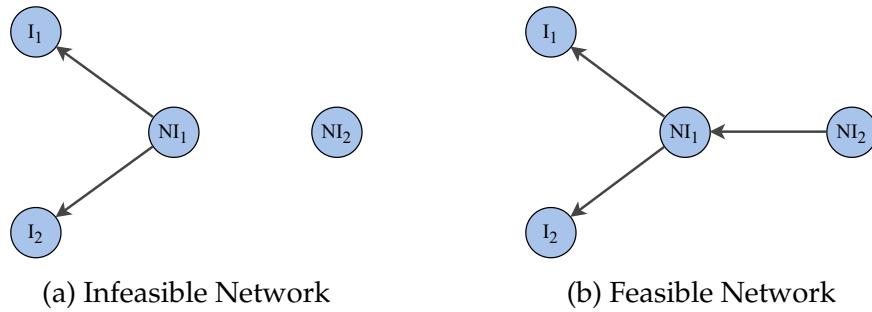

Figure 9.8: Examples of Networks

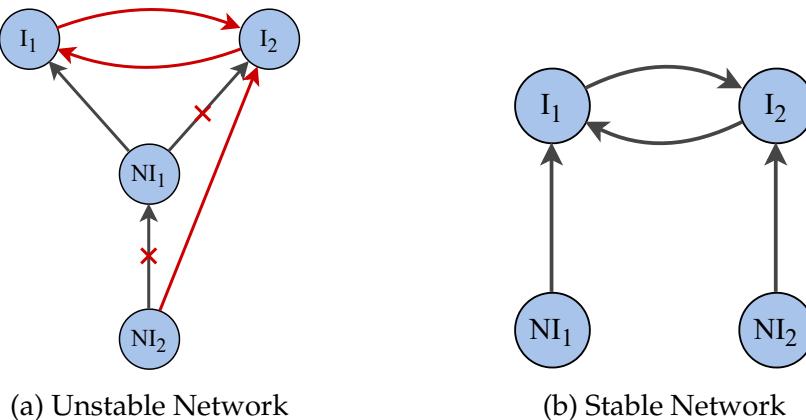

Figure 9.9: Deviations by Banks

We now develop a description of different networks that are stable and compare them to efficient networks.

### 9.7.1 Stable and efficient networks

Let us begin by noting the incentives of a NI lender and an I borrower, respectively:

$$(1 - \alpha)(pR - 1) > (1 - p)V_I; \quad \alpha(pR - 1) > (1 - p)V_{NI} \quad (9.43)$$

This relationship is in their joint interest if the expected returns of the project  $pR - 1$  are greater than the expected cost of default  $(1 - p)(V_I + V_{NI})$ , i.e.,  $pR - 1 > (1 - p)(V_I + V_{NI})$ . Observe that if the lender and borrower find it attractive to create the link, then it is also in their collective interest. In other words, individual incentives to create a link are lower than desirable. For the study of networks to be interesting it must be the case that indirect lending is profitable. This motivates the restriction on parameter values:  $\alpha^2(pR - 1) > (1 - p)V_{NI}$ .

A key concept in the analysis of stable networks is intermediation spread. Consider the arrangement bank  $i$  lends one unit at face value  $D$  to  $j$  who invests the unit. Consider next the indirect arrangement in which  $i$  lends one unit to  $kj$  at face value  $D_1$ , who lends the unit at face value  $D_2$  to  $j$ , and  $k$  makes the investment. The face value of debt is set in such a manner so as to ensure that in expectation each party (including the mediator) receives its share of expected net surplus. Formally,

$$D_1 = \frac{(\alpha^2(pR - 1) + 1)}{p} < D_2 = D = \frac{\alpha(pR - 1) + 1}{p} \quad (9.44)$$

$D_2 - D_1$  represents the intermediation spread. The intermediation spread provides us with a measure of the incentive for a bank to move from being an indirect to a direct lender.

In particular, recall that in deciding whether to form a link, a bank compares the returns from the link against the risks of bank failure. With this in mind, let us define

$$\kappa = \frac{\alpha(1 - \alpha)X}{(1 - p)V_I} \quad (9.45)$$

where  $X = pR - 1$  is the net expected return of one unit investment in the project:  $\kappa$  is the ratio of the intermediation spread per unit divided by the expected cost of default, for an I bank. We can define a similar ratio for a NI bank. It is helpful to define the following pieces of additional notation:

$$\tilde{\kappa} = \max\{\alpha, (1 - \alpha)\frac{V_{NI}}{V_I}\} \quad \bar{\kappa} = 1 + \frac{q}{2(1 - q)}. \quad (9.46)$$

In what follows, we will assume that a pair of NI and I banks always have an incentive for forming a link, i.e., conditions are met, i.e.,  $\kappa \geq \tilde{\kappa}$ . Let us start by delineating the set of networks that can be stable. Observe that if  $\kappa < \tilde{\kappa}$  then every NI bank must be creating a link in any stable network. So the only candidates for stable network are as in Figure 9.10. Within this set, networks (d), (g) and (h) can be eliminated using straightforward arguments. Network (d) cannot be stable because bank  $NI_1$  has two units of loans available and can therefore increase its profits by forming a link with bank  $I_2$ . Bank  $I_2$  clearly has

an incentive to form this link given  $\kappa \geq \tilde{\kappa}$ . Next consider network (g): Observe that bank  $NI_2$  has an incentive to connect with  $I_1$  so as to access its investment opportunity (this is strictly profitable in the state when bank  $I_2$  does not have an opportunity). Bank  $I_1$  can hope to raise its intermediation rents by forming this link as it can act as an intermediary for bank  $I_2$ . Finally, consider network (h). Clearly banks  $NI_1$  and  $I_2$  have an incentive to carry out the deviation because by doing so, they sidestep bank  $I_1$  and thereby lower their intermediation payments to  $I_1$ . Putting together points together, we are left with networks (a)-(c) and (e).

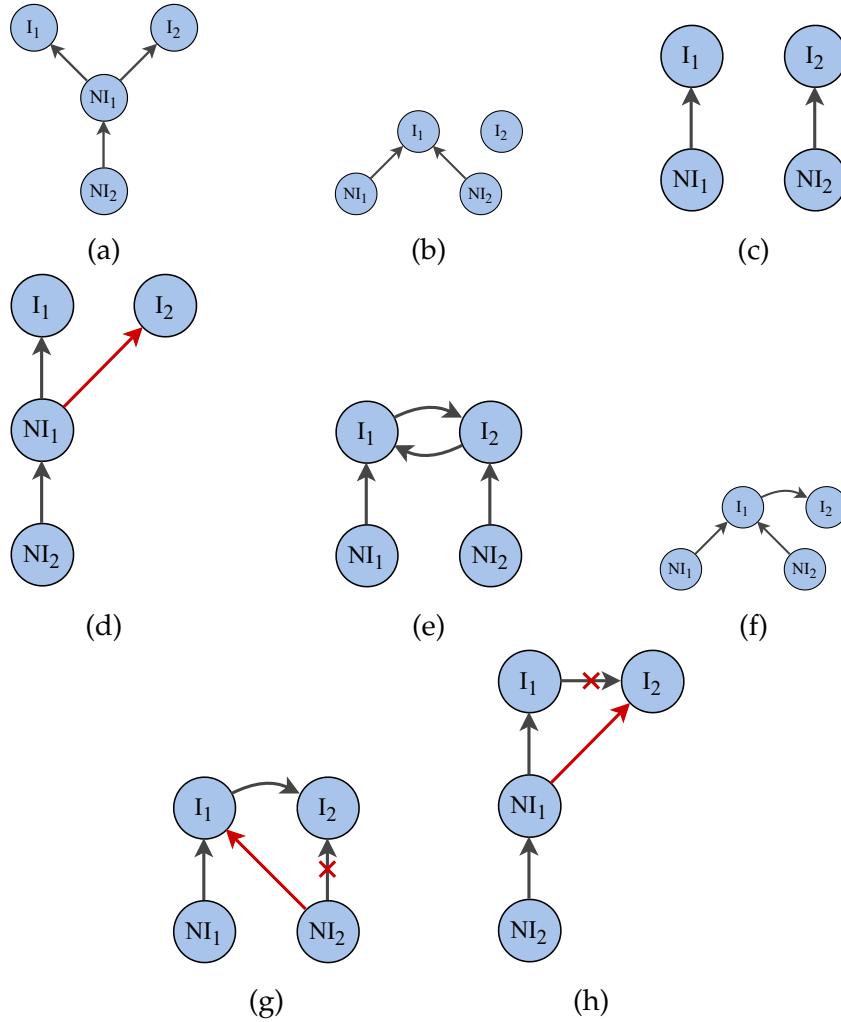

Figure 9.10: Candidates for Stable Networks

The next proposition provides a characterization of equilibria in the economy with four banks.

**Proposition 9.6.** Suppose that  $\kappa \geq \tilde{\kappa}$ . Then network (a) is stable if  $\kappa \leq \tilde{\kappa}$ ; networks (b) and (c) are stable if  $\kappa \leq 1/2$ ; network (d) is stable if  $\kappa \geq 1$ ; and network (e) is stable if  $\kappa \geq 1/2$ .

The proof of the proposition involved checking the incentives of banks. A question at the end of the chapter asks for these details to be worked out. Here, we will focus on the incentives for the formation of a core-periphery network (d), in which the I banks constitute the core.

Consider the two networks (a) and (e). Observe, that in network (a) an I bank is involved in a default only if it made an investment. By contrast, in network (d), all banks are involved, as long as one of the I banks is active. Thus there is higher systemic risk in network (d). We will now show that there are circumstances under which the two I banks and bank  $N_2$  have an incentive to deviate from network (a) and create network (d). This deviation is illustrated in Figure 9.9. Consider the different investment opportunities that may arise: first, if only  $I_2$  receives the investment opportunity then  $I_1$  serves as the intermediary for  $NI_1$  and captures some intermediation rents. The cost is the potential for default triggered if investment in  $I_2$  fails. So, banks  $I_1$  and  $I_2$  will undertake this deviation if the intermediation spread ( $D_2 - D_1$ ) is sufficiently high relative to the cost of the default. This yields us the condition  $\kappa \geq 1$ . Note that  $NI_2$  must benefit from joining the coalition.

We next discuss efficient networks, i.e., the network that maximizes the total surplus subject to feasibility and individual rationality. Given the condition  $\kappa \geq \tilde{\kappa}$ , it follows that every  $NI$  bank must have a link. Moreover, it is strictly better to have both  $NI$  banks feeding into both I banks, in the event that only one I bank receives the investment opportunity. Given this maximum investment size, the goal is to minimize expected loss of default due to failure of project(s). This yields the star network (a) in Figure 9.10, with a  $NI$  bank at the centre.

Figure 9.11 summarizes our study of stable and efficient networks. It shows how stable networks may be under-connected as well as over-connected relative to efficient networks. The under-connectedness arises due to the familiar problem of positive externalities in linking (and incomplete appropriation of surplus), while the over-connectedness arises because banks have incentives to create links to divert surpluses for themselves.

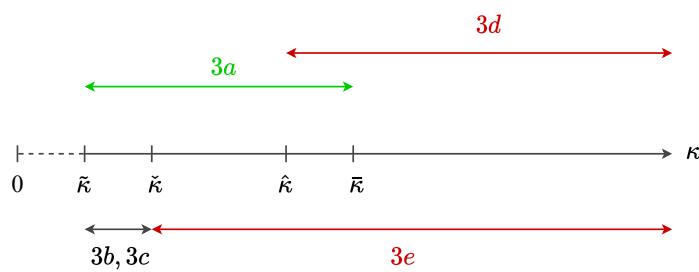

Figure 9.11: Stable and Efficient Networks: Summary

These arguments have been developed in the context of a four bank example. Figure 9.12 illustrates the pattern of core-periphery networks that arise when we consider many  $I$  and  $NI$  banks.

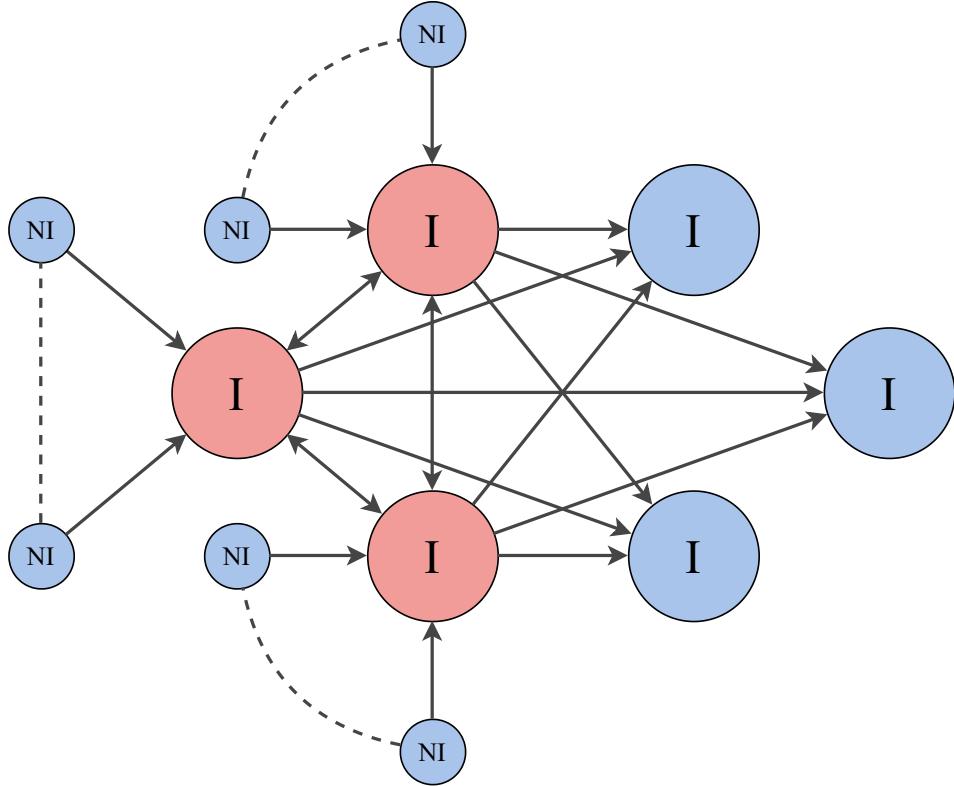

Figure 9.12: Core-periphery with Many Banks

Let us summarize what we have learnt with this model of intermediation. Financial institutions have incentives to capture intermediation rents through borrowing and lending decisions. By doing so, they tilt the division of surplus along an intermediation chain in their favor. The key finding is that these strategic incentives create pressures for the creation of a core-periphery network. This network exhibits excessive exposure to counterparty risk, relative to the efficient network.

## 9.8 Reading Notes

Financial contagion is a old idea: financial booms and busts may be seen as an instance of this phenomena and they go back a long way, classic historical studies include Kindleberger [2001] and Mackay [2018]. This chapter focuses on the narrower question of how measurable connections between institutions reflected in their borrowing/lending and eq-

uity relations can create a pathway for the spread of shocks and how different structures of connections can give rise to amplification of original shocks. The study of networks and their impact on financial contagion is important as it provides a basis for the design of appropriate targeted interventions.

The literature on financial network has grown especially rapidly since the last financial crisis of 2008. The empirical research describes the rich variety of connections between financial institutions... It has also plotted a wide range of network relations. Empirical studies of networks include Martinez-Jaramillo, Alexandrova-Kabadjova, Bravo-Benitez, and Solórzano-Margain [2014], Anand, Craig, and von Peter [2014], Anand, van Lelyveld, Banai, Friedrich, Garratt, Hałaj, Fique, Hansen, Jaramillo, Lee, et al. [2018], Bech and Atalay [2010] for the US, Upper and Worms [2004], and Craig and Von Peter [2014] for Germany, and Blasques, Bräuning, and Van Lelyveld [2018] for the Netherlands.

A number of papers have empirically studied the process of financial contagion, see e.g., Wiggins, Piontek, and Metrick [2019], Wiggins and Metrick [2019], and Khandani and Lo [2007]. For overviews of this work, see Glasserman and Young [2016], Jackson [2019] and Jackson and Pernoud [2020].

Turning to theoretical studies of financial contagion, Eisenberg and Noe [2001] presents an elegant early model of bank networks that clarifies the deeply interconnected nature of bank obligations. This model takes as given the linkages between financial institutions. Allen and Gale [2000] provides a foundation for linkages between banks, based on a combination of negatively correlated timing of liquidity shocks. These two early papers, along with Rochet and Tirole [1996], form the basis of most of the subsequent literature on financial contagions. The more recent literature has taken a more sophisticated approach to the modeling of networks and bankruptcy costs play a more prominent role, see e.g., Rogers and Veraart [2013], Cabrales, Gottardi, and Vega-Redondo [2017], Elliott, Golub, and Jackson [2014], Galeotti and Ghiglino [2021], Gai and Kapadia [2010], Gai, Haldane, and Kapadia. [2011], Glasserman and Young [2015], Gofman [2017], and Acemoglu, Ozdaglar, and Tahbaz-Salehi [2015b], Acemoglu, Ozdaglar, and Tahbaz-Salehi [2015a]. There are a number of excellent surveys of this work, see for example Cabrales, Gottardi, and Vega-Redondo [2016], Glasserman and Young [2016] and Jackson and Pernoud [2020].

There is a growing literature on the formation of financial networks. The conventional view is that institutions establish links with one another as a way of diversifying risk and facilitating intermediation. At a general level, the process of liquidity intermediation and the incentives of different actors to create rents are central to these models. In this perspective the early theoretical models of network formation as in Goyal and Vega-Redondo [2007] provide a general approach to brokerage and intermediation and the architecture of

networks. A number of papers place this general approach within a finance context with the appropriate instruments and institutional constraints; these papers include Acemoglu, Ozdaglar, and Tahbaz-Salehi [2015a], Erol and Vohra [2018], Babus and Hu [2017], Gofman [2017], Wang [2016], Cabrales, Gottardi, and Vega-Redondo [2017], In't Veld and Hommes [2020], Castiglionesi and Navarro [2007] and Georg [2013]. We presented a model taken from Farboodi [2017] as it helps us understand some of the economic forces that give rise to a core-periphery financial network.

I thank Antonio Cabrales and Agatha Pernoud for helpful comments on earlier drafts of the chapter and Maryam Farboodi for sharing materials relating to her work on financial network formation.

## 9.9 Questions

1. Consider the network given in Figure 9.13.
  - Consider a shock that lowers the inflow to bank A from 210 drops to 140. Compute the net equity of the banks after this shock.
  - Consider a shock that lowers the inflow to bank A from 210 drops to 20. Work out the net equity of the banks after this shock.

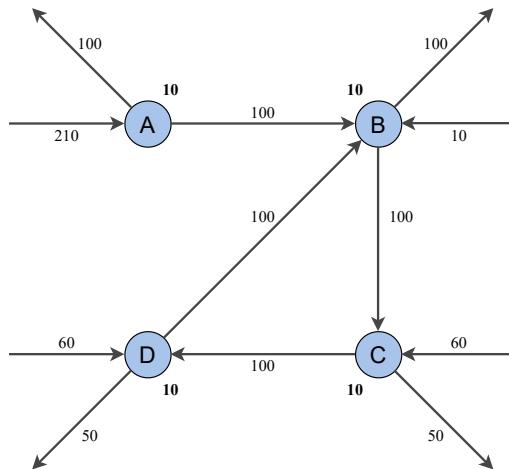

Figure 9.13: Original Network

2. Consider the four-region Allen and Gale [2000] economy, with regional liquidity demands in state  $S_i$ ,  $i = 1, 2$ , as specified in the table below. Each state takes place with equal probability.

		Regional liquidity demand				
		Region				
		State	A	B	C	D
	$S_1$		0.75	0.25	0.75	0.25
	$S_2$		0.25	0.75	0.25	0.75

There is a liquid asset which represents a storage technology. Investment in a long asset is available at  $t = 0$ . Per unit invested in the long asset, the yield is of  $r = 0.4$  at  $t = 1$  (premature liquidation), and of  $R > 1$  at  $t = 2$ . Assume that the period utility function is of the form  $u(c_t) = \ln(c_t)$ .

- (a) Denote as  $y$  and  $x$  the per capita amounts that the social planner invests in the short and long assets, respectively. The feasibility constraint is thus  $y + x \leq 1$ . Noting that at  $t = 0$  the probability of being an early or a late consumer equals 0.5, derive the first-best allocation. Verify that this allocation is incentive compatible.
- (b) Consider now decentralization. Describe the combination of investment decisions and interbank deposits that achieve the first-best allocation when (i) the representative bank of a region holds deposits in the representative banks of all other regions (complete structure); and (ii) the representative bank of region **A** deposits in the representative bank of region **B**, the latter deposits in the representative bank of region **C**, and so on (incomplete structure). For each case, explain the sequence of withdrawals if state  $S_1$  takes place.
- (c) Now suppose that a state  $\tilde{S}$ , which was assigned zero probability at  $t = 0$ , takes place. In this state, regions **B**, **C** and **D** have a liquidity demand of 0.5, but region **A** faces a demand of  $0.5 + \varepsilon$ .
  - Consider the incomplete structure and set  $\varepsilon = 0.1$  and  $R = 1.5$ . Show that there is no contagion. Would your results change if  $\varepsilon$  was larger?
  - Suppose now that  $\varepsilon = 0.1$  and  $R = 1.2$ . Show that there is contagion when the structure is incomplete but not when it is complete.
3. Consider the model described in section 9.5. Show that when default costs are large, generalized default of all banks is easier in a ring network than in the complete network.
4. This question is inspired by the idea of ‘robust yet fragile’ networks (see e.g., Cabrales, Gottardi, and Vega-Redondo [2017] and Acemoglu, Ozdaglar, and Tahbaz-Salehi [2015a]).

Consider a model where banks face shocks of size  $z$  with distribution  $F$ . Consider the class of networks in which nodes are partitioned into equal size distinct cliques (the empty and complete network are extreme points of this class). Suppose that every bank has assets worth 1. A bank fails if the sum total of assets in its clique is smaller than the shock  $z$ . There is a positive cost of a bank failure.

- Develop a model to examine the trade-offs between small and large cliques.
  - How does the nature of  $F$  related to the optimal size of cliques.
  - In our study of optimal networks that face contagious shocks we showed that multiple components may be optimal depending on the nature of the conflict technology and the relative size of defender and adversary resources. Discuss the similarities and differences between the models and the results.
5. Consider the model of network formation presented in section 9.7. Suppose that  $\kappa \geq \tilde{\kappa}$ , where  $\kappa$  and  $\tilde{\kappa}$  are as defined in that section. Show that network (a) is stable if  $\kappa \leq \tilde{\kappa}$ ; networks (b) and (c) are stable if  $\kappa \leq 1/2$ ; network (d) is stable if  $\kappa \geq 1$ ; and network (e) is stable if  $\kappa \geq 1/2$ .

# Chapter 10: Wars

## 10.1 Introduction

War and violent conflict are a recurring theme in human history. Historically, war typically occurred between neighbouring kingdoms and a war between two rulers would in turn affect their neighbours. Larger wars have generally brought multiple opponents into play and alliances play a central role in such wars. In different ways then interlinked conflict appears to be a defining feature of conflict. We would like to understand how resources and the patterns of physical contiguity shape wars, how alliances affect the belligerence of different parties, what are the incentives to create alliances? This chapter develops theoretical models in which inter-linkages are represented as networks. Our questions are then addressed by formulating models of conflict games on networks and models of network formation.

We take the view that relations between actors – of enmity or friendship – can be modeled as signed links of a network, with positive links signifying amity and negative links indicating enmity. Our first object of study is how a given pattern of links affects the incentives and the intensity of war. The theoretical framework combines networks with contest success functions and gives rise to a game on a network. The analysis draws attention to the role of connections – the sum of friendly and unfriendly links – in shaping behaviour. We apply this insight to understand the fighting intensities of different groups in the Great War of Congo. The theoretical framework permits a consideration of policy questions such as the effects of the withdrawal of particular foreign powers and of an arms embargo on the intensity of conflict. In the discussion on contests in networks, the network is taken as given. This is a reasonable starting point and is plausible as most groups stuck to their alliances during the Second Congolese War. But at a higher level there arises the question of what alliance structures are stable more generally. This is the subject to which we turn next.

We present a theoretical model for the study of stable alliances. In this model, countries can attack each other, form alliances, and trade with each other. The study of this model

helps us understand the forces that shape incentives to form alliances and to wage war. In particular, we show that in the absence of large trade flows, attempts to form alliances and attack opponents lead to shifting and unstable alliances: this instability makes peace hard to sustain. But if there are large gains from trade between countries then alliances will be formed and these alliances in turn will deter war. We apply these theoretical insights to understand the frequency of wars in the years prior to the Second World War and the long period of peace after that.

Finally, we use networks as a representation of contiguity and access and we study the dynamics of war and conquest. Kingdoms are nodes and the links represent contiguity. The resource base of kingdoms and the technology of war affects their chances at winning a war. Victory in a war brings rewards in the form of new territories (that come with their own resources). Winning rulers therefore expand their kingdoms and can wage war against new opponents. The theoretical analysis uncovers the role of the resources, the technology, and the network, in shaping the incentives of individual rulers to wage war. The attack strategies of rulers determine the dynamics of conflict and the paths of conquest. We apply the theoretical insights of the model to reflect upon the processes that gave rise to the First Chinese Empire, the Roman Empire, and the Spanish Empire in the Americas.

## 10.2 Netwars

Individual actors and organisms seek to acquire more resources and expand their influence. One possible avenue through which to obtain resources is to appropriate them through conflict. However, agents may face constraints on whom they can target for conflict. The extensive literature on wars shows that a significant majority of them take place among physically proximate entities (Caselli, Morelli, and Rohner [2014]). Traditional models of conflict have focused on bilateral conflicts. As bilateral conflicts create spillovers to other conflicts and as the spillovers are mediated by the pattern of neighborhood relations, it is important to understand the principles of interconnected conflict. This section develops a framework for thinking about such principles.

We start with an early model of conflict on networks taken from Franke and Öztürk [2009]. There is a set  $N = \{1, \dots, n\}$ ,  $n \geq 3$ , of individuals that are located in an undirected network  $g$ . The links between individuals reflect enmity: so for instance, links can be thought of as a shared border between two regions/countries. The set of rivals of individual  $i$  is given by  $N_i(g)$ . Individual  $i$  is engaged in  $n_i(g) = |N_i(g)|$  conflicts. Individual  $i$  chooses a strategy  $e_i(g) = (\{e_{ij}\}_{j \in N_i(g)})$ , that specifies a level of effort  $e_{ij}$ , for every  $j \in N_i(g)$ . The outcome of each bilateral conflict is probabilistic and depends on the in-

vestment in conflict by  $i$  and  $j$ . For concreteness, suppose with investments  $e_{ij}$  and  $e_{ji}$  the probability of winning for  $i$  is given by

$$p_{ij}(e_{ij}, e_{ji}) = \frac{e_{ij}}{e_{ij} + e_{ji}}, \quad (10.1)$$

so long as  $e_{ij} + e_{ji} > 0$ . If  $e_{ij} + e_{ji} = 0$ , the probability of either player winning is  $1/2$ . The cost of investment is given by the function

$$c(e_i) = \left( \sum_{j \in N_i} e_{ij} \right)^2 \quad (10.2)$$

Let us suppose that the prize from winning a conflict is  $Z$ , while the cost of losing is  $-Z$ . The payoffs of individual  $i$  under effort profile  $e = (e_1, \dots, e_n)$ , are

$$\Pi_i(e) = Z \sum_{j \in N_i} [p_{ij}(e_{ij}, e_{ji}) - p_{ji}(e_{ij}, e_{ji})] - c(e_i). \quad (10.3)$$

Let  $e^*(g) = (e_1^*, \dots, e_n^*)$  be a Nash equilibrium. We will take as given that there exists a unique equilibrium and that all links are actively contested. Define  $E_i^*(g) = \sum_{j \in N_i(g)} e_{ij}^*$  as the aggregate fighting effort of player  $i$  in network  $g$ . Equilibrium investments satisfy, for every individual  $i \in N$ , and for every link  $g_{ij}$ ,

$$\frac{Ze_{ki}^*}{[e_{ik}^* + e_{ki}^*]^2} = E_i^*(g), \forall k \in N_i. \quad (10.4)$$

Define  $E^*(g) = \sum_{i \in N} E_i^*(g)$  as the aggregate intensity of conflict. The following result describes equilibrium outcomes in some well known networks.

**Proposition 10.1.** *A conflict equilibrium exhibits the following properties.*

1. *Regular networks:* Conflict intensity is increasing in degree and in the number of individuals. Individual investment and expected payoff is decreasing in degree. Expected payoff is negative for all individuals.
2. *Star network:* Conflict intensity is increasing in the number of peripheral individuals. For the central individual, link specific (aggregate) investment is decreasing (increasing) and the expected payoff is decreasing in the number of peripheral individuals. For the peripheral player, conflict investment is declining and payoffs are increasing in the number of peripheral individuals.

The result is fairly intuitive: involvement in a greater number of conflicts leads to a worse expected outcome for an individual as the convex costs of conflict come into play.

In the star network, greater number of peripheral players benefits the peripheral players at the expense of the hub.

While the result is obtained for specific networks only, it offers us a first impression of how the inter-connections in conflict shapes individuals' fighting efforts. In a regular network, increasing density of the network raises the overall level of conflict and lowers payoffs. The central individual facing more peripheral opponents is obliged to make larger investments but earns a lower payoff. The peripheral players gain as their number grows, because the central opponent player is more overstretched and hence less effective.

### 10.3 Alliances and Conflict

Large scale wars like the World Wars, The Korean War, and the Vietnam War involve alliances among many nation states. Indeed, alliances have been a central feature of war and violent conflict throughout history. In this section, we study wars between parties who are members of alliances.

When players A and B form an alliance they hope to support each other – possibly by sharing resources and information. Thus an alliance may strengthen the position of both A and B vis-a-vis other opponents. This benefit comes with a potential downside: the effort of A benefits A but also benefits B. This spillover makes A's effort a public good and can lower the incentives of A to exert effort. An alliance between A and B will have effects on other opponents: they may be obliged to raise efforts in the face of such an alliance. Moreover, in large scale conflicts, it may be the case that A and B are in an alliance while B is in an alliance with other players X and Y. This leads us to a study of fighting in a network of alliances.

With these preliminary observations in place, let us consider the following model of fighting in a network of alliances taken from König, Rohner, Thoenig, and Zilibotti [2017]. They study conflict among  $N = \{1, \dots, n\}$ ,  $n \geq 2$  players that have positive (allies) and negative (enemies) relations. There is a prize of value  $V$ , that may reflect the value of land and natural resources. The relations between the players are captured in a network of links,  $g$ . A pair of players can be *allies* or *enemies*, or *neutral*. Thus, for any pair of players  $i, j$ , a link:

$$g_{ij} = \begin{cases} 1, & \text{if } i \text{ and } j \text{ are allies,} \\ -1, & \text{if } i \text{ and } j \text{ are enemies,} \\ 0, & \text{if } i \text{ and } j \text{ are in a neutral relationship.} \end{cases} \quad (10.5)$$

The players simultaneously choose fighting efforts; so player  $i \in N$  chooses effort  $x_i \in$

IR. The role of the network is modeled in a specific manner: a player's effort is reinforced by the efforts of its friends and weakened by the efforts of its enemies. This idea is captured in the idea of effective effort,  $\varphi_i$  as follows:

$$\varphi_i(g, \mathbf{x}) = x_i + \beta \sum_{j=1}^n g_{ij}^+ x_j - \gamma \sum_{j=1}^n g_{ij}^- x_j, \quad (10.6)$$

where  $g_{ij}^+$  refers to links between allies,  $g_{ij}^-$  refers to links between enemies,  $\beta, \gamma \in [0, 1]$  are spillovers from allies and enemies, respectively.

It is worth noting some special cases of this formulation: when there are no friends or enemies the model yields a standard contest between  $n$  opponents. Observe that the notion of allies is subtle: consider an example with two allies. They contest for a prize, but their efforts are boosted by the efforts of the ally. On the other hand, when the two opponents are enemies their efforts are damped by the efforts of the enemy.

Given a network  $g$  and effort profile  $x = (x_1, \dots, x_n)$ , the payoff to player  $i$  is determined by a Tullock contest function:

$$\Pi_i(g, \mathbf{x}) = V \times \frac{\varphi_i(g, \mathbf{x})}{\sum_{j=1}^n \varphi_j(g, \mathbf{x})} - x_i. \quad (10.7)$$

Throughout our interest will be in interior solutions, outcomes in which all players are active, and we will assume that such outcomes exist and are unique. As is standard in games on networks, equilibrium efforts are interior and unique when spillovers across group effects are suitably small (for a general discussion of the issues see the chapter on structure and strategy)

In such an active outcome, every player will set its efforts at a level where the marginal costs are equal to the marginal returns. Differentiating individual payoffs with respect to efforts we arrive at the following first order condition for the optimal individual efforts:

$$\frac{\partial \pi_i}{\partial x_i} = V \frac{\sum_{j=1}^n \varphi_j - \varphi_i(1 + \beta d_i^+ - \gamma d_i^-)}{\left(\sum_{j=1}^n \varphi_j\right)^2} - 1 = 0, \quad (10.8)$$

where we have dropped the dependence of  $\varphi$  on the network and the efforts, set  $d_i^+$  to be the number of allies and  $d_i^-$  to be the number of enemies of player  $i$ . Observe that a player's efforts augment the efforts of its friends (enemies) and therefore makes them more (less) competitive in the contest.

We would like to express the equilibrium effort of a player explicitly in terms of the network. In order to do so, it is helpful to proceed via a derivation of equilibrium effective

effort. The first step is to rewrite the first order condition to obtain the following expression for effective effort:

$$\varphi_i = \frac{1}{1 + \beta d_i^+ - \gamma d_i^-} \left( 1 - \sum_{j=1}^n \varphi_j \right) \sum_{j=1}^n \varphi_j. \quad (10.9)$$

Summing over all players yields:

$$\sum_{i=1}^n \varphi_i = \left( 1 - \frac{1}{\sum_{i=1}^n \frac{1}{1 + \beta d_i^+ - \gamma d_i^-}} \right). \quad (10.10)$$

The following pieces of new notation help us in simplifying the expressions:

$$\Gamma_i^{\beta,\gamma}(g) = \frac{1}{1 + \beta d_i^+ - \gamma d_i^-}, \text{ and } \Lambda^{\beta,\gamma}(g) = 1 - \frac{1}{\sum_{i=1}^n \Gamma_i^{\beta,\gamma}(g)}. \quad (10.11)$$

We may refer to  $\Gamma_i$  as the local hostility level as it is increasing in the number of enemies of  $i$  and decreasing in the number of allies of  $i$ . Using the new notation, equilibrium aggregate effective effort is given by

$$\sum_{i=1}^n \varphi_i = \Lambda^{\beta,\gamma}(g), \quad (10.12)$$

This in turns allows us to write the individual effective effort as

$$\varphi_i(g, \mathbf{x}) = \Lambda^{\beta,\gamma}(g)(1 - \Lambda^{\beta,\gamma}(g))\Gamma_i^{\beta,\gamma}(g). \quad (10.13)$$

Define  $\Gamma^{\beta,\gamma}(g) \equiv (\Gamma_1^{\beta,\gamma}(g), \dots, \Gamma_n^{\beta,\gamma}(g))^\top$ . Equilibrium effort may be expressed in matrix form as follows:

$$(\mathbf{I}_n + \beta \mathbf{G}^+ - \gamma \mathbf{G}^-) \mathbf{x} = \Lambda^{\beta,\gamma}(g)(1 - \Lambda^{\beta,\gamma}(g))\Gamma^{\beta,\gamma}(g). \quad (10.14)$$

When the matrix  $\mathbf{I}_n + \beta \mathbf{G}^+ - \gamma \mathbf{G}^-$  is invertible,

$$\mathbf{x} = (\mathbf{I}_n + \beta \mathbf{G}^+ - \gamma \mathbf{G}^-)^{-1} \left( V \Lambda^{\beta,\gamma}(g)(1 - \Lambda^{\beta,\gamma}(g))\Gamma^{\beta,\gamma}(g) \right). \quad (10.15)$$

Before delving into the formal derivations it is useful to briefly reflect on the strategic effects in this environment. First consider the direct effects of a player's enemies. As an enemy raises her efforts it follows from equation (10.6) that an individual's effective efforts go down. This raises the marginal returns from own efforts. Thus the efforts of enemies

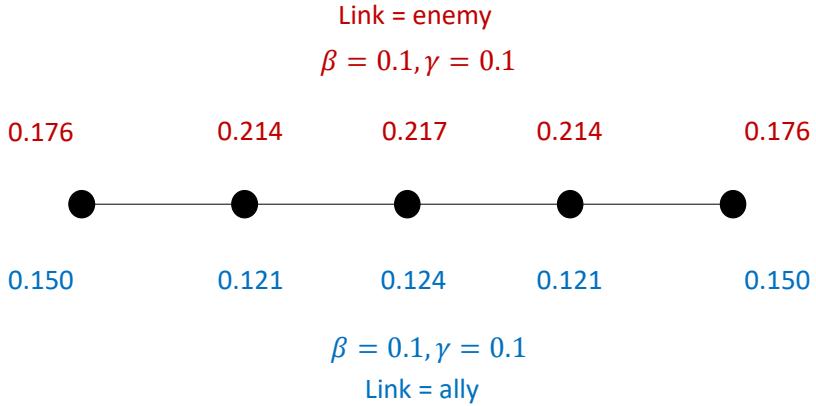

Figure 10.1: Line Network: Enemies only in Red. Allies only in Blue.

are strategic complements. Similarly, we can reason that efforts of friends are strategic substitutes. Turning to indirect effects, consider the enemies of my enemies. As they raise effort, an individual's enemies raise efforts and that induces the individual in question to raise efforts. On the other hand, as the friends of an individual's friend raise efforts, the friends lower efforts and that induces the individual in question to raise efforts. This brief discussion helps us see the complex interplay of positive and negative strategic effects through the paths of the network.

The principal result of the analysis provides a relation between the network centrality of a player and its war effort. To develop a sense for how allies and enemies shape network centrality and efforts, we present the example of a line network in Figure 10.1. In this network, there are five nodes, and we set  $\gamma = 0.1, \beta = 0.1$ . In the case where all links represent enemies, the centrality measure related to the network of hostilities, measures the local hostility levels along all walks reaching  $i$  using only hostility connections, where walks of length  $k$  are weighted by the geometrically decaying hostility externality  $\gamma^k$ . As the discounted number of walks emanating from a node in a line network is higher the more central an agent is, the player in the middle of the line has the highest centrality, and centralities decrease moving away from the middle of the path. Next consider the situation where the links reflect friendships. The centrality is determined by  $b_{\cdot,i}(-\beta, G^+)$ . Thus a player's neighbour gets negative weight, and his neighbour's neighbour gets positive weight. This means that centrality is falling as we move from the edge of the line to the next player and then rising again as we arrive at the centre of the line. Let us now develop the relation between networks and fighting effort for networks that combine both friendship and enmity links.

Define  $c_i^{\beta,\gamma}(G)$  as player  $i$ 's centrality in the network  $G$ . The vector of centrality:

$$\mathbf{c}^{\beta,\gamma}(G) \equiv \left( \mathbf{I}_n + \beta \mathbf{G}^+ - \gamma \mathbf{G}^- \right)^{-1} \boldsymbol{\Gamma}^{\beta,\gamma}(G). \quad (10.16)$$

Equipped with this definition of centrality, equilibrium effort levels can be expressed as

$$x_i(G) = \Lambda^{\beta,\gamma}(G) \left( 1 - \Lambda^{\beta,\gamma}(G) \right) c_i^{\beta,\gamma}(G). \quad (10.17)$$

Equilibrium payoffs are given by

$$\pi_i(G) = (1 - \Lambda^{\beta,\gamma}(G)) \left( \Gamma_i^{\beta,\gamma}(G) - \Lambda^{\beta,\gamma}(G) c_i^{\beta,\gamma}(G) \right). \quad (10.18)$$

For sufficiently small cross player effects, i.e., when  $\beta$  and  $\gamma$  are close to 0, the centrality measure defined in (10.16) may be expressed as a sum of centrality in the friends network, centrality in the enemies network and a term that captures higher order cross relation effects, i.e.,

$$\mathbf{c}^{\beta,\gamma}(G) = \mathbf{b}(\gamma, g^-) + \mathbf{b}(-\beta, g^+) - \boldsymbol{\Gamma}^{\beta,\gamma}(g) + O(\beta\gamma), \quad (10.19)$$

where

$$\mathbf{b}(\gamma, g) = (\mathbf{I}_n - \alpha \mathbf{g})^{-1} \boldsymbol{\Gamma}^{\beta,\gamma}(g) \quad (10.20)$$

is the Katz-Bonacich centrality (similarly for  $\mathbf{b}(-\beta, g^+)$ ), while  $O(\beta\gamma)$  involves second and higher order terms.

One interesting implication of these derivations is that the ratio of efforts of two players is equal to the ratio of their centralities.

$$\frac{x_i(G)}{x_j(G)} = \frac{c_i^{\beta,\gamma}(G)}{c_j^{\beta,\gamma}(G)}. \quad (10.21)$$

When higher order terms are ignored, the centrality measure is increasing in  $\gamma$  and in the number of first-degree enemies, whereas it is decreasing in  $\beta$  and in the number of first-degree alliances. We use this simple prediction of the theory in our study of the Great War of Congo.

#### CASE STUDY: THE GREAT WAR OF CONGO

The Democratic Republic of Congo (in what follows, Congo) has a population of 68 million and is the largest Sub-Saharan African country. This population belongs to over

200 ethnic groups. Congo gained independence from Belgium in 1960 but has experienced instability and wars for extended periods. As a consequence of this political instability it is one of the poorest countries in the world, in spite of having some of the large deposits of a number of valuable minerals (such as copper, gold, diamonds, cobalt, uranium, coltan and oil). Income level in 2020 was at 40% of the 1960 level; the per capita income was 400 USD, this was less than 1% of US. Quality of life is very low: life expectancy is 20 years less than US. A major reason for this dire situation is violent conflict. The conflict in Congo involves many interconnected domestic and foreign actors. Our discussion of the War of Congo draws heavily on König, Rohner, Thoenig, and Zilibotti [2017] and the Encyclopedia Britannica.

The first point to note is that the war in Congo is closely connected with ethnic conflicts in neighboring countries such as Rwanda and Uganda. In 1994, Hutu radicals took control of the Rwandan government and allowed ethnic militias to carry out the killing of nearly a million Tutsis and moderate Hutus. After they lost power in Rwanda, over a million Hutus fled Rwanda and sought refuge in the Congo (that was then ruled by Mobutu Sese Seko). These Hutu militias ran into conflict with local Tutsi groups. As ethnic tensions mounted, a large coalition of African countries, that included Uganda and Rwanda, supported an anti-Mobutu rebellion that was led by Laurent-Desire Kabila. The First Congo War (1996–1997) ended with Kabila's victory.

However, Kabila's relationship with Uganda and Rwanda soon turned sour and he ordered all Rwandan and Ugandan troops to leave the country. As a result, new ethnic clashes erupted in Eastern Congo and the crisis escalated into a larger war. This led to the Second Congo War.

The Second Congo War lasted from 1998 until 2003 is regarded as the deadliest war of the 21st century. The eastern part of the Congo became a bloody battlefield that was as bitterly contested as the Western Front in World War I. The armies of nine countries and a number of militias were involved. Angola, Namibia, Chad, Sudan, and Zimbabwe backed Kabila's Congolese government forces, while troops from Burundi, Rwanda, and Uganda supported anti-Kabila rebels. Mass rapes were reported in areas of conflict, and large sections of the Congo were stripped of resources as organized combat between professional armies gave way to brigandage and plunder. It is estimated that over three million people (most of whom were civilians) were killed in the fighting or died of disease or malnutrition. A peace agreement was signed in 2002 and the war officially ended in 2003, but fighting has continued in different parts of Congo even after that.

After a major reshuffling at the end of the First Congo War, the web of alliances and enmities between the main armies and rebel groups has remained largely stable in the period

1998–2010. There are 80 groups in all; for a complete list of the groups see König, Rohner, Thoenig, and Zilibotti [2017]. There were 4 Congolese state army groups, 47 domestic Congolese non-state militias, 11 foreign government armies, and 18 foreign nonstate militias.

We will think of a group as a player and represent it as a node in the network. The average degree of a node is 5.35 (here degree refers to both friends and enemies; this is therefore a sparse network), the average distance in the network is 2.35 (groups are close to each other), and the network is unequal as the most connected groups have a very large number of links. Table 10.1 presents an overview of the eight most connected groups: Congolese Army under J Kabil (FARD-JK), Congolese Army under Laurent Kabil (FARD-LK), Uganda, Rally for Congolese Democracy, Goma (RCD-G), Rally for Congolese Democracy, Kisangani (RCD-K), Military Forces of Rwanda 1994–1999 (RWA94), Military Forces of Rwanda 2000– (RWA00), Rally for Congolese Democracy (RCD). Figure 10.2 summarizes the relations between the 80 different groups that were active over the period of the Second Congo War: friends in blue, enemies in red, and neutral represented by absent ties.

Name	Allies	Enemies	Total Links	Fights
FARD-JK	16	26	42	88
FARD-LK	21	16	37	49
UGANDA	9	13	22	21
RCD-G	4	14	18	41
RCD-K	5	13	18	28
RWA94	7	10	17	8
RWA00	4	11	15	17
RCD	11	4	15	8

Table 10.1: Main Groups: Allies, Enemies and Fights. Data from [www.acleddata.com](http://www.acleddata.com)

Table 10.1 brings out the great inequality in number of links and it helps us see the effects of number of allies and enemies on fighting effort. We see that even among groups with the same number of links, the relative number of allies and friends matters – more enemies leads to higher levels of fighting. Let us now describe the network of friends and enemies.

Our initial idea would be that there are distinct groups of allies who are all friends among themselves and that have enmity relations with members of other groups. The actual pattern of relations in Congo is richer and more complicated. To see this we proceeded as follows. We first plotted the friendship ties only: this gives us to Figure 10.2. Then we removed all nodes that have no friends and added the enmity links among the remaining groups. This yields us the network given in Figure 10.3. We see that there is a dense web of friendship ties within two large clusters but we also see that there are enmity ties within

these clusters and some friendship ties across the clusters. These figures suggest why it might be helpful to go beyond a cluster level analysis and to consider the details of the pairwise links.

The data source for the fighting effort is ACLED ([www.acleddata.com](http://www.acleddata.com)). This data set contains 4676 geolocalized violent events in the Congo involving 80 groups. The theory predicts that friends depress and enemies raise fighting effort of a group. Figure 10.4 plots this relationship in the Great Congo War. On the x-axis we plot the (log of) sum of numbers of friends (positive) and enemies (negative), and on the y-axis we present the number of fights. The patterns of fighting are broadly consistent with the predictions of the theory.

The network approach to the study of the war can help us uncover the potential effects of different changes in the environment. For instance, we can ask how would withdrawal of foreign players like Uganda and Rwanda effect the fighting? This question can be addressed by comparing the fighting level observed with the fighting level in a network in which these two groups – Uganda and Rwanda – are taken out of the network. Given their centrality in the alliance network, their withdrawal could sharply reduce the level of fighting. By contrast, removal of peripheral players like Zaire or Zambia would have relatively minor effect on the level of conflict.

Similarly, we can examine the implications of arms embargo on certain groups. Such an embargo would raise the costs of fighting for these groups. An increase in the costs of fighting for a group will lower the fighting by that group and this will lower the fighting of its enemies and raise the fighting of its allies. These effects will percolate through the network of alliances. Imposing an embargo on a central group can therefore significantly lower overall fighting.

Let us summarize what we have learnt about large scale wars from this model. Interconnections involving alliances is a common feature of large scale wars. The model helps us appreciate how the network of relations shapes the fighting efforts of opponents and the aggregate level of fighting. A key prediction of the model is that individual fighting effort is increasing in the number of enemies and falling in the number of friends. This prediction is consistent with the empirical evidence from the Great War of Congo.

## 10.4 Alliances, Trade, and War

An important point to note about wars is that the frequency of wars between countries has declined significantly over the past 200 years. In particular, wars were more common from 1800 until the Second World war than in the period since then. One way of developing a better feel for the great change in frequency of wars is to consider the number of wars in

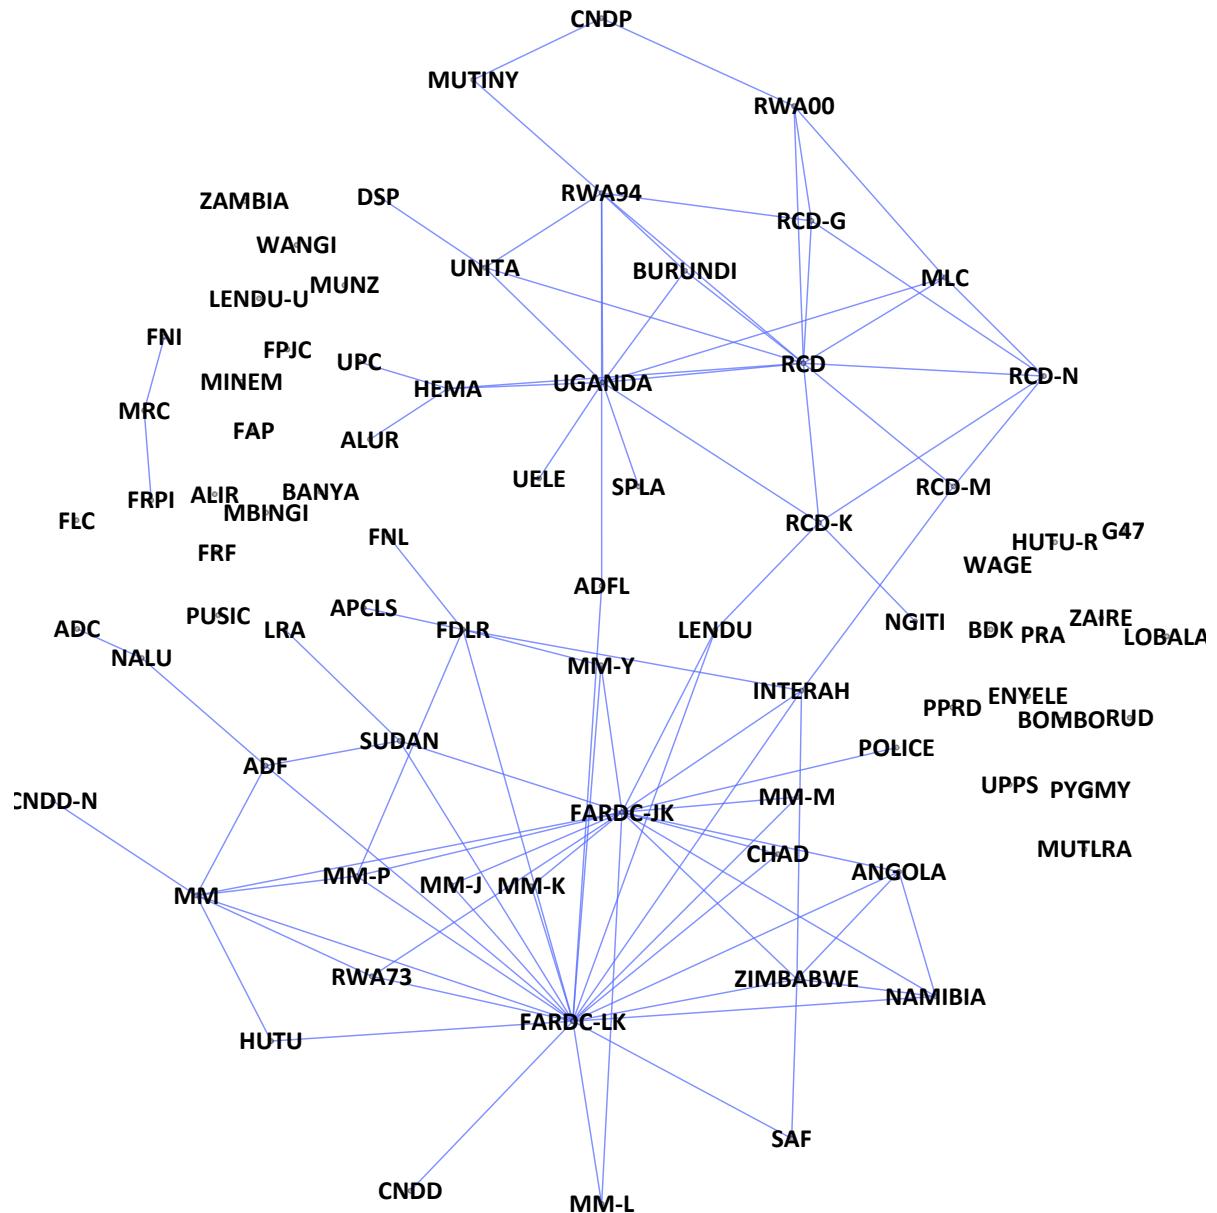

Figure 10.2: The Great War in Congo: Friends. Data from [www.acleddata.com](http://www.acleddata.com)

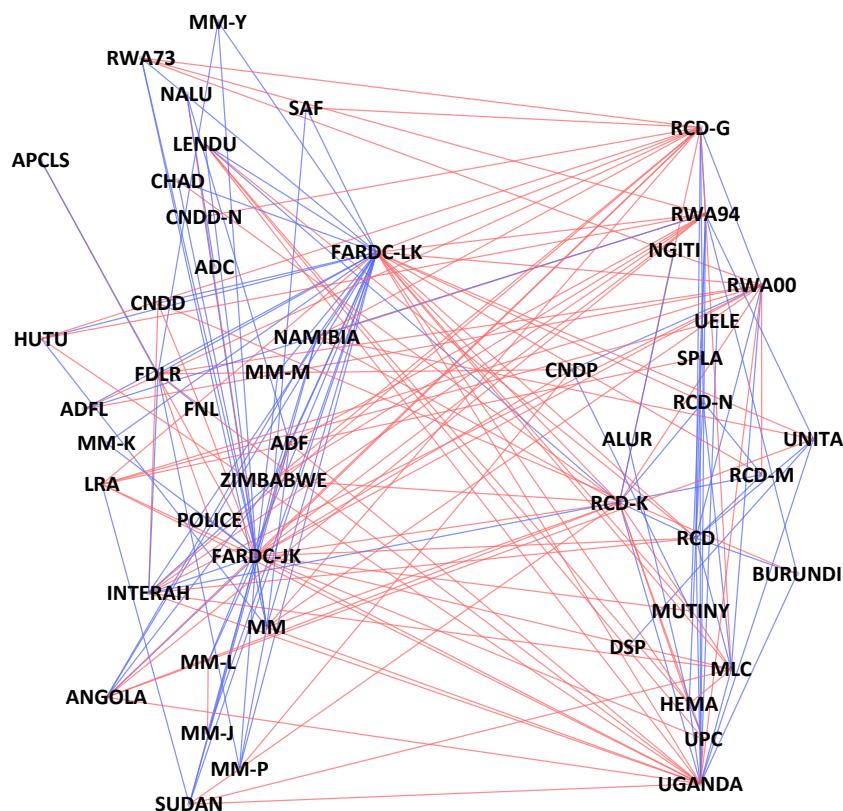

Figure 10.3: The Great War in Congo: Friendship in Blue, Enmity in Red. Data from [www.acleddata.com](http://www.acleddata.com)

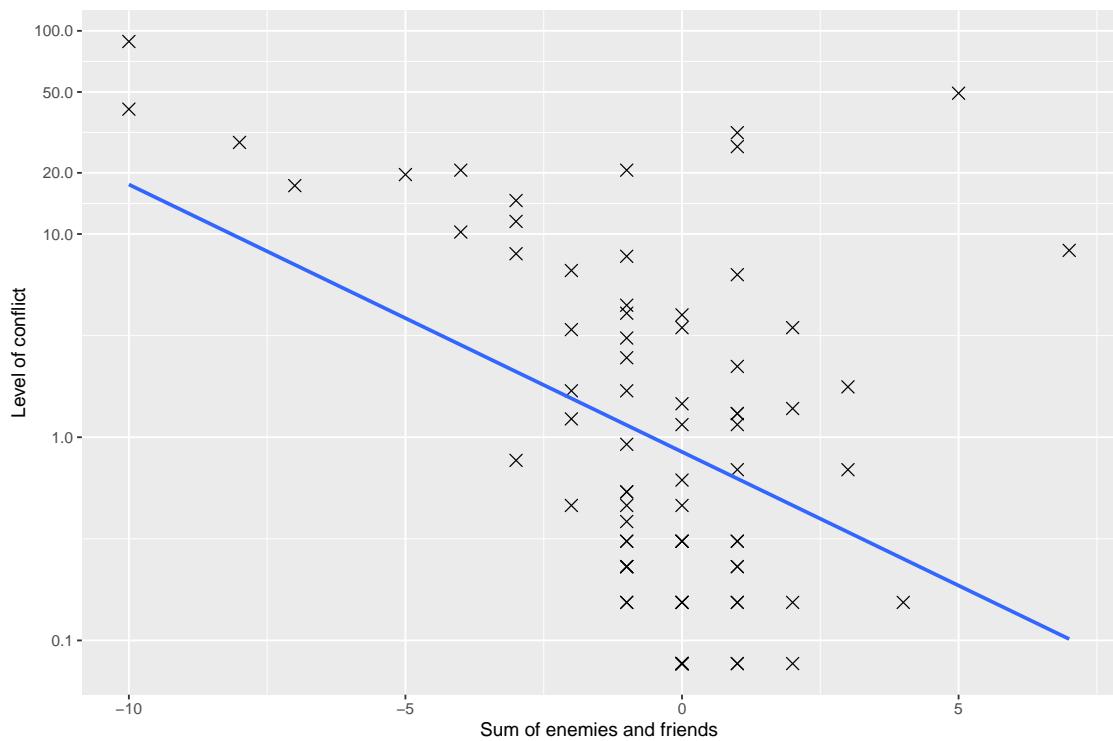

Figure 10.4: Friends and Enemies and Level of Fighting. Data from [www.acleddata.com](http://www.acleddata.com)

a year in relation to number of distinct pairs of countries in that year. Between 1820 and 1959, we find that there were .00056 wars per year per pair of countries. By contrast, from 1960 to 2000 the average was only .00005 wars per year. Thus wars were a tenth as likely in the period after as compared to before 1960. Figure 10.8 provides an overview of this trend. This section examines the factors that can account for this change in frequency of war. Let us begin by noting that two other variables have registered significant changes over the same period – the density and stability of alliances and the size of international trade. This section presents a theoretical model taken from Jackson and Nei [2015] that helps us understand the co-movements in the frequency of war, the changes in trade, and the nature of alliances.

Our data is taken from Directed Dyadic Interstate War Data Set (Maoz, Johnson, Kaplan, Ogunkoya, and Shreve [2019]). The nature of military alliances changed dramatically over this period. Between 1816 and 1950 a country had 2.5 alliances on average (if we exclude the decade of 1940s, this number drops even further to 1.7). By contrast, between 1951 and 2003 the number of alliances per country grows by a factor of more than four and was over 10.5. Thus, there were significantly more alliances in the post Second War war than before it. This change in the number of alliances was accompanied by a great change in their persistence or stability. To see this we ask what fraction of alliances at year  $t$  are also

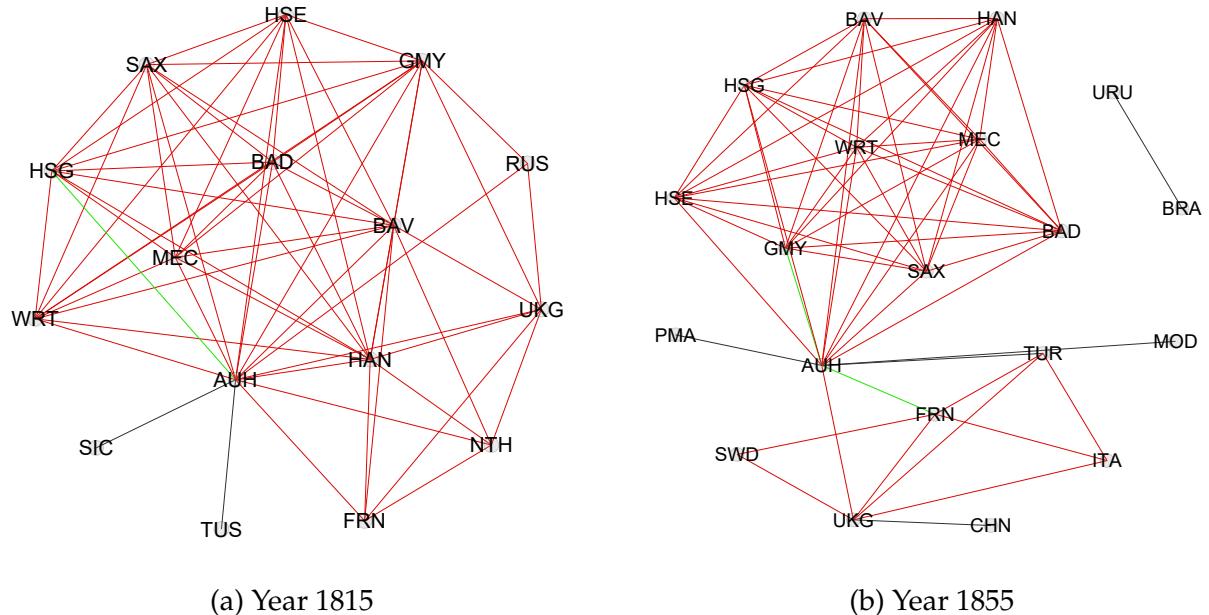

Figure 10.5: Alliances: multilateral in red, bilateral in grey, both in green. Data from Maoz, Johnson, Kaplan, Ogunkoya, and Shreve [2019]. Set.

present at year  $t + 5$ . For the period from 1816 to 1950, we find this number of to be 0.695. By contrast, the number of the period from 1950 to 2003 is 0.949! in other words, there is a 30% chance that a given alliance disappears in the next five years in the period prior to the second World War, while there is only a 5% chance that this happens in the period after the Second World War.

Figures 10.5-10.7 present alliance networks from the nineteenth and twentieth century to illustrate these trends. In the early 19<sup>th</sup> century the networks were sparse and rapidly evolving. This is brought out by the Figures 10.5. The labels for the different entities in Figures 10.5 are as follows: AUH-Austria-Hungary; BAD-Baden; BAV-Bavaria; BRA-Brazil; CHN-China; FRN-France; GMY-Germany; HAN-Hanover; HSE-Hesse Electoral; HSG-Hesse Grand Ducal; ITA-Italy; MEC-Mecklenburg-Schwerin; MOD-Modena; NTH-Netherlands; PMA-Parma; RUS-Russia; SAX-Saxony; SIC-Two Sicilies; SWD-Sweden; TUR-Turkey; TUS - Tuscany; UKG-United Kingdom; URU-Uruguay; WRT-Wuerttemburg. We also see that the alliance network is sparse and is evolving.

Figures 10.6 and 10.7 illustrate the situation post World War II. This period witnessed increasingly dense networks with largely stable alliances that are separated by continent and ideology: the networks contain densely connected subsets of states, that are bridged

by a few larger countries.

Turning to international trade, we note that there were two major periods of growth, one, in the latter half of the 19<sup>th</sup> century and the beginning of the 20<sup>th</sup> century that was disrupted by the First World War. Trade suffered greatly between the two world wars. It picked up again after the Second World War, recovering to its 1914 levels in the 1960s. It has continued to grow at an increasing rate thereafter. Table 10.2 provides an overview of this trend.

We see that trade has increased dramatically after World War II, growing by almost a factor of four.

Year	1850	1880	1913	1950	1973	1985	1993	2012
Percent	5.1	9.8	11.9	7.1	11.7	14.5	17.1	25.3

Table 10.2: World merchandise exports as percentage of GDP. Source Jackson and Nei [2015], Krugman [1995]

There are  $N = \{1, \dots, n\}$ ,  $n \geq 3$ , countries. Individual countries can attack each other, form alliances, and trade with each other. A link between two countries signifies an alliance. The collection of alliances is denoted by a network  $g$ . Let  $g - i$  denote the network obtained by deleting all alliances that involve country  $i$ . Each country  $i \in N$  is endowed with a military strength  $M_i \in \mathbb{R}_+$ . For any subset of countries  $C \subseteq N$ , let  $M(C) = \sum_{i \in C} M_i$  be their collective military strength. If there is a war between  $C_1$  and  $C_2$ , with  $C_1$  being the aggressor, then  $C_1$  wins if  $M(C_1) > \rho M(C_2)$ . The parameter  $\rho > 1$  reflects a relative advantage of being the defender and  $\rho < 1$  reflects a relative advantage of being the aggressor.

The notion of ‘vulnerability’ plays a key role in the analysis. A country  $i$  is vulnerable at a network  $g$  if there exists a country  $j$  and a coalition  $C \subseteq N_j(g) \cup \{j\}$  such that  $j \in C$ ,  $i \notin C$  and

$$M(C) > \rho M(i \cup (N_i(g) \cap C^c)) \quad (10.22)$$

where  $C^c$  is the complement of  $C$ . In this instance, country  $j$  is said to be a potential aggressor. This is saying that there is a coalition of  $j$  and some of their neighbors such that the combined might of the coalition is greater than the defensive might of  $i$  and its neighbors (that are not in the coalition). This definition thus brings out the role of alliance ties: an

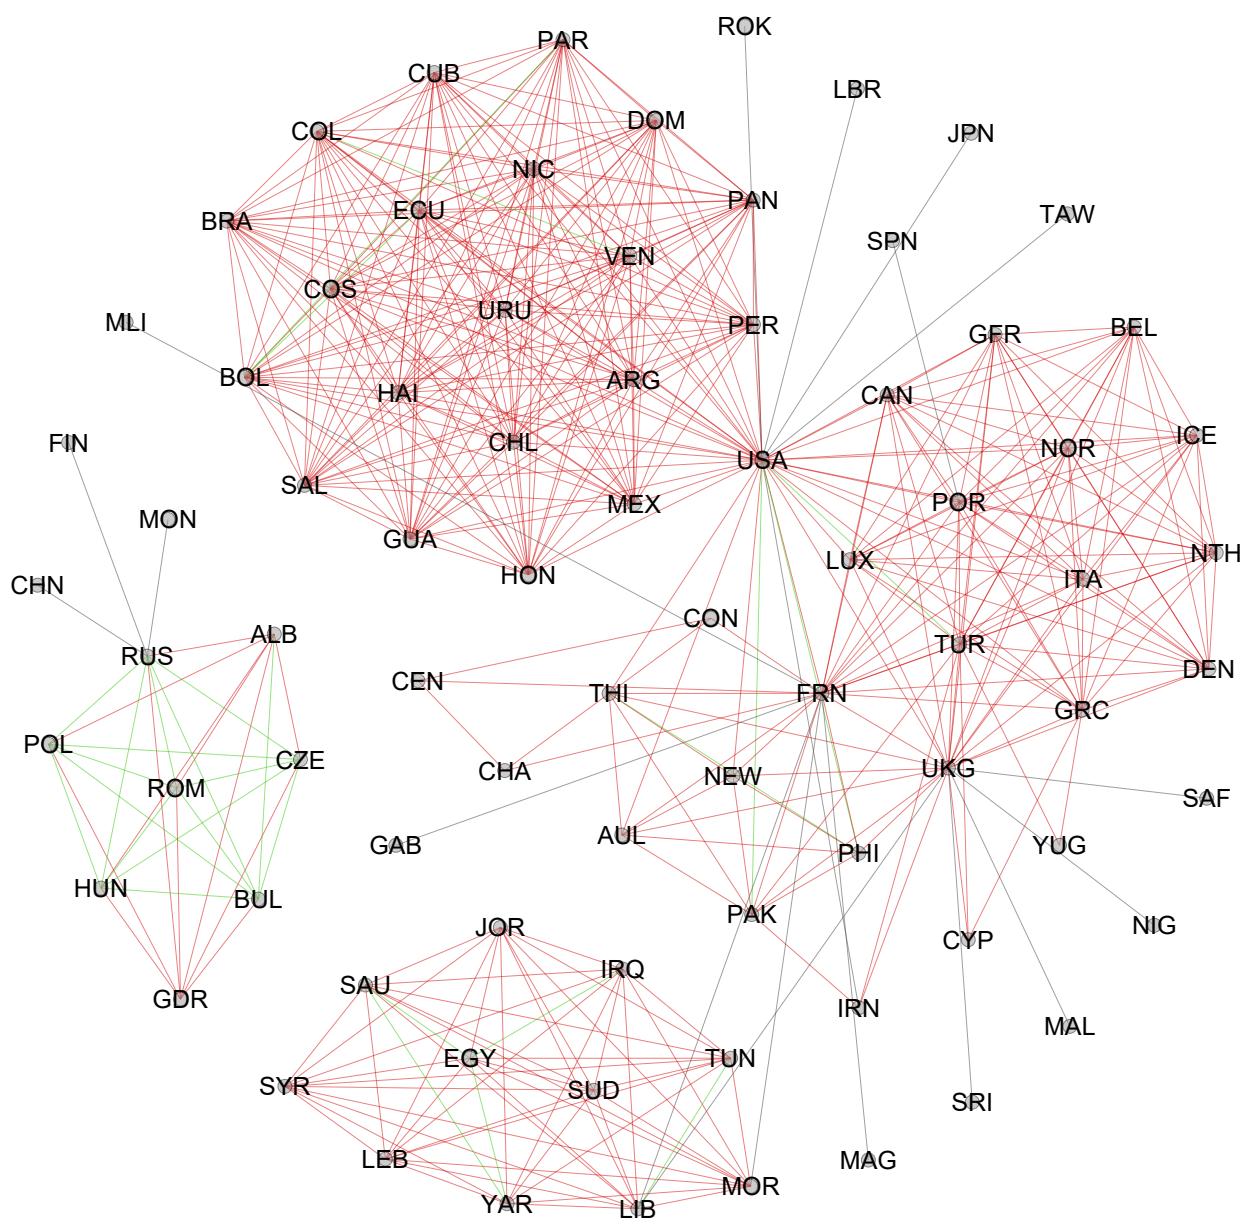

Figure 10.6: Alliances: 1960 (multilateral in red, bilateral in grey, both in green). Data from Maoz, Johnson, Kaplan, Ogunkoya, and Shreve [2019].

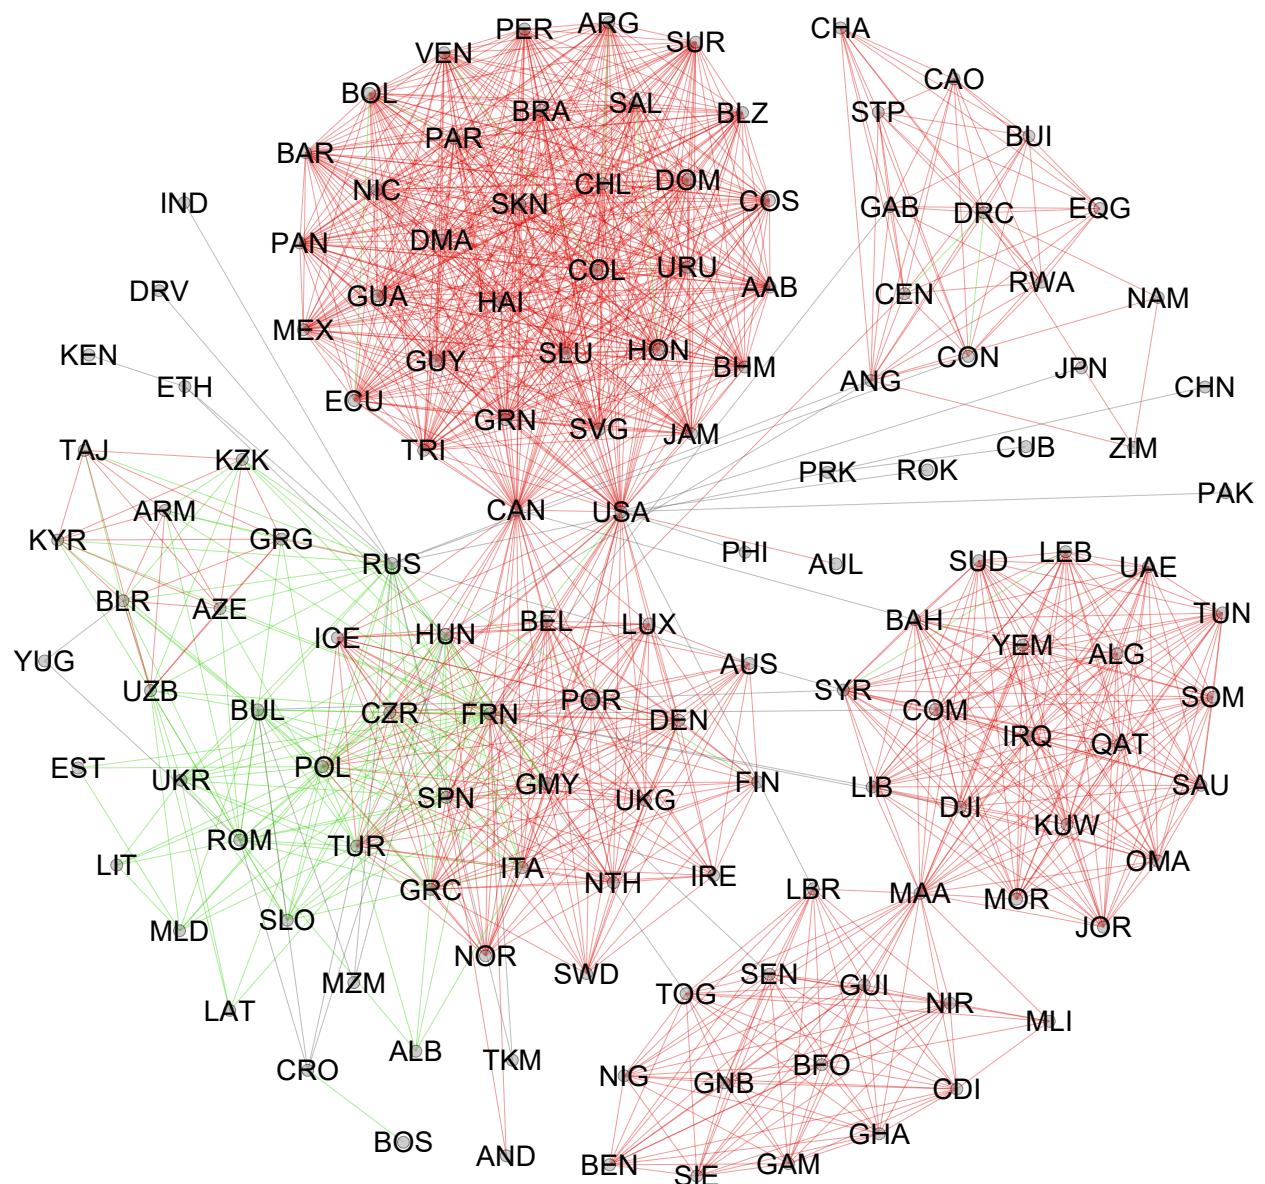

Figure 10.7: Alliances: 2000 (multilateral in red, bilateral in grey, both in green). Data from Maoz, Johnson, Kaplan, Ogunkoya, and Shreve [2019].

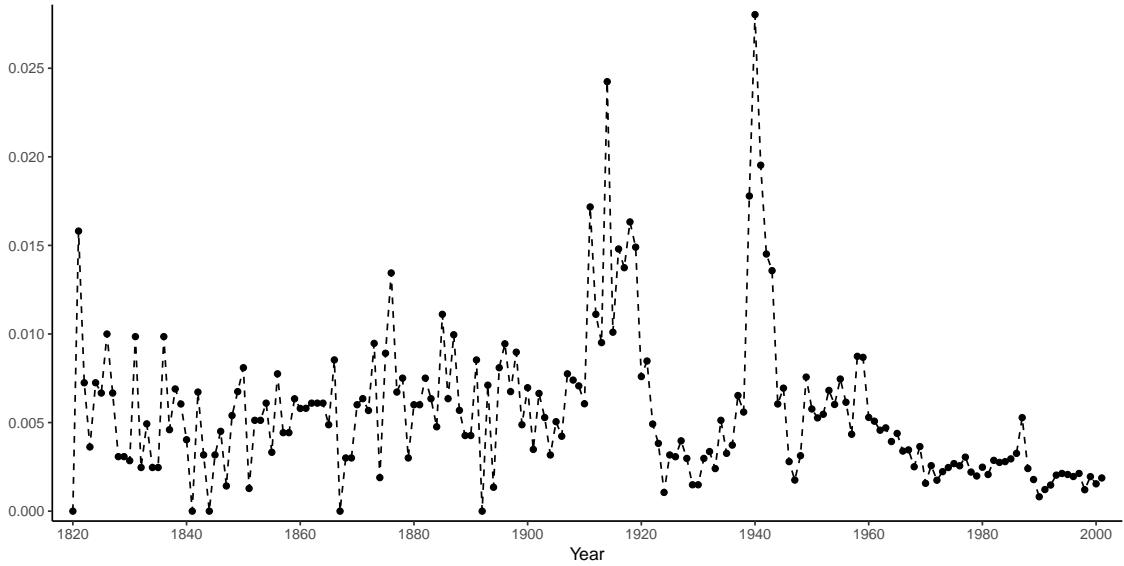

Figure 10.8: Probability of War between Country Pairs: 1820-2000. Source Jackson and Nei [2015]

alliance creates the potential for asking for support when faced with a threat (however as ties are not exclusive, it is possible that an ally may also switch sides and become part of a rival grouping). This definition of feasible attacking and defending coalitions may be interpreted as another assumption about the technology of war (in the same spirit as the contest success function); for instance, there could be asymmetries in what sort of subnetwork a coalition has to be to attack or defend (e.g., attackers might need to be a clique).

This idea is illustrated in Figure 10.9. Country 2 and its allies (3 and 4) attack country 1 (which is defended by 5). Country 1 is vulnerable if  $M(\{2, 3, 4\}) > \rho M(\{1, 5\})$ . Without getting into further details, we may assume that winning is desirable and that losing a war is undesirable.

We are interested in understanding alliance networks that are stable in the sense that no country is vulnerable, and that no one wishes to delete an alliance and no pair of countries wishes to add an alliance link.. Suppose that there is a cost  $c_{ij} > 0$  to keeping a link between pair of countries  $i, j$ . These costs will be taken to be small relative to the spoils from a successful war.

With this notation in place, a network  $g$  is war-stable if

1. no country is vulnerable at  $g$  (else that country will be invaded and conquered).
2.  $\forall g_{jk} \notin g$  no country is vulnerable at  $g + g_{jk}$  (this discourages new links),
3.  $\forall g_{jk} \in g$ , both  $j$  and  $k$  are vulnerable at  $g - g_{jk}$  (this discourages the deletion of exist-

Figure 10.9: Left- Vulnerable country. Right- Ring Network

ing links).

The notion of war-stability (and the other stability definition war-and-trade stable below) has the same essential structure as the "usual" pairwise stability notion we introduced in chapter 3. In all cases the considerations are very similar: links have to benefit both parties and that all beneficial links are added. The definitions on stability in this section place these considerations in the context of war and peace and alliances.

Taken one at a time the requirements for stability are reasonable, but they are difficult to satisfy jointly. To see this tension between the three requirements let us consider the complete network. For this network to be war-stable no country must be vulnerable. But this means that for every country  $\rho M(i) \geq M(N \setminus \{i\})$ . This however implies that country  $i$  is not vulnerable in the network  $g - g_{ik}$  for any  $j \neq i$  thereby showing that the complete network is no war-stable. Consider next a regular network as depicted in Figure 10.9. There are five countries in this network. Let us first ensure that no country wishes to form a link. Consider a link  $g_{53}$ . In order for country 1 not to be vulnerable to the addition of this link, it must be that  $\rho M(1) \geq M(\{2, 3, 4, 5\})$  (as it must not be vulnerable to 3 and its allies 2, 4, and 5). But note that this implies that 1 is not vulnerable in the original ring even if it deletes a link (with respect to any coalition of rivals). This contradicts war-stability of the ring network.

On the other hand, the empty network is war-stable if no country is vulnerable and if no two countries can gang up to successfully attack a third country. Suppose that resources of countries are ordered as follows:  $M_1 \geq M_2 \geq \dots \geq M_n$ . Then a sufficient condition for the empty network to be war-stable is that  $\rho M(\{n\}) \geq M(\{1, 2\})$ .

These considerations are general and form the basis for the following result.

**Proposition 10.2.** *If  $n \geq 3$  then there are no non-empty war-stable networks.*

In words, there exists no network with alliances that is war-stable. The argument shows us that there is a very fine line between profitable alliances and vulnerability: if an alliance

between  $i$  and  $x$  is necessary for sustaining  $i$  then  $x$  could form an alliance with another country  $z$  that would render  $i$  vulnerable. This suggests that there may be rapidly shifting alliances as countries try and take advantage and navigate this delicate balance. This is reminiscent of the empirical patterns from the nineteenth century that we mentioned above: during the nineteenth century and the first half of the twentieth century, roughly one-third of the alliances present at any time were dissolved within a 5 year period. The dynamics of shifting alliances went hand in hand with the frequency of wars in this period.

Here is a sketch of the proof for this result. Consider a non-empty war stable network  $g$ . There must be a country  $i$  that has an alliance with country  $k$ . In order for this link to be incentive compatible – there must be no incentive to delete a link –  $i$  must be vulnerable in  $g - g_{ik}$ . Thus, there is some  $j$  and  $C \subset N_j(g - g_{ik}) \cup \{j\}$  with  $i \notin C$  and  $M(C) \geq \rho M(C')$ , for every  $C' \subset \{i\} \cup N_i(g - g_{ik}) \cap C^c$ , where  $C^c$  is the complement of set  $C$ .

As  $g$  is war-stable,  $i$  is not vulnerable at  $g$ : it must be that  $k \notin C$  and in particular that  $g_{jk} \notin g$ . However, if the link  $g_{jk}$  is added to create network  $g + g_{jk}$ , then  $C \cup \{k\}$  can defeat  $i$ , because  $M(C \cup \{k\}) \geq M(C)$  and therefore  $M(C \cup \{k\}) \geq \rho M(C')$ , for any feasible  $C'$  that can defend  $i$ , i.e.,

$$M(C \cup \{k\}) \geq M(C) > \rho M(C'), \quad (10.23)$$

for any feasible  $C'$  that can defend  $i$  in  $g + g_{jk}$ . This means that  $j$  and  $k$  can form a link that makes  $i$  vulnerable, contradicting the hypothesis that  $g$  is war-stable. As  $g$  was an arbitrary non-empty network, this also completes the proof.  $\blacksquare$

Turning to the period after World War II, a major change was the introduction of nuclear weapons. It has been widely argued that this profoundly altered the incentives to wage large scale wars. One way to interpret this within the model is to say that with widespread availability of nuclear weapons countries were no longer vulnerable to attacks. The only war-stable network is the empty network. However, the empirical evidence we presented above shows that alliances became more popular and their stability increased greatly. Moreover, this trend was accompanied with an increase in international trade. To reconcile these trends, we introduce international trade into the theoretical model.

Suppose that a country earns a payoff  $u_i(g)$  from network  $g$ . The utility reflects gains from trade. Let us adapt the notion of vulnerability as follows. Denote by  $E_{ik}(g, C)$  the net gains to country  $k$  if country  $i$  is conquered by coalition  $C$  (of which  $k$  is a member). Given a network  $g$ , a country  $i$  is said to be *vulnerable despite trade* if there exists a country  $j$  and a coalition  $C \subseteq N_j(g) \cup \{j\}$  such that  $j \in C$ ,  $i \notin C$  and

1.  $M(C) > \rho M(i \cup (N_i(g) \cap C^c))$ , and

- 
2.  $u_k(g - i) + E_{ik}(g, C) \geq u_k(g)$ , with a strict inequality for some  $k$ .

The utility  $u_k(g - i)$  brings out the potential implications of an elimination of  $i$ , as this may enhance or lower the payoffs of country  $k$ . We will say that a link  $g_{jk}$  is war-beneficial if it lets  $j$  and  $k$  attack a third country  $i$  and the net gains to conquering  $i$  outweigh any losses to adding the link for both  $j$  and  $k$  (i.e., the definition of vulnerable despite trade from above, but with the left-hand side being  $u_k(g + g_{jk} - i) + E_{ik}(g, C)$  and the inequality strict for at least one of  $j$  or  $k$ ). Let us define network  $g$  to be *war-and-trade stable* if

1. no country is vulnerable despite trade at  $g$ ,
2.  $\forall g_{jk} = 0$ , if  $u_j(g + g_{jk}) > u_j(g)$  then  $u_k(g + g_{jk}) < u_k(g)$ , and  $g_{jk}$  is not war-beneficial, and
3.  $\forall g_{jk} = 1$ , either  $u_j(g - g_{jk}) \leq u_j(g)$  or  $j$  is vulnerable despite trade at  $g - g_{jk}$ , and similarly for  $k$ .

In other words, a network of alliances is war and trade stable if no country is vulnerable despite trade, if no two countries can add an alliance that is mutually profitable (through economic or through war), and either economic or conquest considerations prevent every country from severing any of its links.

For simplicity, we will consider a symmetric setting in what follows. Suppose that utility from a network depends only on the degree and on the number of alliances. Thus

$$u_i(g) = f(d_i(g)) - cd_i(g) \quad (10.24)$$

where  $d_i(g)$  is the degree of  $i$ . Let the function  $f$  be concave, nondecreasing, and suppose that there is some  $d \leq n - 1$  such that  $f(d) < cd$ . Finally, let  $d^*$  maximize  $f(d) - cd$ . This is a simple model of gains from trade and costs of having trading relationships that abstracts from heterogeneity in goods and trading partners, and from interdependencies in trading relationships beyond diminishing returns.

The reward from conquest is important in what follows. We will set  $E_{ij}(g; C)$  as the reward to country  $i$  from conquering country  $j$ . We set  $E_{ij}(g; C) = E(d_i(g))/|C|$ , so that rewards from conquest depend on the degree of the conquered country and are divided equally among the members of the winning coalition. Let us refer to the game with these assumptions as the symmetric payoffs game.

**Proposition 10.3.** Consider the symmetric payoffs game with  $d^* \geq 2$ .

- If  $E(d^*) \leq 2[f(d^*) - f(d^* - 1) - c]$ , then a  $d^*$ -regular network is war and trade stable network if

$$\rho \geq \frac{d^* + 1}{d^* - 1}.$$

Recall that a network is pairwise stable if no two countries weakly benefit from adding a link (at least one strictly), and no single country benefits from deleting some link. Note that any network that is  $d^*$  regular is pairwise stable. Suppose that  $g$  is pairwise stable with respect to  $u$ . Then it follows that if no country is vulnerable despite trade at  $g$  or  $g + g_{jk}$ , then  $g$  must be war and trade stable. So to prove the result we need to show this is true under the given assumption on  $E(\cdot)$ , for any  $d^*$  regular network.

First, note that no country  $i$  is vulnerable to any coalition  $C$  that does not include any of its neighbors (even if this comes from the addition of a link not involving any neighbors), because  $\rho \geq (d^* + 1)/(d^* - 1)$ . Thus, we need only verify vulnerability to a coalition that involves at least one neighbor (and possibly involves the addition of a link).

Next observe that a neighbour that has  $d^*$  links will not want to attack  $i$ . This is because any coalition that succeeds must involve at least two countries and if all neighbours have  $d^*$  links then under the condition  $E(d^*)/2 \leq (f(d^*) - f(d^* - 1) - c)$  being part of such a coalition is not profitable. Finally, consider the case where all  $i$ 's neighbours in the attacking coalition have  $d^* + 1$  links. This means that the coalition involves at most two of  $i$ 's neighbors as at most one new link can be formed. However,  $\rho \geq (d^* + 1)/(d^* - 1) \geq (d^* + 2)/(d^*)$  and so the attacking coalition cannot defeat  $i$  and its remaining neighbors, regardless of whether it contains one or two of  $i$ 's neighbors. ■

Observe that the regular networks identified as war and trade stable are not war-stable. Thus we have shown one route through which economic forces – working through gains from trade – support stable networks and thereby place limits on the extent of conflict. The condition shows that with sufficient gains from trade – reflected in the condition  $E(d^*) \leq 2 \leq [f(d^*) - f(d^* - 1) - c]$  – the potential spoils of a war against a trading partner are outweighed by the loss in trade value, and so countries are never attacked by one of their own allies.

Let us summarize what we have learnt about alliances, trade, and war. We considered a model of network formation that yields two interesting insights. The first insight is that in a pure conflict setting individual attempts to form alliances and attack opponents leads to shifting and unstable alliances. This instability is consistent with the constantly shifting structures and recurring wars that occurred throughout the nineteenth and first half of the twentieth centuries. The second insight is that the presence of large gains from trade can sustain stable alliance structures where no country is vulnerable to attack by a coalition of

enemies. This too is consistent with the empirical trends. In the period since 1950, wars have greatly subsided in parallel with the huge increase of trade.

In this model conflict is implicit: countries do not allocate resources and wage war on other countries. Thus the impact of alliances on the incentives to allocate resources for conflict are not explicitly considered. This public good aspect to coalitions is potentially important (and is related to our discussion of alliances in the previous section).

## 10.5 Conquest and Empire

*The history of the world .... is an imperial history, the history of empires. Empires were systems of influence or rule where ethnic, cultural or ecological boundaries were overlapped or ignored. Their ubiquitous presence arose from the fact that .... the endowments needed to build strong states were very unequally distributed. Against the cultural attraction, or physical force, of an imperial state, resistance was hard, unless reinforced by geographical remoteness or unusual cohesion.* Darwin [2007]; page 491

In the study of history, a recurring theme is that the presence of small kingdoms is accompanied by bloody conflict; rulers fight each other incessantly, small parcels of land are exchanged, treasures are plundered, and capture of human beings is common. However, once a ruler acquires a large advantage relative to his neighbours, he then quickly goes on to take them over, one after the other, and to create an empire. Classical studies on the formation of empire include Polybius [2010], Tacitus [2009] and Khaldun [1989]. We begin with the discussion of three major historical empires to lay out broad aspects of the formation of empire.

### FIRST CHINESE EMPIRE

We start with a discussion of one of the turning points in world history: the emergence of the first empire in China in 221 BC. The discussion draws heavily on Lewis [2010] and Overy [2010]. In China, the years between 475 BC and 221 BC were characterized by almost uninterrupted warfare between seven major states which is referred to as the *Warring States Period*. The seven major kingdoms were Qin (located in the far west) the three Jins (located in the center on the Shanxi plateau; Han south along the Yellow River, Wei located in the middle, Zhao the most northernmost of the three), Qi (centred on the Shandong Peninsula), Chu (with its core territory around the valleys of the Han River), and Yan (centered on modern-day Beijing). Initially, wars led to changes in the power of the different

dynasties but all the kingdoms survived. However, from 320 BC to 221 BC, there was a major consolidation and, by 221 BC, the Qin defeated all the other kingdoms and unified the entire area under one ruler, Qin Shi Huang. Figure 10.10 illustrates these dynamics.

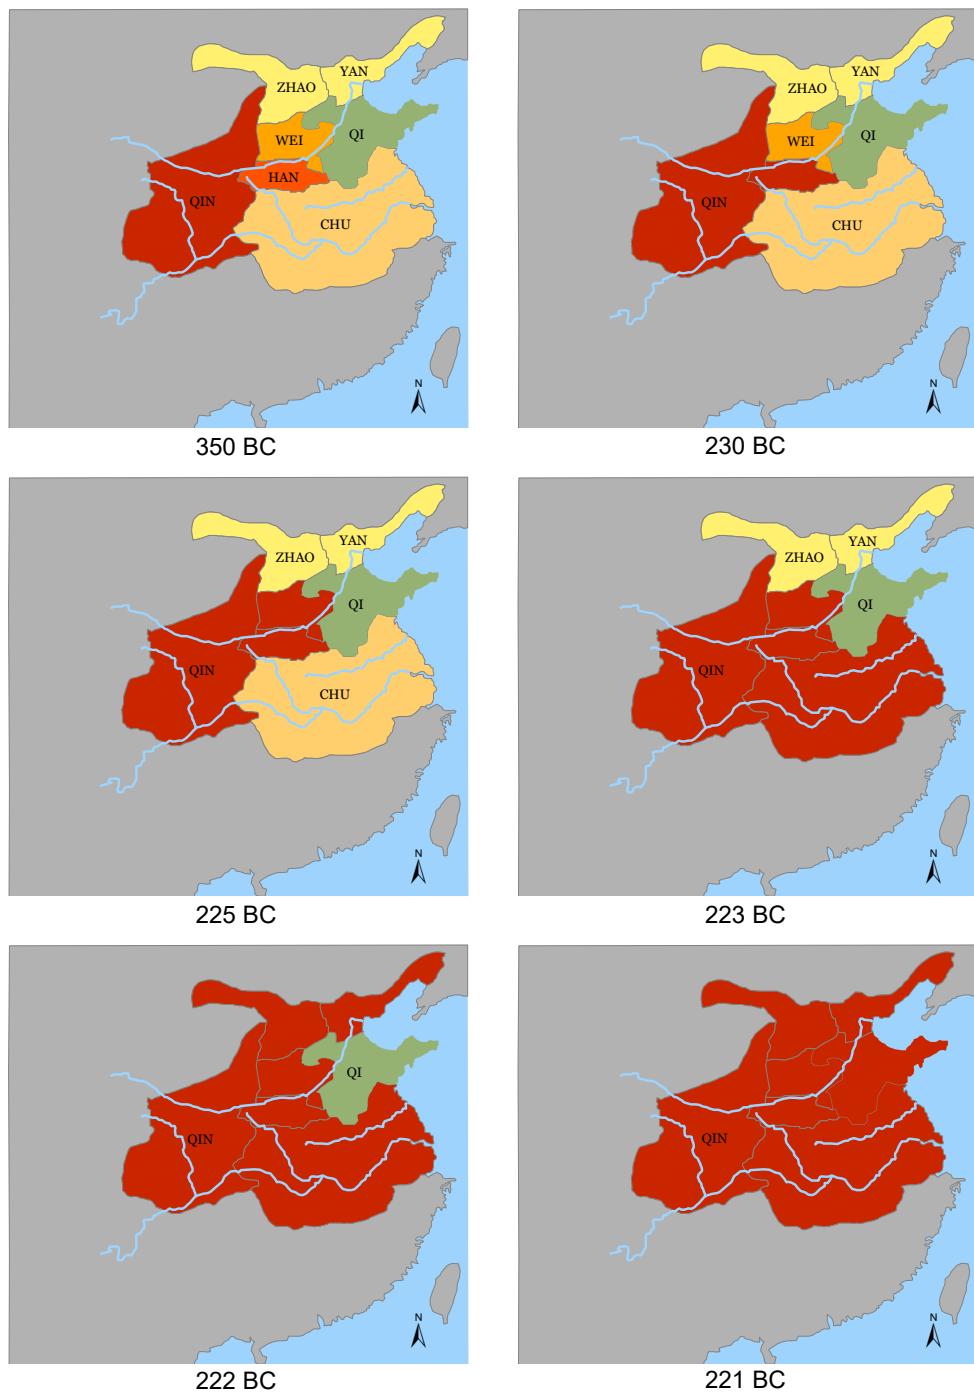

Our *final* observation concerns the frontiers of the empire: the Qin empire was bounded by forests in the South, deserts and the Tibetan Plateau on the West, wasteland in the North and the Pacific Ocean in the East. These physical features, especially in the South, the West and the East, presented a physical constraint on further expansion.

### THE ROMAN EMPIRE

The Roman Empire has had a profound impact on the history of the Mediterranean area (and more broadly across Europe), over the past two and a half thousand years. Our discussion draws on Kelly [2006] and Polybius [2010]; the historical record is taken from the Encyclopedia Britannica, Scarre [1995], and Wittke et al. [2010]. Figures 10.11 and 10.12 summarize the expansion of Roman empire over the period 500 BC – 30 BC. In these Figures, we distinguish physical contiguity from sea-based contiguity that was made possible after the development of a Roman navy; the latter are represented with ‘dashed’ lines.

We begin with the Early Roman Empire and first describe the period 500 BC to 272 BC. Rome’s first major war against an organized state was fought with Fidenae (437–426 BC), a town located just upstream from Rome. Rome next fought a long and difficult war against Veii, an important Etruscan city not far from Fidenae. The conquest of Veii opened southern Etruria to further Roman expansion. Rome then proceeded to found colonies at Nepet and Sutrium and forced the towns of Falerii and Capena to become its allies. During the period 348–295 BC, Rome rapidly rose to a position of hegemony in Italy south of the Po valley. A key moment was the Third Samnite War (298–290 BC): Samnites persuaded the Etruscans, Umbrians, and Gauls to join them. Rome emerged victorious at the battle of Sentinum in 295 BC. The next major event was the Pyrrhic War, 280–275 BC. The conflict between Rome and Pyrrhus lasted 5 years and ended in a final Roman victory in 275 BC at Beneventum.

The period from 272 BC to 30 BC witnessed a massive expansion of the Roman empire across the Mediterranean Sea and most of modern western Europe. Rome first began to make war outside the Italian peninsula during the Punic wars against Carthage (in North

Africa) around 264 AD. By 146 AD, Rome had defeated Carthage and taken over direct control over large parts of North Africa, and through its conflict with Carthage it also expanded its influence in Iberia. The wars with Macedonia led to control over Greece by 148 BC, and the defeat of the Selucid Emperor in 188 BC led to control over Asia Minor. Further conquests over the next hundred years would result in Rome's conquest of large parts of modern Spain and most of modern France (Kelly [2006], Polybius [2010]). Figure 10.12 illustrates this growing hegemony.

### THE SPANISH EMPIRE IN THE NEW WORLD

European imperial expansion starting from around 1500 AD reshaped the medieval world and gave rise to the age of global empires. The expansion of Spanish domains in the newly discovered continent of America illustrates this moment in imperial history in a especially dramatic form.

Our discussion draws on Elliott [2006] and the historical record in taken from the Encyclopedia Britannica. Spanish conquest in the Americas started with the first voyage of Columbus in 1492 AD. This voyage created a new link in the contiguity network as it made a new island 'accessible'. Equipped with the superior technology from Europe the Spanish quickly captured this island. The indigenous population was almost entirely annihilated,

and the island became part of the Spanish domain. Moving onto Central America, the Spanish conquistador Hernan Cortes defeated the Aztecs in Mexico City by 1521 AD, and the Aztec Empire was largely conquered by 1532 AD. Continuing, on land and by sea, Spanish conquest had reached Cartagena by 1532 AD, and Caracas had been captured by 1567 AD. Further south, Francisco Pizzaro defeated the Inca ruler in 1532, and Spain set up the Viceroyalty of Peru in 1542, a vast area that included most parts of South America (other than the Portuguese Empire and Venezuela). The Mayans were defeated and the area of southern Mexico, Belize, Guatemala, and Honduras fell into Spanish hands. El Salvador was eventually entirely taken over by 1697 AD. Figure 10.13 illustrates this process.

European military technology played a central role in the dramatic speed and scale of these conquests. For instance, in 1532 AD, Pizarro captured the Inca emperor with 167 men fighting an imperial Inca army of between 5000-10,000 men. In 1536, 190 conquistadors held out for a year against an Inca army of over 100,000 men (Hoffman [2015]). In addition to military superiority, the Europeans were also helped by the vulnerability of indigenous populations in America to diseases such as small pox and measles. Almost 95% of the Aztec population died due to diseases introduced by the Spanish over the period. The indigenous population under the Incas was similarly greatly reduced due to epidemics of

diseases brought by the Spanish. So the indigenous populations and its leadership could not present a real resistance to the conquistadors. In this context, the Spanish conquistadors were able to overwhelm opponents with significantly larger armies.

This record of war and conquest in China, Rome and America leads us to ask: what are the circumstances under which rulers will choose to fight? What is the optimal timing of attack, now or later? When will the resource advantage of a ruler translate into domination over neighbours? What are the limits to the size of the empire? We now develop a theoretical framework to explore these questions.

### 10.5.1 The Strategy of Conquest

We study a dynamic game in which rulers seek to maximize the resources they control by waging war and capturing new territories. There are three building blocks in our model: the interconnected ‘kingdoms’, the resource endowment for every kingdom, and the contest success function. This model is taken from Dziubinski, Goyal, and Minarsch [2017].

Let  $V = \{1, 2, \dots, n\}$ , where  $n \geq 2$  is the set of vertices. A node  $i \in V$  is endowed with resources,  $r_i \in \mathbb{R}_{++}$ . The nodes are connected in a network, represented by an undirected graph  $g$ . A link between two nodes signifies ‘access’. Access may reflect physical continuity. But, in principle, it goes beyond geography: we do not restrict attention to planar graphs. So our model allows for ‘virtual’ links, i.e., links made possible by advances in military and transport technology.

Every node  $i \in V$  is controlled/owned by one ruler. At the beginning, there are  $\mathbb{N} = \{1, 2, \dots, n\}$  rulers. Let  $\circ : V \rightarrow \mathbb{R}$  denote the ownership function. The resources of ruler  $i \in \mathbb{N}$  under  $\circ$ , are given by

$$R_i(\circ) = \sum_{v \in \circ^{-1}(i)} r_v \quad (10.25)$$

The network together with the ownership configuration induces a neighbor relation between the rulers: two rulers  $i, j \in N$  are *neighbors* in network  $g$  if there exists  $u \in V$ , owned by  $i$ , and  $v \in V$ , owned by  $j$ , such that  $g_{uv} \in g$ . Figure 10.14 illustrates nodes, resource endowments, and connections; nodes controlled by the same ruler share a common colour. The light line between nodes represents the interconnections, the dotted lines encircling nodes owned by the same ruler indicate the ownership configuration, and the thick lines between nodes reflect the induced neighborhood relation between rulers.

When two rulers fight, the probability of winning is specified by a *contest success function*. We consider symmetric contest success functions with no ties. Given two rulers,  $A$  and  $B$ , with resources  $x_A \in \mathbb{R}_{++}$  and  $x_B \in \mathbb{R}_{++}$ , respectively,  $p(x_A, x_B)$  is the probability

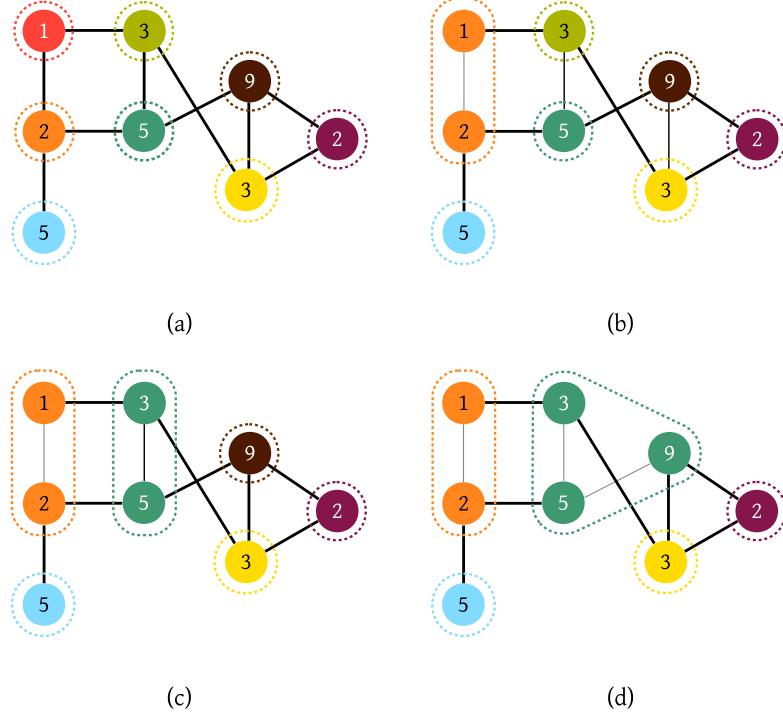

Figure 10.14: Neighboring Rulers

that  $A$  wins the conflict and  $p(x_B, x_A)$  is the probability that  $B$  wins the conflict. We shall use the Tullock Contest Function in our analysis of conflict.

$$p(x, y) = \frac{x^\gamma}{x^\gamma + y^\gamma},$$

where  $\gamma > 0$ . Larger resources enhance the prospects of success. In our discussion, for expositional simplicity, we will focus furthermore on the case where  $\gamma > 1$ . Here the probability of success rises more than proportionately with respect to the ratio of resources.

The game takes place in discrete time: rounds are numbered  $t = 1, 2, 3, \dots$ . At the start of a round, one of the ruler is picked with equal probability from the set of remaining rulers. The chosen ruler, (say)  $i$ , chooses either to be peaceful or to attack one of his neighbors. If a ruler attacks a rival, he does so with all his current resources. If he chooses peace, one of the remaining rulers is picked, and asked to choose between war and peace, and so forth. If no ruler chooses war, the game ends. If the attacker loses, the round ends. Otherwise, the attacker is allowed to attack neighbors until he loses, chooses to stop, or there are no neighbors left to attack. When two rulers  $i$  and  $j$  fight, the winner takes over the entire kingdom of the loser (and also inherits the boundaries, and hence the connections). For

simplicity, we assume that there are no losses or costs of war; our arguments also hold so long as the losses are relatively small.

This dynamic is illustrated in Figure 10.14: the orange kingdom wins the war with the red kingdom and expands. This expansion brings it in contact with new neighbors, the light and dark green kingdoms. The game ends when all rulers choose to be peaceful (the case of a single surviving ruler is a special case, as there is no opponent left to attack). Observe that, given these rules, the game ends after at most  $n - 1$  rounds. It may of course end earlier: this happens if all the rulers choose peace at a round.

A *state* is a pair  $(\circ, P)$ , where  $P \subseteq N$ , is the set of rulers who were picked prior to  $i$  and chose peace at  $\circ$ . Ruler  $i$ , picked at state  $(\circ, P) \in \mathcal{O} \times 2^{N \setminus \{i\}}$ , chooses a sequence of rulers to attack. A sequence  $\sigma$  is *feasible* at  $\circ$  in graph  $G$  if either  $\sigma$  is empty, or if  $\sigma = j_1, \dots, j_k$  and for all  $1 \leq l < k$ ,  $j_l \notin \{i, j_1, \dots, j_{l-1}\}$  and  $j_l$  is a neighbor of one of the rulers from  $\{i, j_1, \dots, j_{l-1}\}$  under  $\circ$  in  $G$ . A sequence  $\sigma$  is *attacking* if it is non-empty. Let  $N^*$  denote the set of all finite sequences over  $N$  (including the empty sequence). A *strategy* of ruler  $i$  is a function  $s_i : \mathcal{O} \times 2^{N \setminus \{i\}} \rightarrow N^*$  such that for every ownership configuration,  $\circ \in \mathcal{O}$ , and every set of rulers,  $P \subseteq N \setminus \{i\}$ ,  $s_i(\circ, P)$  is feasible at  $\circ$  in  $G$ .<sup>1</sup> Given ruler  $i \in N$  and graph  $G$ , the set of strategies of  $i$  is denoted by  $S_i$ ;  $S = \prod_{i \in N} S_i$  denotes the set of strategy profiles.

The probability that ruler 1 with resources  $R_1$  wins a sequence of conflicts with rulers with resources  $R_2, \dots, R_m$ , accumulating the resources of the losing opponents at each step of the sequence is

$$p_{\text{seq}}(R_1, \dots, R_m) = \prod_{k=2}^m p \left( \sum_{j=1}^{k-1} R_j, R_k \right). \quad (10.26)$$

Given  $\circ$ , a set of rulers,  $P$ , and a strategy profile  $s = (s_1, s_2, \dots, s_n) \in S$ , the probability that the game ends at  $\circ'$ , is given by  $F(\circ' | s, \circ, P)$ . We shall refer to a final ownership configuration as an *outcome*. The expected payoff to ruler  $i$  from strategy profile  $s \in S$  at state  $(\circ, P)$  is:

$$\Pi_i(s | \circ, P) = \sum_{\circ' \in \mathcal{O}} F(\circ' | s, \circ, P) R_i(\circ'). \quad (10.27)$$

Every ruler seeks to maximize his expected payoff, in other words capture of resources occupies centre stage in this model.

The goals of rulers and the motivations for war have been extensively studied. In the well known history of the Peloponnesian war written by Thucydides we already find a

---

<sup>1</sup>Observe that the only feasible sequence for rulers who do not own any nodes, and for the ruler who owns all nodes, is the empty sequence.

discussion of this subject. Thucydides [1989] says that there are three motives for war: greed, fear and honor. Hobbes [1886] elaborates on this as follows:

So that in the nature of man, we find three principal causes of quarrel. First, competition; secondly, diffidence; thirdly, glory. The first maketh men invade for gain; the second, for safety; and the third, for reputation. The first use violence, to make themselves masters of other mens persons, wives, children, and cattle; the second, to defend them; the third, for trifles. (Hobbes [1886]; page 64)

These observations are consistent with historical evidence. The Roman Empire was founded on a series of hard fought campaigns. During the 2<sup>nd</sup> and 1<sup>st</sup> century BC, Roman generals waged ever more extensive wars and campaigns. Victory yielded land for the expanding Roman population, large number of slaves, and huge quantities of booty: in 50 years from 200-150 BC, the equivalent of 30 metric tonnes of gold was seized. In 62 BC, the victorious Pompey returned from the East with booty worth nearly 70 tonnes of gold (Kelly [2006]). Equally important was the high esteem in which successful generals were held. The highest honour for a general in Rome was a "Triumph": a march of the general with his army through the city of Rome.

The second example concerns European global empires:

... the arch-characteristic of European imperialism was expropriation. Land was expropriated to meet the needs of plantations and mines engaged in long-distance commerce. Slave labour was acquired and carried thousands of miles to serve the same purpose. Native peoples were displaced, and their rights nullified, on the grounds that they had failed to make proper use of their land. Both native peoples and slaves (by different forms of displacement) suffered the effective expropriation of their cultures and identities. (Darwin [2007]; page 24)

Control over resources remains a major motivation for wars in the contemporary world. For instance, the presence of large oil reserves has been suggested as a potential explanation for conflict in the Middle-East. The historical and political science literatures have suggested a potential role for natural resources in many cases of wars. Motivated by this descriptive literature, and the relatively large number of changes in boundaries between countries in the twentieth century, Caselli, Morelli, and Rohner [2015] present evidence that the presence and location of oil resources has significant and quantitatively important effects on inter-State conflicts in the period after World War 2.

Returning to the formal model, we say that strategy profile  $s \in S$  is a Markov perfect equilibrium of the game if and only if, for every ruler  $i \in N$ , every strategy  $s'_i \in S_i$ , and

every state,  $(\phi, P) \in \mathbb{O} \times 2^{N \setminus \{i\}}$ , it holds that  $\Pi_i(s \mid \phi, P) \geq \Pi_i((s'_i, s_{-i}) \mid \phi, P)$ . Standard arguments can be employed to establish that for a connected network  $G$ , for any symmetric contest success function,  $p$ , and any resource endowment,  $r \in \mathbb{R}_{++}^V$ , there exists an equilibrium and all equilibria are payoff equivalent.

The first step is to understand the basic incentives to wage war. In our model, a ruler picked to fight needs to decide whether to fight or to remain peaceful, and if fighting is desirable then to decide whom to attack. The answer to these questions turns on the coefficient  $\gamma$  in the contest function. When  $\gamma > 1$ ,  $x^\gamma$  has increasing returns to scale and when  $\gamma < 1$ , it has diminishing returns to scale. This is critical in shaping expected returns to waging war. In particular, suppose  $x > y$ . It is then easy to check that

1. If  $\gamma > 1$  then  $(x + y)p(x, y) > x$  (*strong rewarding*).
2. If  $\gamma < 1$ , then  $(x + y)p(x, y) < x$  (*weak rewarding*).

Under a strong rewarding CSF, the expected resources of the stronger player are higher than her current resources and the expected resources of the weaker player are lower. The opposite is true in case of a weak rewarding CSF. This means that if rulers have unequal resources and are myopic, no peace is possible (so long as  $\gamma \neq 1$ ). In our game, rulers are far sighted and care only about the long run outcome. In this setting, a ruler may decide not to fight a neighbour as that brings him in contact with a more powerful ruler.

To develop a feel for some of the forces at work in this setting we present two examples. The first example concerns the role of the contest function.

### **Example 10.1.** Role of Technology

Suppose that three rulers have equal resources, given by  $x$  and  $\gamma = 0$ . If two rulers have fought then the state must contain one ruler with resources  $2x$  and the other ruler with resources  $x$ . It follows that the poorer ruler has a strict incentive to wage a war. Anticipating this consider the incentives of rulers at the initial state with three active rulers. As rulers have equal resources and the network is complete, all three rulers have the same incentives. As the probability of surviving two wars is  $1/4$ , the expected payoff from waging a war is  $3x/4$ . This tells us that there are no wars in equilibrium. By contrast, consider a very large  $\gamma$ . When there are two rulers, one of them must have  $2x$  resources and the other  $x$ . The ruler with more resources wins a war with probability close to 1, and therefore expects to increase payoffs. Anticipating this order of moves in the two ruler state, at the initial state all three rulers have a strict incentive to wage war. This is because at the initial state the expected payoff on waging a war is  $3x/2$  and this is larger than the expected payoff from

no one fighting. We see that with large  $\gamma$ , rulers will wage war leading to a hegemony. This example brings out the role of the technology of war in shaping dynamics of conquest.  $\triangle$

**Example 10.2.** Role of resources

We next consider an example that brings out the role of resources. As before, for simplicity consider three rulers linked to each other. Suppose that resources are very unequal: for example, rulers 1 and 2 have equal resources,  $x$  and ruler 3 has resources  $3x$ . When  $\gamma = 0$ , the two poorer rulers now wish to fight, while the rich ruler does not wish to fight. The outcome is war and hegemony. As  $\gamma = 0$ , the probability of becoming hegemon is equal for three rulers. Thus conflict and conquest is equalizing. Next consider the case where  $\gamma$  is very large. Now ruler 3 will win any war she fights. She therefore has a strict incentive to fight two wars. The outcome will be hegemony of ruler 3. In this setting war reinforces initial inequality.  $\triangle$

We now turn to a more general study of the dynamics of conquest. Consider three rulers with resources  $x, y$  and  $z$ . The expected payoffs to waging two wars are

$$p(x, y)p(x + y, z)(x + y + z). \quad (10.28)$$

while the expected payoff to waiting are

$$p(x, y + z)(x + y + z). \quad (10.29)$$

It is possible to show that a ruler prefers to wage two wars if  $\gamma > 1$  and that he will prefer to wait if  $\gamma < 1$ . Thus if  $\gamma > 1$  there is a no-waiting property while if  $\gamma < 1$  then opponents prefer to wait. This is because if  $\gamma > 1$  then  $x^\gamma$  is supermodular and because of that  $p$  has the no-waiting property and if  $\gamma < 1$  then  $x^\gamma$  is submodular and because of that  $p$  has the waiting property. Thus we note that strong rewarding  $p$  is necessarily no-waiting (because increasing returns to scale imply supermodularity) and weak rewarding  $p$  is necessarily waiting (because diminishing returns to scale imply submodularity). A question at the end of the chapter further explores this relationship between  $\gamma$  and the incentives to wage war.

We build on this incentive to develop the equilibrium analysis of the game of conquest. Given ownership configuration  $\circledcirc$ , the set of *active* rulers at  $\circledcirc$  is

$$\text{Act}(\circledcirc) = \{i \in \mathbb{R} : \emptyset \subsetneq \circledcirc^{-1}(i) \subsetneq V\}.$$

In words, an active ruler is someone who controls at least one vertex but does not control all vertices. An ordering of the elements of the set  $\text{Act}(\circlearrowleft) \setminus \{i\}$ ,  $\sigma$ , such that the sequence  $\sigma$  is feasible for  $i$  in  $G$  under  $\circlearrowleft$  is called a *full attacking sequence* (or f.a.s.). Figure 10.15 illustrates the execution of such a sequence (for the orange kingdom).

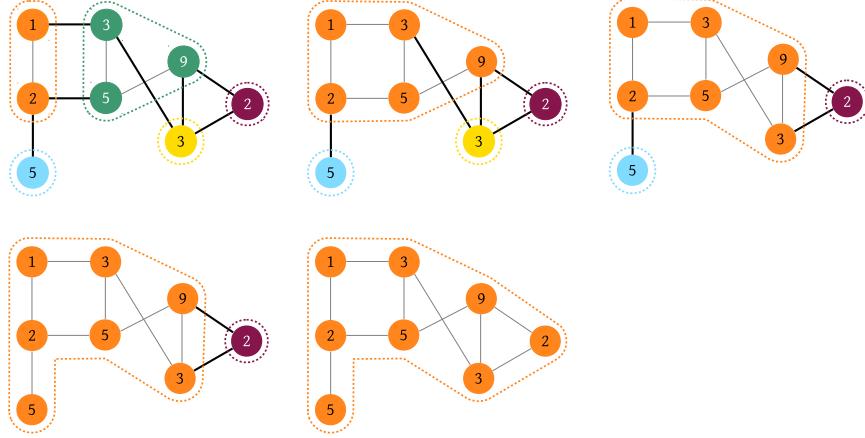

Figure 10.15: Full Attacking Sequence

Our main result on war and conquest and the extent of empire concerns the strong rewarding case.

**Proposition 10.4.** Consider a rich rewarding contest success function that satisfies 10.5.1. Suppose  $g$  is a connected network and let  $r \in \mathbb{R}_{++}^V$  be a generic resource profile. In equilibrium, every active ruler chooses to attack a neighbor if  $|A(\circlearrowleft)| \geq 3$ , and at least one of the active rulers attacks his opponent if  $|A(\circlearrowleft)| = 2$ . The outcome is hegemony and the probability of becoming a hegemon is unique for every ruler.

The result predicts incessant fighting, preemptive attacks, and long attacking sequences, for all rich rewarding contest functions, for any connected network, and for generic resources.

The argument builds on the notion of a *strong* ruler. A ruler is said to be *strong* if he has an attacking sequence  $\sigma = i_1, \dots, i_k$ , where for all  $l \in \{1, \dots, k\}$ ,

$$\sum_{j=0}^{l-1} R_{i_j}(\circlearrowleft) > R_{i_l}(\circlearrowleft).$$

In other words, at every step in the attacking sequence, the ruler has more resources than the next opponent. The set of *strong* rulers at ownership configuration  $\circlearrowleft$  is

$$S(\circlearrowleft) = \{i \in \text{Act}(\circlearrowleft) : i \text{ has a strong f.a.s. } \sigma \text{ at } \circlearrowleft\}.$$

A ruler who is not *strong* is said to be *weak*. It is worth noting that (generically) in any state, the ruler with the most resources is strong, while the ruler with the least resources is weak. Thus both sets are non-empty in every network and for (generic) resource profiles.

The first step in the proof shows that, assuming that all other rulers choose peace in all states, it is optimal for a strong ruler to choose a full attacking sequence. This is true because the contest success function is rich rewarding and so a strong ruler has a full attacking sequence that increases his resources in expectation, at every step, along the sequence. The second step extends the argument to cover opponents who choose war. If opponents are active then the no-waiting property tells us that it is even more attractive to not give them an opportunity to move. For a strong ruler it is therefore a dominant strategy to use an optimal full attacking sequence. The final step in the proof covers non-strong rulers to establish that with 3 or more active rulers, it is optimal for *every* ruler to choose a full attacking sequence. Observe that we have already shown that every non-strong ruler knows that he will be facing an attack sooner or later. This means that waiting can only mean that the opposition will become (larger and) richer. The no-waiting property then tells us that every ruler must attack as soon as possible. If there are only two active rulers then the richer ruler has a strict incentive to attack the poorer opponent (this follows from the definition of the rich rewarding contest function).

We now study the role of the network in shaping conquest dynamics. A preliminary remark is that for fixed resources and sufficiently large  $\gamma$  it is never optimal to attack a richer ruler if other options are available. The optimal strategy for a strong ruler must involve attacking a poorer ruler at every stage in the attack sequence. Such a sequence is clearly not available for a weak ruler: the probability of a weak ruler becoming a hegemon converges to zero, as  $\gamma$  grows. Whether a ruler is strong or weak depends both on the distribution of resources and on the position of the ruler in the contiguity network. Figure 10.16 helps us bring out this point: relatively rich kingdoms such as those with resources 16 and 17 are weak, while less rich kingdoms such as those with resources 8 and 9 and are strong.

It is helpful to define the boundary of a set of vertices  $U \subseteq V$  in  $G$  is

$$B_G(U) = \{v \in V \setminus U : \text{there exists } u \in U \text{ s.t. } uv \in E\}$$

A set of vertices,  $U$ , is *weak* if  $G[U]$  is connected,  $B_G(U) \neq \emptyset$ , and for all  $v \in B_G(U)$ ,  $r_v > \sum_{u \in U} r_u$ . A weak set of vertices is surrounded by a boundary, constituting of vertices, each of which is endowed with more resources than the sum of resources of vertices within the set. It is easy to see that, for any initial state  $\circledcirc$ , a ruler is weak if his vertex belongs to a

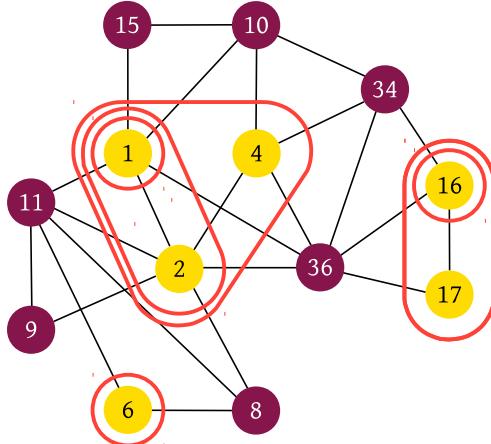

Figure 10.16: Weak rulers (surrounded by thick lines) and strong rulers

weak set and, otherwise, the ruler is strong.

### 10.5.2 Mapping Theory onto Formation of Historical Empires

It is illuminating to view the rise of the three historical empires we discussed above through the lens of the model presented in the previous section. We revisit

**Chinese Empire:** In line with the theoretical prediction, over a period stretching several hundred years, there was incessant warfare. To appreciate the time line of gradual and then very rapid expansion of empire, consider a slight variation on the contest function in which a tie arises with probability related to the size of the armies of the opponents. In the period prior to 360 BC, the armies were small and battles indecisive for the fate of a ruler. The period after 360 BC witnessed major reforms of the Qin minister, Shang Yang. After these reforms and the accompanying technological developments, the scale and violence in a war changed dramatically: now elimination of the losing ruler and conquest of his kingdom became much more likely, especially in a war between the Qin and one of the other warring states.

... the rise of Qin to dominance and its ultimate success in creating a unified empire depended on two major developments. First, under Shang Yang it achieved the most systematic version of the reforms that characterized the Warring States. These reforms entailed the registration and mobilization of all adult males for military service and the payment of taxes. While all Warring States were organized for war, Qin was unique in its extension of this pattern to every level of society, and in the manner in which every aspect of administration was devoted to mobilizing and provisioning its forces for conquest. (Lewis, 2010; page 38-39).

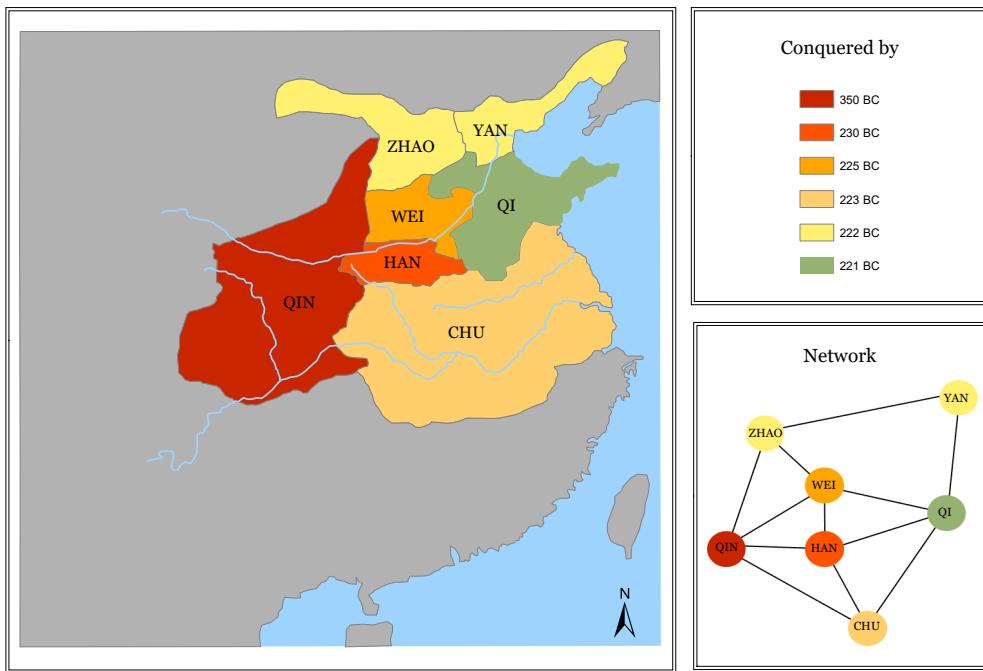

These reforms meant that the ruler had the resources – both in terms of army size and in terms of tax revenue – to wage large scale wars. Equipped with such a large army the Qin ruler was able to implement a long attacking sequence: in 230 BC, Qin conquered Han, the weakest of the Seven Warring States. In 225 BC, Qin conquered Wei, followed in 223 BC by the conquest of Chu. The size of the army was crucial in this contest: the first Qin invasion was a failure, when 200,000 Qin troops were defeated by a much larger Chu army with around 500,000 troops. The following year, Qin mounted a second invasion with 600,000 men and they defeated the Chu state. At their peak, the combined armies of Chu and Qin are estimated to have been in excess of a million soldiers. Qin conquered Zhao and Yan in 222 BC. Finally, in 221 BC, Qin turned its attention to the last surviving Warring State opponent: the Qi. In the face of the great threat Qi surrendered.

In line with the theory, there was a tendency to attack the weaker states first before the stronger ones. Han, the weakest of the seven, was the first to fall. Qin's policy of attacking the nearby states and befriending the faraway states was partly determined by proximity and partly driven by the fact that Han and Wei were relatively weak, while Qi and Chu had the most resources. Yan was also a weak state and was the object of attack by Zhao and Qi. The table below provides the size of armies during the late Warring States Period.

Kingdom	Size of Army	End Year
Qin	800,000	-
Chu	800,000	BC 223
Qi	600,000	BC 221
Zhao	500,000	BC 222
Wei	400,000	BC 225
Han	300,000	BC 230
Yan	300,000	BC 222

Table 10.3: Chinese Kingdoms: Army Size and End Year: Zhao and Xie [1988] (pages 18-19)

Our final observation concerns the frontiers of the empire: we recall that the Qin empire was bounded by forests in the South, deserts and the Tibetan Plateau on the West, wasteland in the North and the Pacific Ocean in the East. These physical features, especially in the South, the West and the East, presented a physical constraint on further expansion. We may therefore interpret China as a distinct 'component' of the world network, somewhat isolated from other parts of the world. The first Chinese Empire was a hegemon that was 'limited' by the connectivity of the physical contiguity network.

Figure 10.17: The First Chinese Empire: Summary. Source: Overy [2010].

**Roman Empire:** Turning next to the Roman Empire, our theoretical analysis draws attention to four features in this process. Again, in line with the theoretical prediction, Rome was at war for much of this period: its vast territory had been acquired through a long series of hard fought campaigns over a period of over 500 years. The second point pertains to the pace of expansion: over the period 500 BC – 272 BC, the expansion was slow and limited to the Italian peninsula. This relatively slow pace of expansion would be consistent with outcomes in a slightly extended extension of our model in which the probability of ties is proportional to the size of the armies employed. However, once Rome had taken over the Italian peninsula, further expansion was rapid. Polybius [2010] presents a detailed discussion of the expansion during the period from 220 BC to 167 BC: a period that saw Rome take over parts of North Africa, Greece and Asia Minor. Later on, the period until 30 BC, saw a further massive expansion of Roman rule that led to rule over almost the entire coast around the Mediterranean Sea and over much of modern Western Europe. The final observation concerns the limits of the empire: the boundaries came to be defined by the Atlantic Ocean in the West, the Rhine and the Danube River in the North, the Sahara Desert in the South, and the Euphrates River in the East. Over the subsequent four hundred years, these boundaries would be contested but they would describe the limits of the empire broadly: these boundaries are consistent with the theoretical prediction that the size of the empire is limited by the ‘connectivity’ of the contiguity network.

**Spanish Empire:** Our theoretical analysis draws attention to three aspects of this development. The first is the developments in Europe involving the successes of the Castilian kingdom through the 15<sup>th</sup> century. These successes set the stage for even further expansion across the world. The second point is the incessant fighting between the Spanish and the native kingdoms in both North and South America during this period. The third and key point is the reconfiguration of the contiguity network. This was made possible by the discovery of new sea routes to different parts of the world – the Caribbean Islands (and eventually America) by Columbus in 1492 AD. This discovery happened alongside a major change in the technology of war – the advancement of gunpowder and corresponding advances in the design of fortresses and the navy; for a systematic study of military revolution, see Rogers [1995a] and Parker [1988]. Taken together these developments significantly altered the configuration of the contiguity network as well as the military resources of combatants: previously ‘unknown’ parts of the world now became ‘accessible’ and open to conquest. Imperial expansion now proceeded along this new network and gave rise to a truly global Spanish empire spanning three continents Europe, North America and South America.

Let us summarize what we have learnt about the dynamics of conquest. Wars of conquest among neighbours have been a recurring feature of history. These wars give rise to dominant rulers and these rulers eventually create empires. Even today, most of the world’s population lives in a few large countries or integrated large communities like the European Union. The model is highly stylized but it helps us understand why rulers wish to fight, how institutional reforms can create resource advantages, and how these resources can support contiguous expansion leading to an empire. The extent of the empire is limited by the connectivity of the contiguity network.

## 10.6 Reading Notes

For a general introduction to network based violent conflict see Arquilla and Ronfeldt [2001] and Zhu and Levinson [2011]. This literature brings together contest success functions and networks within a unified framework. For an introduction to contest functions, see the elegant and compact treatment offered in Konrad [2009]. For a general survey of the subject of conflict, see Garfinkel and Skaperdas [2012]. There is a large literature on conflict in networks, for a survey see Dziubiński et al. [2016].

Sections 10.2-10.5 take up the study of security and conflict in a setting where nodes in the network are active players.

Section 10.3 covers static models of conflict on networks and draws heavily on the work

of Franke and Öztürk [2015] and König, Rohner, Thoenig, and Zilibotti [2017]. The model of Franke and Öztürk [2015] builds on a large literature of contests and conflict see e.g., Hillman and Riley [1989] and Appelbaum and Katz [1986]. The model in König, Rohner, Thoenig, and Zilibotti [2017] builds further on this strand of work and the theory of games on networks especially in the use of centrality measures discussed by Freeman [1979] and introduced into economics by Ballester, Calvó-Armengol, and Zenou [2006]). I am grateful to Michael Konig for providing me the data from his paper and also for clarifying a number of points in the theoretical model.

In the discussion on the Great War of Congo the network is taken as given. This is a reasonable starting point and it is plausible as most groups stuck to their alliances during the Second Congolese War. But at a higher level as we investigate possible policies to reduce the fighting it is clear that large scale interventions will alter the environment and this will give rise to new incentives for forming and dissolving alliances. These considerations led us to examine stable alliance structures and their effects on the frequency of wars. We presented a model taken from Jackson and Nei [2015]; for related work in this vein, the interested reader is referred to Huremovic [2014], and Hiller [2017]. We note that an important concern in the study of alliances is free riding among the parties; for an elegant summary of the literature on this topic, see Bloch [2012]. The study of alliances where efforts is endogenous remains an open problem.

The final part of the chapter move from static models of conflict to the dynamics of conquest and appropriation. Classical studies on the formation of empire include Polybius [2010], Tacitus [2009] and Khaldun [1989]. Starting with Gibbon [1776] there is a long tradition of modern work on empires, some well known works are Braudel [1995], Darwin [2007], Elliott [2006], Lewis [2010], Morris and Scheidel [2009], and Thapar [1997, 2002]. Section 10.5 locates contests in a dynamic context and builds on the work of Hirshleifer [1995] and Krainin and Wiseman [2016] and the large body of work in history on the motivations underlying war and conquest (Thucydides [1989], Hobbes [1886] and Darwin [2007]). The presentation in section 10.5 is based on Dziubiński and Goyal [2017]. For related models of predation and violence see Piccione and Rubinstein [2007] and Jordan [2006] and Krainin and Wiseman [2016], Levine and Modica [2013], and Turchin [2007]. The distinctive feature of the model presented is the central role of networks in shaping conflict.

I am grateful to Marcin Dziubinski, Ying Gao, Ruohan Qin, Mikhail Safronov, and Bryony Reich for useful comments and for pointing out a number of errors in the original draft.

## 10.7 Questions

1. Consider the model of contests on networks from section 10.2.

- Assume that there exists a unique and interior equilibrium effort in a regular network. Show that equilibrium effort for every link and for every player in a regular network of degree  $d$  is given by

$$e^* = \frac{1}{2} \sqrt{\frac{Z}{d}} \quad (10.30)$$

Show that equilibrium payoff for every player is  $-(dZ)/4$ .

- Assume that there exists a unique and interior equilibrium effort in a star network. Let  $e_c$  denote equilibrium effort of central agent (in every link) and  $e_p$  the equilibrium effort of every peripheral agent.
  - Show that equilibrium efforts are as follows

$$e_i = p_i \sqrt{\frac{Z}{\sqrt{n-1}}}, \forall i \in \{c, p\} \quad (10.31)$$

where  $p_c = 1/(1 + \sqrt{n-1})$  and  $p_p = 1 - p_c$ . Thus the central agent's link specific effort and the peripheral agent's effort are both decreasing in  $n$ . Show that the aggregate effort of the central agent is increasing in  $n$ .

- Show that equilibrium payoff of central agent is

$$-\frac{(n-1)(\sqrt{n-1} + n - 2)}{(1 + \sqrt{n-1})^2} Z \quad (10.32)$$

while the equilibrium payoff of peripheral agent is

$$\frac{n-2 - \sqrt{n-1}}{(1 + \sqrt{n-1})} Z \quad (10.33)$$

- Show that equilibrium payoff of central agent is decreasing, while the equilibrium payoff of the peripheral player is increasing in  $n$ .

2. This question considers fighting in a model of alliances presented in 10.3. Groups simultaneously choose a single fighting effort  $x_i \in \mathbb{R}$ . The efforts of a group are reinforced by the efforts of its allies and weakened by the efforts of its enemies. Effective

effort,  $\varphi_i$  is defined as:

$$\varphi_i(g, \mathbf{x}) = x_i + \beta \sum_{j=1}^n g_{ij}^+ x_j - \gamma \sum_{j=1}^n g_{ij}^- x_j, \quad (10.34)$$

where  $g_{ij}^+$  refers to links between allies,  $g_{ij}^-$  refers to links between enemies,  $\beta, \gamma \in [0, 1]$  are spillovers from allies and enemies, respectively. Given a network  $g$  and effort profile  $x = (x_1, \dots, x_n)$ , the payoff to group  $i$  is determined by a Tullock contest function:

$$\Pi_i(g, \mathbf{x}) = V \times \frac{\varphi_i(g, \mathbf{x})}{\sum_{j=1}^n \varphi_j(g, \mathbf{x})} - x_i. \quad (10.35)$$

In a regular network,  $G_{k^+, k^-}$ , every group  $i$  has  $d_i^+ = k^+$  alliances and  $d_i^- = k^-$  enmities. Given the symmetric structure, there exists a symmetric Nash equilibrium. Show that this equilibrium effort and payoff vectors are given by:

$$x(k^+, k^-) \equiv x_i(G_{k^+, k^-}) = \left( \frac{1}{1 + \beta k^+ - \gamma k^-} - \frac{1}{n} \right) \times \frac{1}{n}, \quad (10.36)$$

$$\pi(k^+, k^-) \equiv \pi_i(G_{k^+, k^-}) = \frac{1 + (1+n)(\beta k^+ - \gamma k^-)}{n(1 + \beta k^+ - \gamma k^-)} \times \frac{1}{n}. \quad (10.37)$$

Show that fighting effort of every group  $x$  is decreasing in  $k^+$  and increasing in  $k^-$ , while  $\pi$  is increasing in  $k^+$  and decreasing in  $k^-$ .

3. Consider the symmetric setting of Proposition 3 (from section 10.4) with a concrete functional form  $f(d) = \sqrt{d}$  and 6 agents,  $N = \{1, 2, 3, 4, 5, 6\}$ .
  - (a) Let  $c = 0.4$ . Find  $d^*$ .
  - (b) Consider the network  $g = \{g_{12}, g_{23}, g_{34}, g_{45}, g_{56}, g_{61}\}$  (a cycle). For what values of  $E(d^*)$  and  $\rho$  is this network war and trade stable?
  - (c) Consider the network  $g = \{g_{12}, g_{23}, g_{31}, g_{45}, g_{56}, g_{64}\}$  (two disconnected triangles). For what values of  $E(d^*)$  and  $\rho$  is this network war and trade stable?
  - (d) Suppose  $d^* = 1$  (a case which is not covered by Proposition 3). Describe 1-regular networks. What conditions on  $E(d^*)$  and/or  $\rho$  make such a network war and trade stable?
  - (e) Either prove lack of existence of war stable networks in one of the other coalition formation rules (e.g., attacking countries all in the same component, attacked country defended by its neighbors), or work through the existence in the one

case where we have existence (attacking and defending coalitions both have to be cliques,  $\rho \in (1, 4/3)$ ).

4. Consider the conquest game from section 10.5. Suppose there are three rulers connected to each other. A ruler can fight the two rulers one after the other or wait and fight the victor of the fight between the other two. Assume the probability of winning is given by the Tullock contest function with parameter  $\gamma \geq 0$ . Show that fighting two battles is better if  $\gamma > 1$ , while waiting a fighting a single battle with the winner of the battle between the other two rulers is better if  $\gamma < 1$ .
5. Consider the conquest game from section 10.5. Suppose there are three rulers connected to each other. A ruler can fight the rich followed by the poor neighbour of the other around. Assume that the probability of winning is given by the Tullock contest function with parameter  $\gamma \geq 0$ . Show that sequence with the poor neighbour followed by rich neighbour is optimal if  $\gamma > 1$ ; the converse hold true if  $\gamma < 1$ .
6. Consider the role of defensive alliances in the conquest game from section 10.5. Suppose that in a round, once a ruler has been picked, all the other active rulers have an opportunity to create alliances. An alliance brings together the resources of all its members to defend a member of the alliance against an attack.
  - Suppose the contest function is Tullock and that  $\gamma$  is large. Assume first that a ruler who is threatened can form an alliance with anyone in the network. In this case hegemony will only obtain if there is a ruler who controls more than one half of aggregate resources.
  - Next suppose that an alliance can only consist of path connected rulers in the residual contiguity network involving all rulers other than the ruler currently picked. Consider a line network with an odd number of rulers. The central vertex has  $(n + 1)/2$  resources and each of the other  $n - 1$  rulers controls exactly 1 unit of resources. Show that it is optimal for the central vertex to launch a full attacking sequence and if  $\gamma$  is large then the probability of central ruler becoming the hegemon is close to 1.

I am grateful to Marcin Dziubinski, Michael Konig, Stephen Nei, Misha Safranov, for detailed comments on an earlier draft of the chapter and for suggestions on possible questions.

# **Part III**

# **Social Networks**

# Chapter 11: The Law of the Few

## 11.1 Introduction

Massive online information networks are one of the defining features of the early twenty-first century. These networks often exhibit staggering inequality: for example, on Twitter the top 10% of the tweeters make over 80% of all tweets; the vast majority of users had hardly any followers but there exists a club of users who each have over 25 million followers! The *Law of the Few* says that in social groups most individuals get most of their information from a very small subset of the group. The aim of this chapter is to develop a theoretical framework that helps us understand the size and great inequality of these networks and to develop methods for assessing their performance.

We are constantly in looking for information in order to make better decisions. We experiment with different alternatives, we read surveys and we connect with others – hoping to learn from their experiences and also to learn from what they may have learnt from their friends and colleagues. There are rewards to making more informed decisions, but acquiring information is costly too. Experiments take time and involve resources; similarly, reading takes time and effort, and connecting with others to talk with them takes time and can be psychologically demanding. The rewards of connecting and spending time with someone will depend on how well informed they are and how much new information they have for us. The novelty of information they provide us will depend in turn partly on how well connected they are to people that we don't already know. Moreover, the quality of information accessed from contacts – its timeliness and accuracy – is higher if the information has to travel less far in the social network.

Building on ideas introduced in chapter 3 (on costs and benefits of linking), Section 11.3 presents a model that builds on these ideas. We suppose that there is a group of individuals each of whom has some information that is of value to everyone. An individual can access the information from another person by forming a link with them. The link is costly. The theory illustrates how a comparison of the costs and rewards of linking leads individuals to join networks, and as they join networks, this means that the network becomes larger

and that makes the network more attractive for others to join – this reinforcing aspect of joining a network pushes toward growth and toward connectivity. Turning to the architecture of network, as the quality of information accessed is higher if someone is closer by in the network, this leads individuals to form links with highly connected and central individuals. The resulting network has a hub and this means it has a small diameter.

Turning to the performance of networks, a network is said to be efficient if it maximizes the sum total of individual rewards less the sum total of linking costs. This formulation has the virtue of defining performance in terms of the concerns of the users of the network. What are the efficient networks and how do they relate to networks that individuals created by individuals? The first step builds on the above reasoning of network growing in value with size to establish that an efficient network is either connected or empty. The next step builds on the following observation: the star network economizes on number of links and also minimizes on distances between nodes.

While the reasoning underlying the process of network formation appears to be simple, the informational demands on an individual who is comparing the costs and benefits of forming a link are very great: she needs to understand the benefits of connecting to different (combinations of) individuals. So she needs to figure out the shortest paths to different members of the network. Moreover, as she contemplates her options, other individuals are active and the network is evolving. So it is far from clear if the theory is meaningful as a guide to network formation in practice.

To develop an appreciation of the scope of an economic approach to reasoning about networks, we present an experiment on this model that is conducted with human subjects. To make the setting realistic, we consider a group of a 100 subjects. Individuals can form and delete links with each other over a period of 6 minutes. The experiment reveals that individuals successfully navigate a very complex environment to create networks in line with the theory.

A key element of the law of the few is specialization in information gathering from external sources: only a small subset of the group invest in personally acquiring information, the vast majority connect with this minority to learn about the world. In the theory presented in section 11.3, everyone has an equal amount of information at the outset. We next turn to a study of the distribution of information that individuals will personally acquire. Section 11.4 extends the theory to allow individuals to choose how much information they personally acquire. This richer model creates an additional trade-off: individuals compare the costs of personally acquiring information against the costs of linking with others to access the information they have acquired. The key result is that if an individual acquires a great deal of information then it becomes attractive for others to not acquire information on

their own but to link with this hard working and information rich individual. The substitutability between information acquisition by others and oneself sets up a potential route to specialization: the main result is that in large populations, the fraction of individuals who personally acquire information is negligible. The small active subset constitutes a clique and everyone forms a link with every member of the clique (giving rise to a core-periphery network).

While the theory yields a sharp result, the computational challenges facing an individual are formidable. Now, in addition to the network structure, individuals have to keep track of the effort invested by others in acquiring information. We present an experiment with human subjects in a laboratory to understand the scope of the theory. We consider a group with 100 subjects that chooses information purchase and linking over a period of 6 minutes. The experiment reveals that subjects specialize in information purchase and linking very much in line with the theoretical prediction.

## 11.2 Empirical Background

Throughout history, information has been passed on mostly via interpersonal communication. But in the first part of the twentieth century, with the coming of age of radio, television and newspaper, there was a expectation that this would change. Mass media would be central to communication and that individual opinions and decisions would be largely shaped by mass media.

However, in a series of path-breaking and highly influential surveys, Lazarsfeld, Berelson, and Gaudet [1948] and Katz and Lazarsfeld [1966] showed that while mass media was important, the majority of individuals (as consumers and voters) made their decisions based on information and advice garnered through social interactions. Their empirical studies led them to propose a two-step model of information. The mass media puts out information that is mainly absorbed by a small fraction of the population, the rest of the population relies on social contacts with this select few. These studies showed that information gathered through social connections played a crucial role in shaping attitudes and decisions pertaining to fashion, movie-going, purchase of goods, voting, and public affairs.

In *People's Choice*, Lazarsfeld, Berelson, and Gaudet [1948] studied the determinants of voting behavior in the American Presidential Election of 1940 in the small midwest town of Erie, Ohio. The study involved repeated interviews of a sample of 2400 voters from May to October 1940 and showed that personal interactions played a key role in shaping voting decisions. In their book, *Personal Influence*, Katz and Lazarsfeld [1966] conducted a survey of 800 female residents of Decatur, Illinois and identified 40% of their sample as potential

leaders in one of the fields of marketing, fashion, and public affairs.

In subsequent years, the role of social influence has been widely documented. For instance, Feick and Price [1987] found that 25 percent of their sample of 1,531 individuals acquired a great deal of information about food, household goods, nonprescription drugs, and beauty products and that they were widely accessed by the rest.

Research on virtual social communities reveals a similar pattern of communication. Zhang, Ackerman, and Adamic [2007] study the Java Forum, an online community of users who ask and respond to queries concerning Java. They identify 14,000 users and find that 55 percent of these users only ask questions, 12 percent both ask and answer queries, and about 13 percent only provide answers.

In Chapter 1, we presented a case study of Twitter. Let us briefly recall some features of this network. Wojcik and Hughes [2019] studied 321 million users and found that the top 10% of tweeters made 138 tweets per month on average and were responsible for 80% of all tweets. Prominent tweeters like Donald Trump, Barack Obama and Katy Perry had over 25 million followers. By contrast the bottom 90% of tweeters on average made 2 tweets per month, their median in-degree was a mere 19!

### 11.3 A simple theory of linking

We present a model of linking taken from Goyal [1993] and Bala and Goyal [2000a].

There is a large of individuals  $N = \{1, \dots, n\}$ , each of whom has been given a distinct piece of information that has value 1. Person  $i$  can access person  $j$  by forming a link with her. A strategy of player  $i \in N$  is a (row) vector  $g_i = (g_{i,1}, \dots, g_{i,i-1}, g_{i,i+1}, \dots, g_{i,n})$  where  $g_{i,j} \in \{0, 1\}$  for each  $j \in N \setminus \{i\}$ . Player  $i$  has a *link* with  $j$  if  $g_{i,j} = 1$ . The set of (pure) strategies of player  $i$  is denoted by  $\mathcal{G}_i$ . A strategy profile is denoted by  $g = \{g_1, \dots, g_n\}$ . There is an equivalence between the set of strategy profiles  $\mathcal{S}$ , and the set of all directed networks on  $n$  nodes. In what follows we will use the network notation. Links are *one-sided* in the sense that they can be formed on individual initiative and the individual forming the link incurs the costs of forming links. The cost of a link is  $k > 0$ .

While the decision to link is taken unilaterally, a link is undirected for the purposes of communication. A link created by A to B allows both A and B to access each other's information: this is the original information (worth 1) that she started with and any information that she has acquired by forming links with others. With this in mind, to describe flow of information, define  $\hat{g}_{ij} = \max\{g_{ij}, g_{ji}\}$  and define the network  $\hat{g}$  correspondingly.

The quality of information decays as it passes along the network: this may be due to the time it takes or due to the noise that gets added to it. To make this idea precise let us

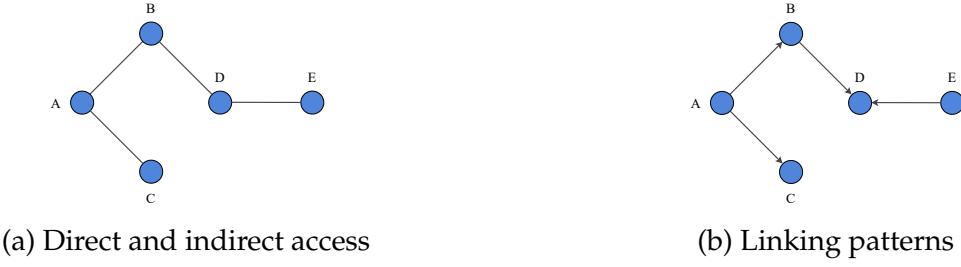

Figure 11.1: Access and Decay

define  $\delta \in (0, 1)$  as a measure of decay. So if person A is one link away from an isolated person B, then A has access to  $\delta \times 1 = \delta$  information from B. If, on the other hand, A is two links away from B then she has access to  $\delta^2 \times 1 = \delta^2$  information from B. Consider the network depicted in Figure 11.1. In this network A is distance 1 away from B and C, distance 2 from D and distance 3 from E. Individual A has access information  $\delta$  each from B and C, information  $\delta^2$  from D, and  $\delta^3$  from E. Building on this example, we shall say that the information accessed by individual  $i$  in network,  $g$ , is

$$1 + \sum_{j \in N} \delta^{d(i,j;\hat{g})}. \quad (11.1)$$

The first term here refers to own information. The term  $d(i,j;\hat{g})$  counts the distance between  $i$  and node  $j$  in the network  $g$ . The summation across individuals reflects the idea that every person has a distinct piece of information.

For expositional purposes, we are taking a very simple and stylized model of information in this section. These payoffs are generalized in the next section and a question at the end of the chapter further explores a game of linking with general payoffs.

The linking decisions of individuals give rise to a directed network. An example of such a network is illustrated on the right side of Figure 11.1. The arrow in the link from A to B indicates that A has formed the link with B. In this network, A has formed 2 links, while B, E have formed one link each.

Figure 11.1 describes the flow of information. Let us define  $d_i(g)$  as the number of links created by person  $i$  in a network  $g$ . The net payoff of individual 1 in network  $g$  is given by  $1 + 2\delta + \delta^2 + \delta^3 - 2c$ . More generally, the payoff to an individual  $i$  in network  $g$  is given by

$$\Pi_i(g) = 1 + \sum_{j \in N} \delta^{d(i,j;\hat{g})} - d_i(g)k. \quad (11.2)$$

A Nash equilibrium is a strategy profile  $g^*$  such that every player is choosing an optimal strategy given the choices of others. i.e.,

$$\Pi_i(g_i^*, g_{-i}^*) \geq \Pi_i(g_i', g_{-i}^*), \forall g_i' \in \mathcal{G}_i. \quad (11.3)$$

We will examine the Nash equilibrium of this game.

First, observe that an equilibrium network must be connected or must have no links at all. We will establish this claim by contradiction. Suppose that  $g$  is an equilibrium network and that there were two distinct groups of connected nodes, i.e., two components  $X$  and  $Y$ , in it. One of them must be weakly larger than the other. Suppose that  $X$  contains (weakly) more nodes than  $Y$ . As the network is not empty, in component  $X$ , there must some individual  $A$  who has created a link with someone else (say)  $B$ . We will argue that individual  $C$  who is in component  $Y$ , will find it strictly profitable to form a link with  $B$ . Such a link will give  $C$  access to everyone that  $A$  accessed through her link with  $B$ , and in addition it will give her access to  $A$  (via  $B$ ). So, if  $A$  finds it profitable to form the link with  $B$ , then  $C$  must find it even more profitable. This shows that the network with two distinct components  $X$  and  $Y$  cannot be an equilibrium. The argument we propose is general and can be applied to rule out any network with links and with multiple components. This is a contradiction that completes the proof.

The above line of reasoning also brings out a general feature of the economics of linking: when an individual forms links with another person, other individuals will have even greater incentives to follow suit. This is a valuable insight and rules out networks with multiple components.

Recall the examples in Chapter I, regular networks as well as different types of core-periphery networks are all connected. Connectedness is thus a fairly permissive requirement. Does economic behaviour by individuals imply any further restrictions on network architectures?

We consider the role of the two economic variables, the costs of linking  $k$  and the level of decay  $\delta$  in shaping incentives for linking. If costs are very small,  $k < \delta - \delta^2$ , then it is attractive to directly link with everyone and this gives rise to the complete network. The maximum return to a single link is the return to a single neighbour and  $n - 2$  indirect neighbours,  $\delta + (n - 2)\delta^2$ . If the cost of a link is more than this return then no one will form any links and the equilibrium network is empty. For costs between these two thresholds a wide range of networks may arise in equilibrium.

To illustrate some of the possibilities let us start with the case  $k > \delta$ . In this case, the empty network is an equilibrium. In addition, if  $k < \delta + (n - 2)\delta^2$  then the star is also an equilibrium. This brings out the challenge of coordination problem in the linking game. An individual's incentives to form links therefore depends on the linking behaviour of others. Finally, observe that if  $\delta - \delta^2 < k$ , then no two spokes will wish to form a link and

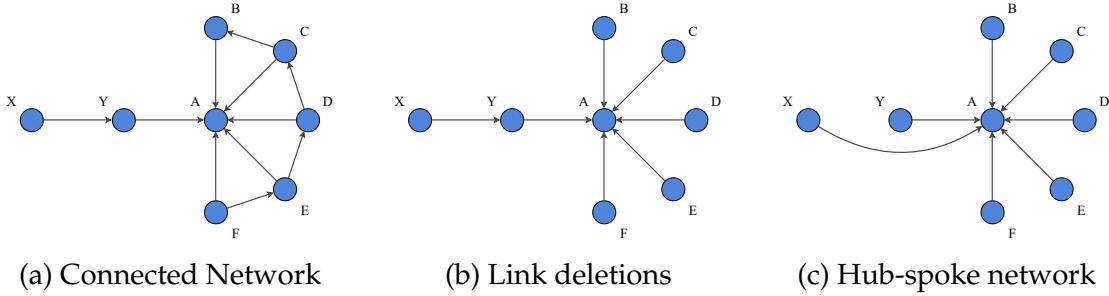

Figure 11.2: Salience of the Hub-Spoke Architecture

since  $k < \delta + (n - 2)\delta^2$  it is optimal to form a single link with the hub. Thus the star is an equilibrium if  $\delta - \delta^2 < k < \delta + (n - 2)\delta^2$ . These observations are summarized in the following result.

**Proposition 11.1.** *Consider the game of linking with payoffs given by (11.2). An equilibrium network is either empty or connected. The complete network is the unique equilibrium if  $k < \delta - \delta^2$ . The star is an equilibrium if  $\delta - \delta^2 < k < \delta + (n - 2)\delta^2$ . The empty network is an equilibrium for  $k > \delta$  and it is the unique equilibrium if  $k > \delta + (n - 2)\delta^2$ .*

To appreciate the economics of network formation at a more general level, it is helpful to consider the situation with  $k > 1$  and  $\delta$  is close to 1. As decay is small, there cannot exist a ‘cycle’ in an equilibrium network. Let us consider a network without a cycle that is not a star. In such a network, there will be at least one pair of individuals who are distance 3 or more apart. Denote the agents farthest apart by  $i$  and  $j$ . They must each have one link (as there are no cycles in the network). Since  $k > 1$  it follows that each of them must be paying for their link. Suppose that individual  $j$  earns a weakly higher payoff as compared to player  $i$ . Let  $j$  have a link with player  $l$  on the unique path between  $i$  and  $j$ . Since the distance between  $i$  and  $j$  is greater than 2 it must be true that individual  $i$  does not have a link with  $l$ . Individual  $i$  can earn a strictly higher payoff if she deletes her current link and instead forms a link with individual  $l$ . This is because she will be at the same distance from all players as player  $j$  in the original network, and, in addition, she will be closer to  $j$  in the new network as compared to in  $g$ . Hence the distance between any two individuals in an equilibrium network cannot be greater than 2. The final step in the argument is to note that the star is the only (acyclic) network in which every pair of players is at a distance of 2 or less.

Figure 11.2 walks us through the logic of this argument with the help of pictures. Start with network on the left of Figure 11.2. In this network, individual  $F$  has no incentive to have a direct link with  $E$ : she can access  $E$  via  $A$ , the loss in benefits  $\delta - \delta^2$  is smaller than the saving in cost  $k$ . Similarly, for individuals  $B-E$ . If we were to delete links, we arrive at

the network on the middle of Figure 11.2. Notice next that X has a strict incentive to delete her link with Y and instead form a link with A. This allows her to shorten distance to B, C, D, E, and F. The distance to Y goes from 1 to 2, but the distance to A correspondingly declines from 2 to 1. This link switch by X yields us the star, at the right of Figure 11.2. This helps us appreciate how individual incentives push toward sparse and unequal networks with a small diameter.

Turning to the question of performance of network, recall that the social welfare from a network  $g$ ,  $W(g)$ , is the sum of individual utilities:

$$W(g) = \sum_{i \in N} \Pi_i(g) \quad (11.4)$$

A network  $g$  is said to be efficient if  $W(g) \geq W(g')$ , for all  $g' \in \mathcal{G}$ .

If the costs of linking are very small,  $k < 2(\delta - \delta^2)$ , it is easy to see that it is socially desirable to form a direct link between every pair of individuals. If on the other hand, the costs of links are very large then at an intuitive level it is clear that no links would be justifiable. We also note that while there is a very rich range of possible networks, the star network is attractive because it economises on the number of links and at the same time keeps the average distance between individuals very low (there are  $n - 1$  links in a star – the minimum number of links it takes to connect  $n$  nodes – and at the average distance is smaller than 2). With these remarks in place, the following result provides a complete description of efficient networks.

**Proposition 11.2.** *Suppose payoffs are given by (11.2). The unique efficient network is (i) the complete network if  $0 < k < 2[\delta - \delta^2]$ , (ii) the star network if  $2[\delta - \delta^2] < k < 2\delta + (n - 2)\delta^2$  and (iii) the empty network if  $2\delta + (n - 2)\delta^2 < k$ .*

We provide a proof of this result as it is instructive to work through the details of the proof of this proposition, as the arguments here are of general interest (the reader will notice that the proof here follows along the same lines as the proof of efficiency in the connections model, in chapter 3).

The joint marginal gains to players  $i$  and  $j$  from forming a link are bounded from below by  $2[\delta - \delta^2]$ . If  $k < 2[\delta - \delta^2]$ , then it follows that forming a link increases social welfare. This means that any incomplete network is welfare dominated by the complete network: in this parameter range, the complete network is uniquely efficient.

Next fix a component  $C_1$  in  $g$ , with  $|C_1| = m$ . Suppose  $m \geq 3$ . Let  $l \geq m - 1$  be the number of links in the component. Then the welfare in  $C_1$  is bounded above by

$$m + l(2\delta - k) + [m(m - 1) - 2l]\delta^2. \quad (11.5)$$

This is because a link ensures direct benefits of  $2\delta$  to each of the connected pairs, the cost of a link is  $k$ , and the closest all other pairs of individuals could be is at distance 2. If the component is a star then social welfare is

$$m + (m - 1)[2\delta - k] + (m - 1)(m - 2)\delta^2 \quad (11.6)$$

where  $m$  reflects stand alone benefits, the second term collects the direct benefits less the costs of links, and the third term reflects benefits of all pairs who are distance two apart.

Under the hypothesis that  $2(\delta - \delta^2) < k$ , expression (11.5) can never exceed (11.6), and the two are exactly equal for  $l = m - 1$ . It can be checked that the star is the only network with  $m$  players and  $m - 1$  links in which every pair of players is at distance of 2 or less. Hence any other network with  $m - 1$  links must have at least one pair of players who are at a distance of 3 or more. This implies that social welfare in any other network with  $l = m - 1$  links is strictly less than social welfare in the star. Thus in an efficient network a component must be a star.

Consider next an efficient network with multiple stars, with  $m$  and  $m'$  individuals, respectively. As the network is efficient the component must have non-negative welfare. It can be shown by direct computation that a single component with  $m + m'$  players has higher social welfare than two components with the star structure. Thus a single star maximizes social welfare in the class of all non-empty networks. Social welfare in a star is given by (11.6) where we substitute  $m$  with  $n$ . It can be checked that the start welfare exceeds welfare in empty network if  $2\delta + (n - 2)\delta^2 > k$ . This completes the argument. ■

An important feature of an economic approach is the systematic exploration of the relation between what individuals wish to do and what is their collective interest. Let us examine this relation in our model. When individual A forms a link with B, she gains access to B, but B also gains access to A. The latter benefit is not taken into account by A if she cares only about her own payoffs: as a result, in our model, networks created by individuals are typically under-connected relative to the networks that they would collectively prefer. This point is clearly brought out both when the costs of linking are small and when they are large. If  $\delta - \delta^2 < k < 2[\delta - \delta^2]$  then the complete network is efficient but it is not an equilibrium (as the returns from first hand links to an individual are smaller than the cost of link). Similarly, if  $\delta + (n - 2)\delta^2 < k < 2\delta + (n - 2)\delta^2$ , then the star network is efficient but no individual has an incentive to form any links: as a result, the unique equilibrium is the empty network.

In this model, linking is driven by individual desire to access others at short distance

and at minimal cost. The theory yields three insights: one, there exist economic pressures for individuals to create sparse and unequal networks that have a short diameter; two, there exist powerful strategic interaction effects that give rise to the possibility of multiple equilibria, and create serious coordination difficulties for individuals (for instance the empty and the star network are both equilibria for a wide range of parameters); three, individual incentives to form links are generally lower than social benefits, so networks created by individuals will generally be sparser than what they would collectively like.

We next comment on how the economic approach relates to the Erdos-Renyi model of random graphs (presented in Chapter 2). Recall that in the Erdos-Renyi model there are two parameters: the probability of linking and the number of nodes. An important result of that model is that the probability of linking must remain at a level above a threshold to ensure that the network remains connected. In a certain sense, the cost of linking performs a similar role in the economic model of linking presented in this section. As the number of nodes grows, the connected network is sustainable for larger and larger costs of a link  $k$  (recall that the star network is stable so long as  $k < \delta + (n - 2)\delta^2$ ). On the other hand, the arguments in the individual linking model reveal a robust multiplicity of outcomes as pointed out above. Coordination issues are central to an economic approach. As the number of nodes grows, the Erdos-Renyi model yields graphs with certain properties, that arise with probability close to 1. Finally, the economic approach offers a definition of the performance of networks founded on individual objectives and helps us appreciate the tension between individual incentives and collective returns. This goes beyond the Erdos-Renyi model and it opens up the space for thinking about interventions that can improve the network.

While the ingredients of the theory are few – the costs of linking and the benefits of linking – and the arguments are simple, it is also clear that, in practice, an individual who is comparing the costs and benefits of forming a link faces a very complex decision: she needs to understand the rewards from linking with different individuals (and also subsets of individuals). To do so, she must be able to compute the shortest paths to various individuals in a large and evolving network. Moreover, even in simple cases, there exist multiple stable networks – e.g., the empty network and the star network in the discussion above – so it is far from clear what networks will actually emerge if individuals were given the payoffs as in the model. To address this concern, we now turn to an experiment with human subjects who play this linking game.

### 11.3.1 Experiment

We report the findings of an experiment on link formation that is taken from Choi, Goyal, and Moisan [2020]. The payoff function is as in equation (11.2). The value of benefits is  $V = 10$  and the decay parameter is  $\delta = 0.9$ . The costs of linking are  $k = 200$ . We will consider a group of 100 subjects.

Given these parameter values, Proposition 11.1 tells us that the empty and star network are both equilibria. In the star network, the hub and spokes earn 901 and 613, respectively. Thus the star network exhibits significant inequality – the hub earns roughly 50% more than the spokes. Individual payoffs in the empty network are equal to 10. Finally, Proposition 11.2 tells us that the star network is the unique efficient network.

Looking ahead, to study the data arising from this large groups, it is more reasonable to consider the statistical properties of networks. With this in mind, we study general aspects of a star network such as density of links, degree inequality and average distances.

**Hypothesis 1** *Subjects create a network that is efficient: it is sparse, unequal, and with small average distances.*

The experiment consists of a continuous time game that is played over 6 minutes. At any point an individual can choose to form and delete links with anyone else. The first minute as a trial period and the subsequent 5 minutes as the game with payment consequences. At the end of each round, every subject is informed, using the same computer screen, of a time moment randomly chosen for payment. Subject are provided detailed information on subjects' behavior at the chosen moment, through the corresponding network structure. The first round was a trial round with no payoff relevance and the only the last 5 rounds were relevant for subjects' earnings. In analyzing the data, we will focus on subjects' behavior and group outcomes from these last 5 rounds.

During a round, at every moment, each subject is informed about the links in their own component and about their own payoff (but not the payoff of any other subject). Figure 11.3 presents the screen observed by a fictitious subject. At any instant in the 6 minutes game, a subject can form/delete a link with any other subject by simply double-clicking on the corresponding node in the computer screen. If the subject forms a link with another subject on the right side of the screen (i.e., someone who is not in the same component), that subject along with the entire component to which they belong would be transferred to the left side of the computer screen. In a case where the subject removes a link with another subject, that subject would be transferred to the right side of the computer screen if they are no longer part of the same component any more and would remain on the left side of the screen otherwise.

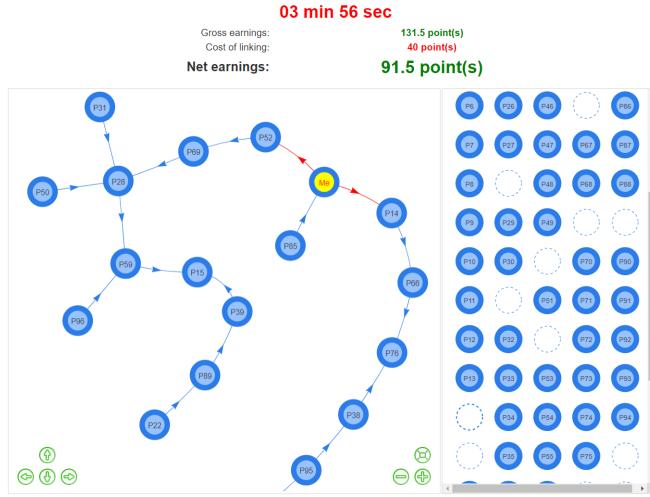

Figure 11.3: Decision screen: linking experiment

On average, a session lasted 90 minutes. On average subjects earned 15.3 euros (this includes a 5 euros show-up fee). The experiments were conducted in the Laboratory for Research in Experimental and Behavioral Economics (LINEEX) at the University of Valencia and the Laboratory for Experimental Economics (LEE) at the University Jaume I of Castellon.

To get a first impression of the outcome of the experiment, we present snapshots of the network at four points in Figure 11.4. These plots suggest that subjects create sparse networks with a few highly connected individuals. Over time one dominant hub emerges. This means that all the individuals are close to each other. As the number of links and small distances are key to efficiency, these snapshots suggest that individual linking gives rise to an efficient network.

We summarize the data from the 20 data relevant round in Figure 11.5 through the time series of four measures – the total number of links, degree inequality, average distance, and efficiency.

The data used from every round of the game consists of 360 observations (snapshots of every subject's choices) selected at intervals of one second. The time series is constructed as follows: for a fixed second  $t$  and for a round  $r$  consider the number of links created  $l_{tr}$ . Sum  $l_{tr}$  across the 24 rounds and then divide through by 24 to obtain an average. This number shows up as the total number of links for second  $t$  in the plot.

By way of background, we note that in these experiments, subjects rapidly coordinate their linking activity and create connected networks: the average size of the largest component was 96.3. So almost everyone belonged to the same component. The statistics below

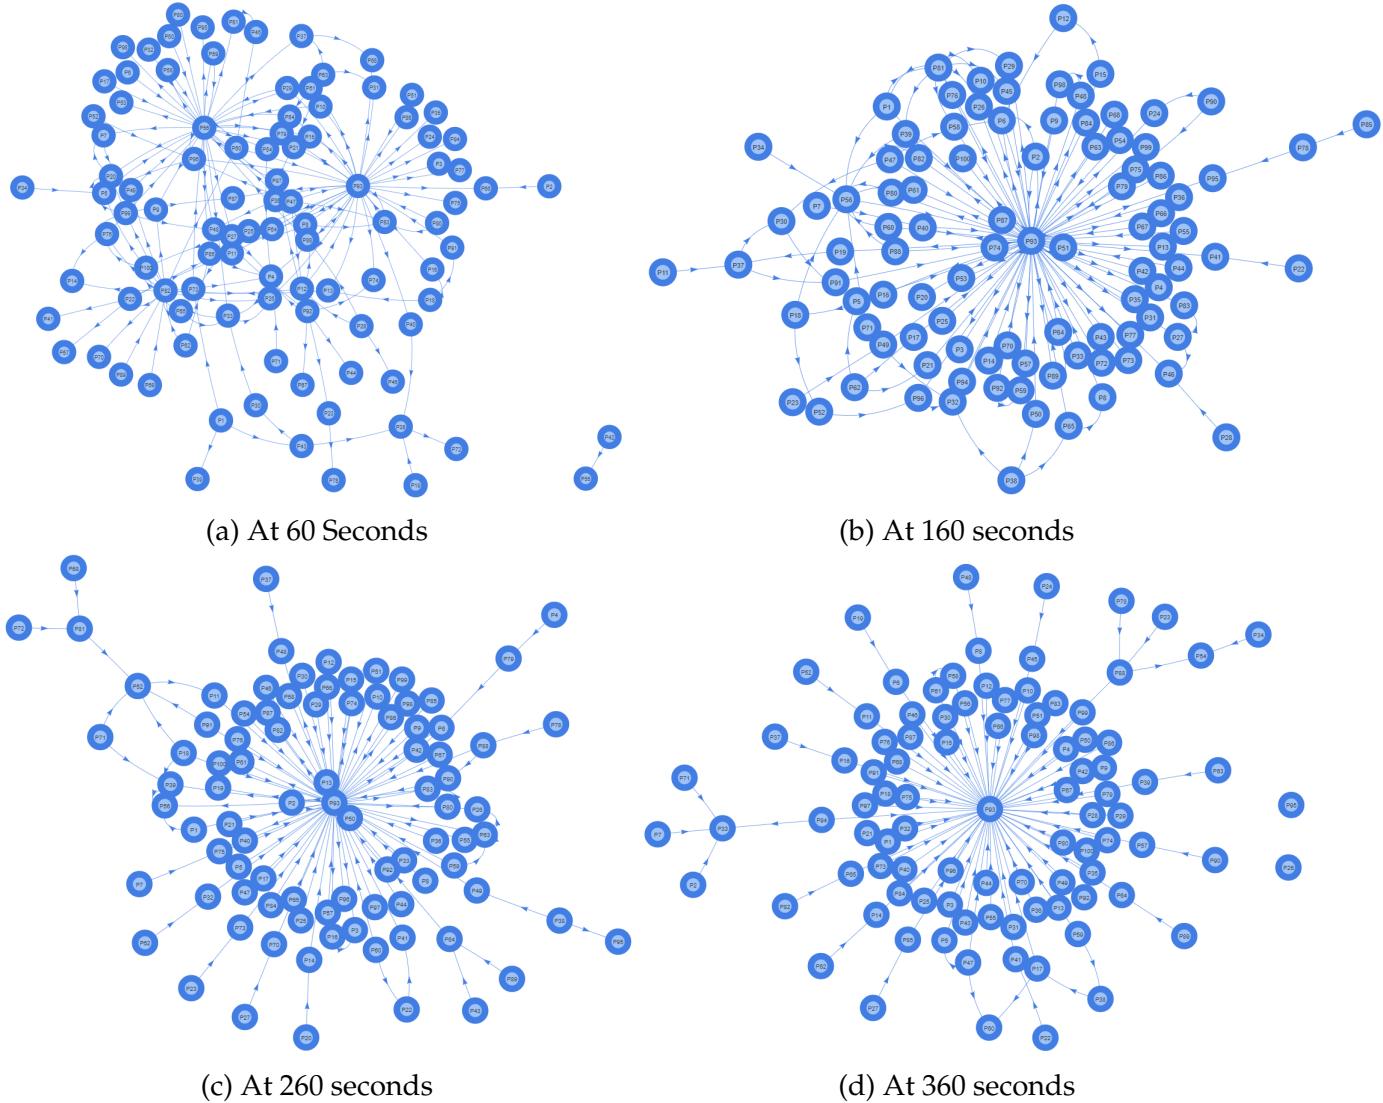

Figure 11.4: The Evolution of an Information Network. Source: Choi, Goyal, and Moisan [2020].

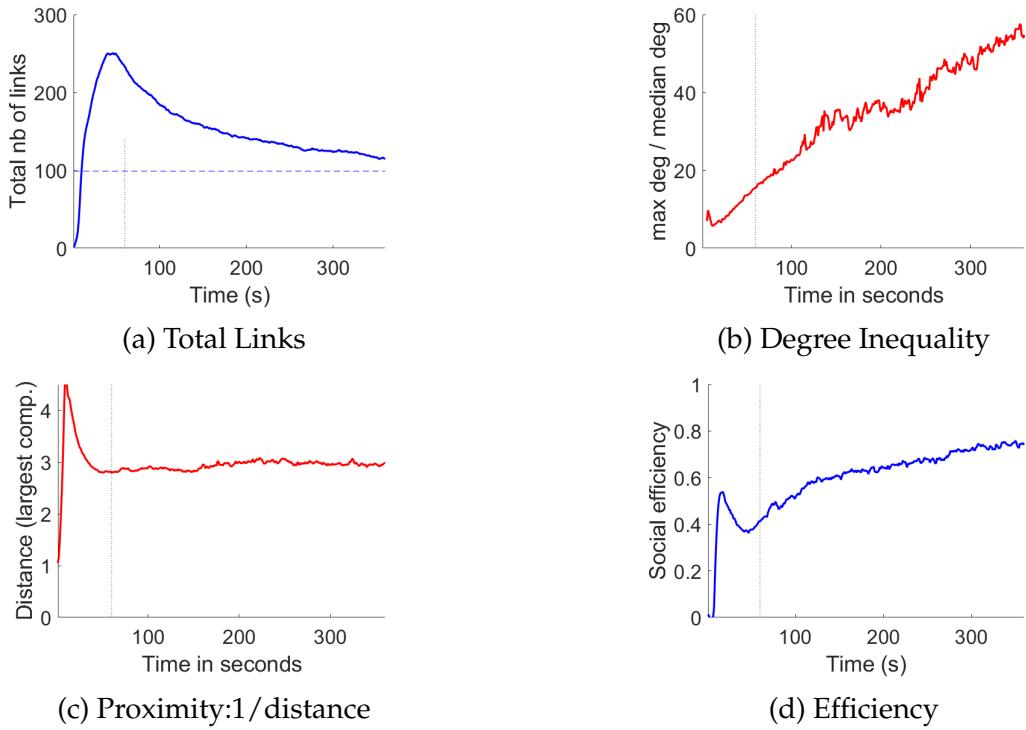

Figure 11.5: Experimental Findings. Source: Choi, Goyal, and Moisan [2020]

on distance pertain to this component.

Figure 11.5a plots the total number of links. The number of links grew at first reaching a level of 250 and then declined steadily until they were a little over around 100 by the end of the experiment. Recall that in a group of 100, the minimal number of links needed for connectedness is 99. Thus subjects were successful in keeping the links close to a minimum.

Next we consider degree inequality: Figure 11.5b presents the ratio of highest degree to median degrees. At the start of the experiment, this ratio is close to 1, but then it grows steadily and by the end it reaches a level over 50. In other words, the most connected node had a degree that is over 50 times more than the median degree.

Figure 11.5c presents the evolution of average distance. We see that fairly early on in the experiment the distance was under 3, and it remains so until the end of the experiment. In view of the group size 100 and the small number of links, this is very low average distance (that is close to the average distance of a star).

Finally, we take up (relative) efficiency: Figure 11.5d presents total payoffs attained as a fraction of maximum possible total earnings. Starting at 50% subjects were able to steadily increase the efficiency and at the end of the experiment they were attaining close to 80% relative efficiency.

We conclude with some remarks on the behaviour of the highly connected individuals.

Figure 11.6 shows that there is intense competition among a couple of individuals to become the hub: this competition takes the form of forming many links. We interpret these links as investments: by forming these links, an individual gets close to others. This makes her attractive as a connector. Once an individual has induced others to become linking with him, she starts deleting links and this induces the newly isolated individuals to respond by forming a link. This process ends with the hub forming almost no links and everyone connects with her.

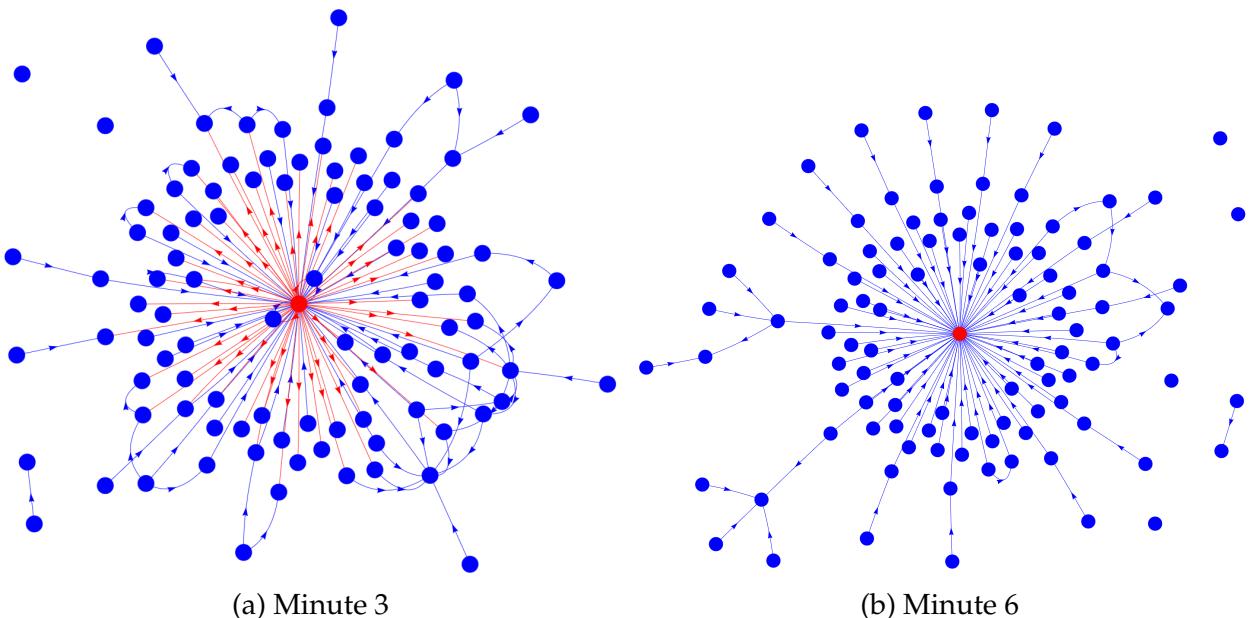

Figure 11.6: Competition to become hub (red links are formed by the red player). Source: Choi, Goyal, and Moisan [2020].

To summarize: The long run outcome of a sparse network with a hub is consistent with the theory we developed in the previous section. However, the experiment reveals an interesting dynamic of large investments and intense competition that underlies the formation of the network. This dynamics goes beyond the theoretical arguments we developed for the star network being an equilibrium.

## 11.4 Who buys information?

A key element in the law of the few is specialization in information acquisition: only a small subset of society actually invests in acquiring information, while most of the others simply connect with them to learn about the world. In the theory presented above, everyone has an equal amount of information at the outset. To understand the determinants of

specialization in purchase of information, we supplement the choices available to individuals. In this richer model, there are therefore three ingredients, one, linking; two, a decay factor; and three, efforts in the purchase of information. The discussion in this section is based on Galeotti and Goyal [2010].

There is a set of individuals  $N = \{1, \dots, n\}$ , where  $n \geq 2$ . Every individual chooses an effort level  $x_i$  and a set of links with others  $g_i$ . A link formed by  $i$  with  $j$  allows  $i$  to access information that  $j$  personally bought and also the information that  $j$  accesses from those she connects to. Let  $s_i = (x_i, g_i)$  be the strategy of individual  $i$  and let  $s = (s_1, \dots, s_n)$  denote the strategy profile of the individuals. The payoff of an individual  $i$  given a strategy profile  $s$ :

$$\Pi_i(s) = f(x_i + \sum_{l=1}^{l=n-1} a_l \sum_{j \in N_i^l(\hat{g})} x_j) - cx_i - d_i(g)k \quad (11.7)$$

where  $a_l \geq 0$ , and  $a_{l+1} \leq a_l$ , for all  $l \geq 1$ ,  $(N_i^l(\hat{g}))$  refers to individuals that are distance  $l$  from individual  $i$  in graph  $\hat{g}$ ,  $c > 0$ ,  $k > 0$ , and  $d_i$  is the number of links created and paid for by individual  $i$ . In the previous section, everyone started with 1 unit of information and for simplicity we assumed that the value of information increasing linearly in the number of people accessed. In the present context, if we were to use a similar linear formulation and the marginal value of information was constant at, say,  $r$  – then individuals would either demand zero or an infinite amount of information, depending on whether  $r$  was smaller or larger than  $c$ . Therefore to make the problem of information demand interesting (and have an interior optimum) we will assume that the marginal value of information declines as an individual has more of it.

**Assumption 11.1.**  $f(0) = 0$ ,  $f(\cdot)$  is strictly increasing and concave. There exists a number  $z$  such that  $f'(z) = c$ , i.e., the marginal benefit is exactly equal to the marginal cost at  $z$ .

Diminishing marginal returns is a reasonable assumption in an information sharing setting: for instance, we may think of the action  $x$  as draws from a distribution, e.g., the price distribution for a product. If the different draws are independent across individuals and players are interested in the lowest price, then the value of an additional draw, which is the change in the average value of the lowest order statistic, is positive but declining in the number of draws. Another possible interpretation is in terms of individuals choosing an action whose payoffs are unknown. Every individual has access to a costly sample of observations – which may reflect personal experience with a product or a technology. A link with another player then allows access to his personal experience. The returns from accessing more samples of information – own and others – are increasing but concave.

We study the Nash equilibrium of this game of information purchase and linking.

Observe that an isolated individual in any network will optimally choose information level  $z$ .

For concreteness and to develop intuitions, following Goyal, Rosenkranz, Weitzel, and Buskens [2017], we will a specific functional form for the value of information:

$$f(y) = \begin{cases} y(29 - y) & \text{if } y \leq 14 \\ 196 + y & \text{else} \end{cases} \quad (11.8)$$

Let us discuss the diminishing returns property with the help of this functional form. Suppose an individual has 5 units of information. How much is one more unit of information worth? To figure this out, we need to work out the difference  $f(6) - f(5)$ . In this example, this number is  $138 - 120 = 18$ . Similarly, one can check that if one already has 8 units of information, the next unit is worth  $180 - 168 = 12$ . So we see that the value of additional units of information declines as one has more information. In particular, if the cost  $c = 11$  then this example the value of  $z$  is given by 9. This number will play an important role in the discussion below.

We next discuss the individual incentives for acquisition of information and for the formation of links. The problem at hand is complicated so we will proceed in steps. First, we will consider the situation where  $a_1 = 1$  and  $a_l = 0$ , for all  $l \geq 2$ .

Consider an individual in isolation: she will choose information up to the point that the incremental value of an additional unit is less than or equal to the cost of information. Then the individual who is on his own will choose exactly 9 units. To see this, observe that the value of the tenth unit is  $190 - 180 = 10 < 11$ . Suppose that A has chosen 9. What would be the response of the other individuals?

To fix ideas, consider an individual and label him ‘B’. How much information should she buy and should she link with A? B accesses 9 units if she links with A. The cost of this information is  $11 \times 9 = 99$  and it costs  $k$  to access A. So it is in her interest to link with A if  $k < 99$ . Observe that once an individual has linked with A, she has access to 9 units of information, so the incremental value of additional information is smaller than the cost of information: so she will choose to acquire 0 units of information personally. The same reasoning applies to all individuals other than A. Therefore, once A chooses 9, if  $k < 99$  then every other individual can do no better than forming a link with A and choosing 0 purchase of information. Thus the star network with A choosing purchase level 9, all other individuals choosing purchase level 0, and forming a link with A constitutes an equilibrium.

To develop this theme further, suppose that  $a_2 = 0$ : so information decays rapidly and

only direct neighbours are useful. Consider a situation where three individuals A, B and C, each choose 3. It follows that an individual D will only link with A if the cost of the link is smaller than the cost of information that D accesses from A. This cost of information is  $11 \times 3 = 27$ . So, if  $k < 33$ , then D will find it profitable to form a link with A, and similarly for B and C. So it follows that the network in which A, B and C (each choosing 3 units of purchase) constitute a core and everyone links to them, constitutes an equilibrium.

In particular, for B to link with A, it must be the case that the link is cheaper than the cost of the information that A acquires. Suppose A acquires  $z$ . For B to link to A it must be the case that  $k < cz$ , otherwise B would be better off purchasing  $z$  on her own and not forming the link with A.

To develop an complete understanding of equilibrium outcomes a key issue concerns the sum total of purchases undertaken by individuals. In the discussion above, we have considered outcomes in which the total purchases of all individuals equal  $z = 9$ . In principle it is possible that total purchases exceed  $z$ . The simplest situation arises when  $k > cz$ : there is a unique equilibrium in which everyone chooses  $z$  and no links are formed. However, the interesting case is when  $k < cz$ : even in this case, total purchases of all individuals may exceed  $z$ .

To see this, consider a game with 4 individuals. The following is an equilibrium outcome: there are two components of two individuals each, and everyone chooses  $z = 4.5$  while one individual chooses a link with the other individual in the component. However, note that in this equilibrium the individual who is choosing a link is indifferent between linking with his current match and an individual in the other component. This suggests that the linking is not a strict best response. Bearing this in mind, we can now state a result that describes all (strict) equilibrium of the game of activity and linking. Define  $I(s) = \{i \in N | x_i > 0\}$ , as the set of individuals who chose positive purchase  $x_i > 0$  under strategy profile  $s$ . The proportion of active players in a strategy profile  $s$  is given by  $|I(s)|/n$ .

**Proposition 11.3.** *Consider the game of information purchase and linking, with  $a_1 = 1$ , and  $a_l = 0$ , for all  $l \geq 2$ . Suppose Assumption 11.1 holds and  $k < cz$ . In a strict Nash equilibrium,  $s^*$ , the sum of information purchases of all individuals is equal to  $z$ . In a large society, in such equilibria, the fraction of active individuals who choose positive purchase is negligible. This active subset constitutes a clique while the rest of the individuals form a link with every individual in the clique.*

Let us sketch the arguments underlying the proof of this result. Fix some strategy profile  $s$ . The total information accessed by individual  $i$  under strategy profile  $s$ ,  $y_i$ , is the sum of her own purchase and the purchase of her neighbours

$$y_i = x_i + \sum_{j \in N_i(\hat{g})} x_j \quad (11.9)$$

We start by noting an important implication of the assumptions on payoffs. In equilibrium, it must be true that for every individual,  $y_i \geq z$ . If  $y_i < z$ , then  $i$  can profitably raise her efforts, as the marginal benefit of the effort at  $y_i$ ,  $f'(y_i)$ , is greater than the marginal cost of effort,  $c$  (this follows from the concavity of  $f$  and the definition of  $z$ ). This implies that, for any active individual  $i$  with  $x_i > 0$  it must be the case that  $y_i = z$ . We have already shown that  $y_i \geq z$ . Suppose that  $y_i > z$ , then  $i$  can profitably lower her efforts, as the marginal benefit of the effort,  $f'(y_i)$ , is lower than the marginal cost of effort.

We next sketch the argument for why the sum total of purchases in a strict equilibrium must equal  $z$ . If total purchases exceeds  $z$ , then we know from the above step that there must exist active individuals who are accessed by some individuals but not by others. It is possible to show that only two configurations of purchases are possible: all positive purchase individuals choose the same activity level and a second one in which they choose two different positive levels (this is an exercise at the end of the chapter). In both cases, it is possible to show that equilibrium implies that the cost of linking must exactly equal the cost of purchase undertaken by such an individual. But then players are indifferent between forming a link and making the corresponding purchase themselves. In other words, the strategies of the players are not a strict best response to the strategies of others.

As total purchase equals  $z$ , and everyone must access at least  $z$ , it follows that, in equilibrium, every individual must access every active individual. This in turn implies that the active individuals must constitute a clique and that inactive players must form a link with every member of this clique.

Finally, consider the specialization in information purchases. Recall that we are considering equilibrium in which the total purchase is  $z$ . We have noted already that for every  $i$ ,  $x_i + \sum_{j \in N_i(\hat{g})} \geq z$ . This means that every player who acquires information personally is accessed by every player in equilibrium. There is therefore at most one player  $i \in I(s)$  with no incoming links, i.e.,  $g_{ji} = 0$ , for all  $j \in N$ . For all other players  $l \in I(s)$ , it must be the case that there is at least one player  $j \in I(s)$  such that  $g_{jl} = 1$ ; but this implies that  $x_l > k/c$ . So the number of ‘incoming links’ players who acquire information personally,  $I(s) - 1$ , is bounded above by  $(zc)/k$ . It follows that  $I(s)/n \leq ([zc/k] + 1)/n$ . The right hand side can be made arbitrarily small by raising  $n$ . This completes the argument underlying the proof. ■

Figure 11.7 illustrates core-periphery networks in which the core is of size 1, 2, 3 and 4, respectively.

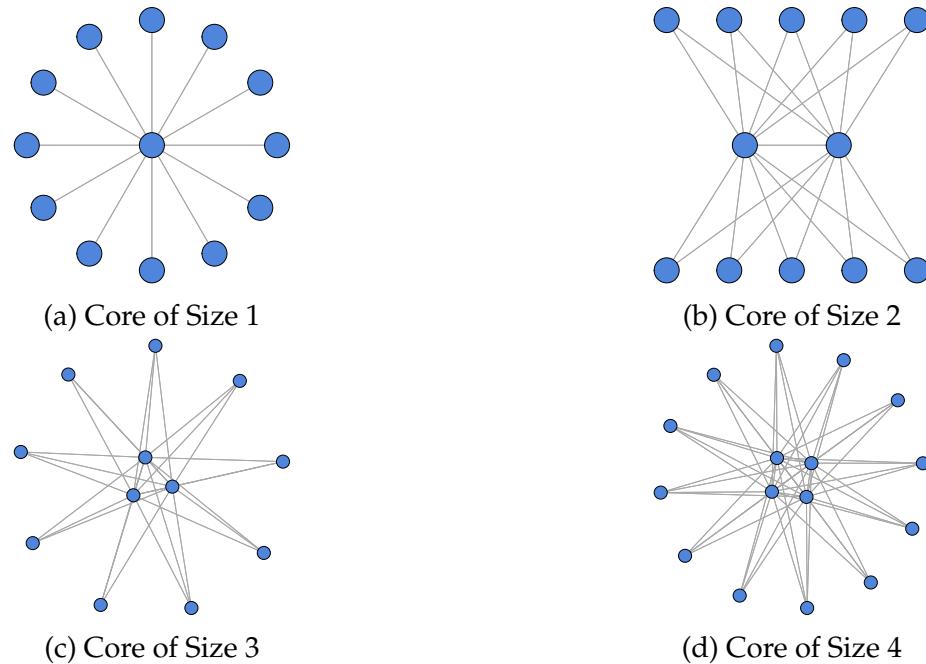

Figure 11.7: Core-Periphery Networks

What does the law of the few imply for individual and collective welfare? A first point to note is that as the cost of purchase is linear, and total effort is the same across these networks, the total cost of effort is equal across the different size cores. Moreover, in these core periphery networks all individuals also access exactly  $z$  units of information. As links are costly, it then follows that the equilibrium with a single core element is most economical and hence maximizes aggregate utility across all core-periphery networks.

Next consider the appropriate level of information purchase. Observe that the purchase level  $z$  equates the return to a single individual with the cost of purchase. However, the social return to an incremental unit of purchase  $z + 1$  is really  $n$  times the private return. Thus the hub individual will choose a level of purchase that is lower than what is collectively desirable. Moreover, the gap between the individually optimal and the socially desirable level of purchase grows with the number of individuals. In large societies characterized by a law of the few network, very little information is actually collected, relative to what would be desirable.

Proposition 11.3 tells us that the number of players personally acquiring information is small relative to the number of players in large societies. But the result is permissive as regards the identity of the hub player. A recurring theme in the empirical literature is that even though hubs seem to have similar demographic characteristics as the others, they have distinctive attitudes that include higher attention to general market information and greater enjoyment in collecting information. One way to incorporate this empirical obser-

vation in the model is to suppose that some players have slightly lower costs of acquiring information (or slightly larger benefits from information) as compared to others. It turns out that this modification has powerful and clear cut effects on who becomes a hub of the network.

To see these effects in the simplest way, let us suppose that one individual (say) Mr A has slightly lower costs of purchasing information as compared to the others. For this low cost player the optimal information level,  $z_A$ , is greater than the optimal information level for other players  $z$ . From the arguments developed in Proposition 11.4 we know that aggregate information purchase by the rest of the population is at most  $z$ . This means that A must personally purchase some information, i.e.,  $x_A > 0$ . If  $x_A = z_A > z$  then the best response of everyone else is clearly to purchase no information and to form a link with A. Next consider the case of  $x_1 < z_A$ : we know, from our discussions earlier that optimality of A's choice implies that  $x_A + y_A = z_A$  and so there is a player  $i \neq A$  with  $x_i > 0$  and  $x_i + y_i = z$ . A key observation is that someone wants to link with  $i$  then it must be profitable for everyone else to do likewise. But then  $i$  accesses all information,  $z_A > z$ , and this contradicts the optimality of  $i$ 's choices. Thus *no* player can have a link with player  $i \neq A$  in equilibrium. Hence,  $i$  must form a link with player A, and, from the optimality of linking, so must every other player. Thus, in any equilibrium, the low cost player is the unique hub. Finally, since every player is choosing positive effort, the equilibrium values of  $x_A$  and  $x_i$  are given by the two equations  $x_A + (n - 1)x_i = z_A$  and  $x_A + x_i = z$ . A question at the end of the chapter works through the details works through the details of this argument.

### 11.4.1 Indirect information access

In the discussion so far, we have assumed that information flows across direct links only. And we have shown that core-periphery networks in which core nodes are active (and constitute a clique) and periphery nodes choose zero purchase but form links with the core members is the unique outcome. We now take up the more natural case indirect information transmission. To develop a feel for the rich range of possibilities that arise, we consider a simple variant in which neighbours are worth 1, twice removed neighbours are worth  $1/2$ , and all further off neighbours are worth 0, i.e.,  $a_1 = 1$ ,  $a_2 = 1/2$  and  $a_l = 0$ , for all  $l \geq 3$ . For concreteness, we will also assume that  $c = 11$  and  $k = 90$ .

We start by noting that with  $c = 11$ , and a reward function  $f$  as given by (11.8), the optimal purchase level  $z = 9$ . The star network with an active hub is an equilibrium in this setting, as in the earlier model with no indirect flow of benefits. We refer to this as the 'pure

influencer' outcome. The left side of Figure 11.8 illustrates the 'pure influencer' outcome. But now a qualitatively very different configuration of purchases can arise in equilibrium. Let us develop this equilibrium.

In this equilibrium, the network is a star: the hub invests 0 and the spokes each invest  $18/n$ . Thus each spoke has access to exactly  $z = 9$  units of information. The hub is content, as she is accessing  $18(n - 1)/n$  units of information and not incurring any costs. The spokes are content, because the link with the hub yields  $9(n - 2)/n$  units of information and her  $18/n$  purchase supplements this so that she accesses 9 units in all (this equates the marginal cost with the marginal rewards). The costs of the  $(11 \times 9(n - 2)/n)$  are higher than the cost of the link (85), for sufficiently large number of spokes. We refer to this as the 'pure connector' outcome, as the hub does not personally purchase any information but is a connector among active spokes. The right side of Figure 11.8 illustrates this 'pure connector' outcome.

Let us briefly relate the equilibrium outcomes with the empirical research on personal influence. Katz and Lazarsfeld [1966] emphasize that social influencers typically have more social ties and also acquire more information (via radio, newspapers, and television). We interpret this as a situation in which influencers acquire information. This is the case depicted in Figure 11.8 on the left of the panel. In other instances, hubs acquire some — possibly a small amount of — information personally, but their numerous contacts provide much new information, that they then communicate to their neighbors and friends. Here the highly connected individual functions primarily as a connector. This is the case depicted on the right side of the panel in Figure 11.8. The interested reader is referred to Gladwell [2006] for an engaging discussion of connectors.

The theory is still relatively simple. It has four ingredients – the costs of information, the costs of linking, and the benefits of direct and indirect linking – but the individual who is contemplating how much information to purchase, and with whom to link, faces a very complex set of computations. She needs to keep an eye on the purchase of individuals and the different paths that connect them to each other. This problem is greatly compounded when the networks are evolving. Also we must note that there is great multiplicity of equilibrium networks – there exist core-periphery networks with cores of different sizes and the identity of the individuals who constitute the core is not pinned down. To develop a better understanding of the scope of the theory in proving an account for the law of the few, we therefore take this game to the laboratory.

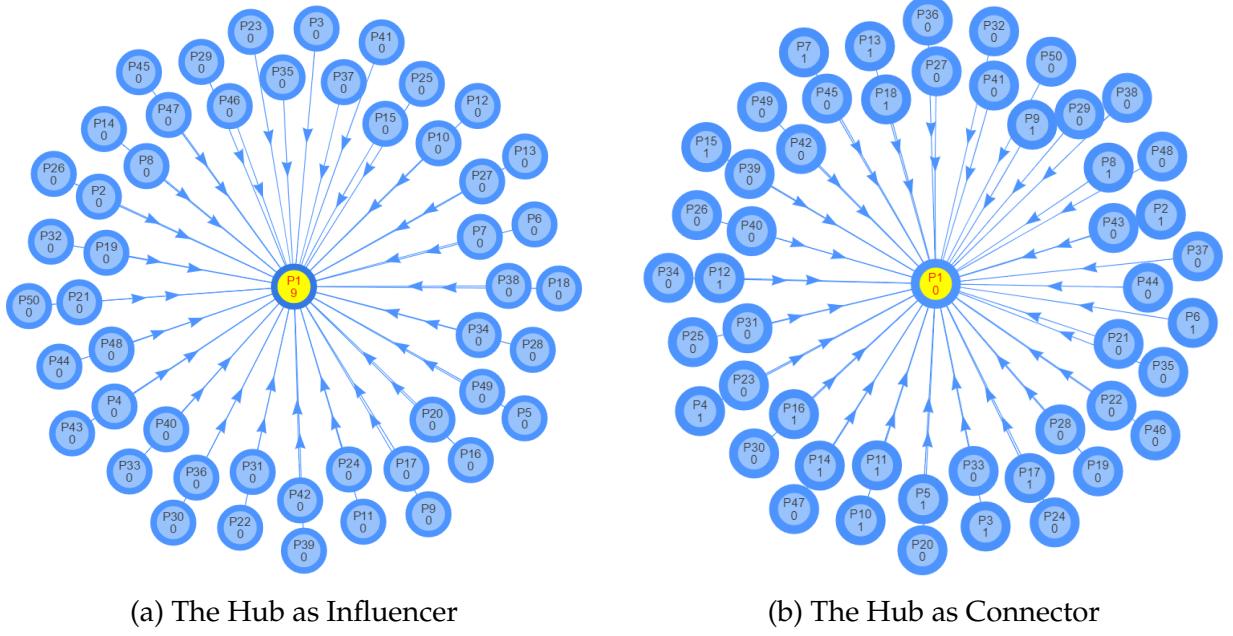

Figure 11.8: Examples of Equilibria

### 11.4.2 Experiment

This section reports the findings of an experiment that is taken from Choi, Goyal, and Moisan [2019]. Human subjects make choices concerning purchases and linking over a six minute interval. The reward function is as given in equation (11.7) and (11.8). The first minute of the experiment is for subjects to get used to the game and is purely for practice: it does not count for payoffs. Once the six minutes end, an instant is picked at random from the last five minutes. The earnings of the subjects are computed for this instant and they are paid these earnings.

For simplicity, the purchases are assumed to take on integer values only and there is an upper bound,  $\bar{x} = 20$ . The cost of a unit of information is  $c = 11$  and the cost of a link is  $k = 95$ ; finally,  $a_1 = 1$ ,  $a_2 = 1/2$ , and  $a_l = 0$ , for all  $l \geq 3$ . Given these parameters, the (stand-alone) optimum effort  $z$  is equal to 9. We will assume that the group consists of 100 individuals.

Given these parameter values, Proposition 11.3 tells us that there exists a pure influencer equilibrium in which a single individual chooses 9, all other individuals choose 0 and form a link with this positive purchase player. There also exists a pure connector outcome with 18 peripheral individuals choosing 1, while the rest of the subjects choose 0. This outcome constitutes an ‘approximate’ pure connector equilibrium (this is an ‘approximate’ equilibrium, because the periphery player who chooses purchase level 1 and forms a link with the hub earns 79.25, whereas she could earn 81 by deleting the link and instead

choosing purchase level 9).

In the pure influencer equilibrium, the hub chooses information purchase of 9, while the spokes choose 0. The hub earns 81, while the spokes each earn 85. In the pure connector equilibrium, the hub chooses purchase level 0, eighteen spokes choose 1 each, while the other spokes choose 0. The hub earns 198, the active spokes 74, and the inactive spokes 85. Hence, there is little earnings inequality in the pure influencer equilibrium, but there are significant inequality in the pure connector equilibrium.

We have noted in our discussion on efficiency that, for any given level of information purchase, the hub-spoke network maximizes aggregate player welfare. Taking together our characterization of equilibrium with our observations on efficiency and equity leads us to propose the following hypothesis.

**Hypothesis 2** *Subjects create efficient networks that are sparse and have small average distance.*

*The most connected subjects purchase more information than the other subjects.*

At the end of each round, every subject is informed, using the same computer screen, of a time moment randomly chosen for payment. The subject is also provided detailed information on subjects' behavior at the chosen moment. While the groups were fixed in a session, subjects' identification numbers were randomly reassigned at the beginning of every round in order to reduce potential repeated game effects. The first round was a trial round with no payoff relevance and the only the last 5 rounds were relevant for subjects' earnings. In analyzing the data, we will focus on subjects' behavior and group outcomes from these last 5 rounds.

There were 3 groups in all; each of them played the 6 minute games six times. Thus a total of 300 subjects participated in the experiment. At the beginning of the experiment, each subject was endowed with an initial balance of 500 points and added positive earnings to or subtracted negative earnings from that initial balance. Subjects' total earnings in the experiment were the sum of earnings across the last 5 rounds and the initial endowment. Each session lasted on average 90 minutes, and subjects earned on average about 18 euros (including a 5 euros show-up fee). The experiments were conducted in the Laboratory for Research in Experimental and Behavioral Economics (LINEEX) at the University of Valencia and the Laboratory for Experimental Economics (LEE) at the University Jaume I of Castellon.

Figures 11.9 and 11.10 present snapshots of the experiment at four points in time. Initially, at minute 1, subject P26 emerges as a hub with the maximum information purchase 20. There are other subjects who make maximal purchase (such as P97). At minute 3, P26 continues to be a hub but has substantially lowered her purchase. Due to this shading of

purchase, she starts to lose some of her links to subject P97 (who has kept her purchase at 20). The transition becomes clearer at the 5 minute mark, when the initial hub subject P26 has lost most of her links to the emerging hub P97. The final figure confirms that this transition to node P97 as the hub is stable, until the end of the game.

The plots presented in Figure 11.11 summarize the data on purchases and networks gathered from these sessions. Let us start with a preliminary remark on the connectivity of the network. The average size of the largest component was 94.8, across the rounds and the groups. So practically everyone belonged to the same component and so the network may be viewed as being connected.

Figure 11.11a presents the evolution of number of total links across the experiment: subjects started around 150 links but the number comes down steadily as the game proceeded and eventually it was close to 100. In a group of 100 this is basically the minimum number of links needed to ensure connectivity of the network.

Figure 11.11b presents the evolution of the ratio of maximum in-degree to mean indegree. At the start this ratio is very high, and it comes down by second 60. After that instant, it rises consistently and throughout the payoff relevant period of the experiment, from second 60 until second 360, the ratio grows steadily and eventually reaches 60. Thus subjects create a network with very unequal degrees.

Figure 11.11c presents the evolution of average distance (in the main component). Proximity between two nodes is the inverse of the distance. The figure shows proximity reaches 0.4 by second 60, and then stays at this level for the rest of the experiment. In other words, the average distance in the network was under 2.5 practically throughout the experiment) a number that is only slightly larger than proximity 2, that would obtain in a star network).

Finally, Figure 11.11d presents the time series of purchases of three types of individuals: the most connected individuals and everyone else. The plot shows that the top two connected individuals at any point make much larger purchases and all the other individuals make small purchases that are tailing off and becoming negligible.

These large purchases of information by competing hubs has the effect of lowering their payoffs. Indeed, the two most connected individuals earn less than the individuals who make low purchases. In a pure connector equilibrium the hub player earns large rents: so there is an incentive to make large information purchases in order to become a hub. The puzzling aspect is that these competing hubs purchase too much information for too long and as a result there is not enough time left to recover their investments. It is possible that they fail to anticipate that the benefits they can reap as a hub later do not sufficiently compensate for the early costs of competing. This could be due to computational complexity: it is indeed difficult to compute expected payoffs from being a hub, and the only way for

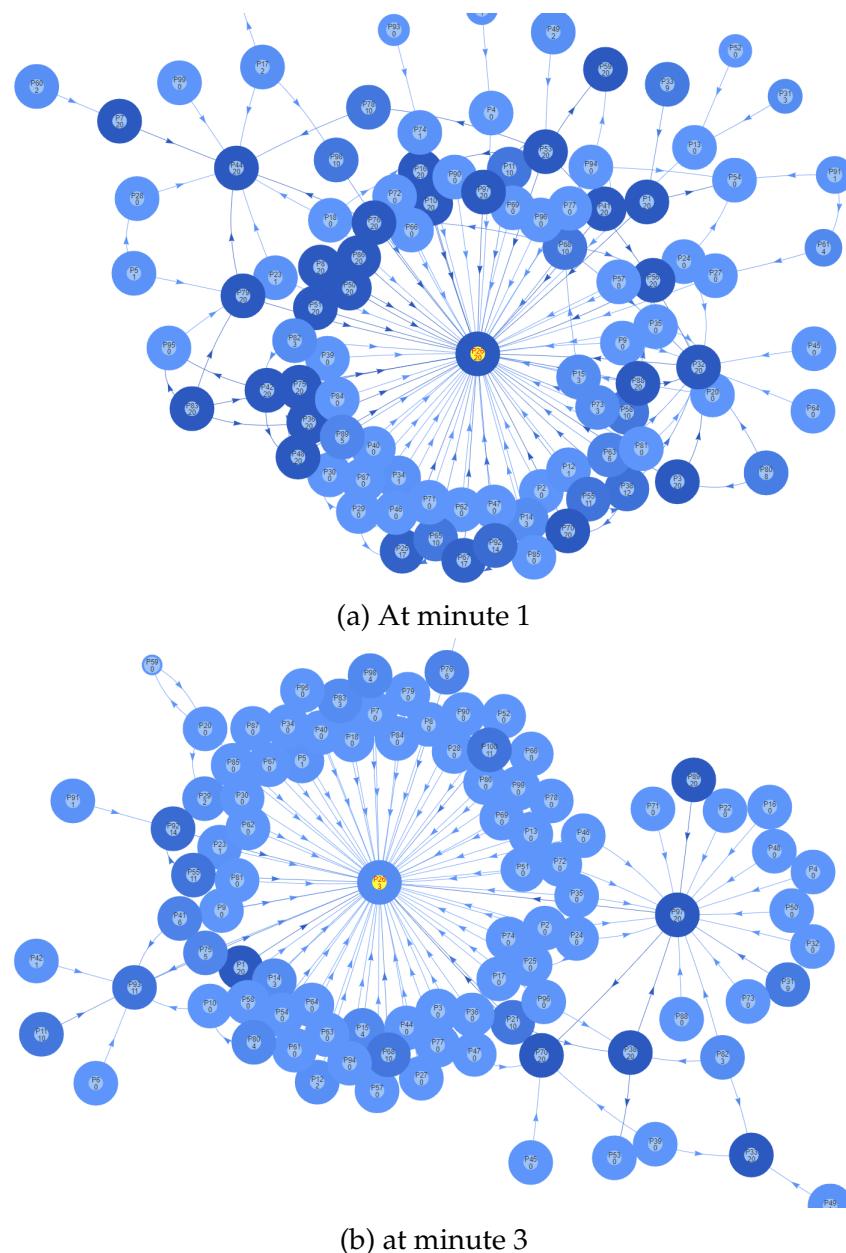

Figure 11.9: Snap shots. Source: Choi, Goyal, and Moisan [2019].

subjects to find out may be to actually reach that position, in which case it is too late to realize the important costs they already paid are not worth the benefits. In the treatment discussed so far, subjects were only shown their own payoffs but not the payoffs of others. We now consider a treatment in which subjects are shown the payoffs of everyone.

Sharing everyone's payoff can potentially help because this information can reduce computational complexity: subjects do not need to compute expected payoffs for being a hub, or wait until they reach that position to find out, they can now simply observe how much others earn by reaching such a position. If they see that payoffs are not large then they may compete less aggressively. This treatment also tests the alternative hypothesis on status or efficiency, because seeing others' payoffs should not have any effect on their behavior in that case.

As in the baseline treatment, this experiment also considers 3 groups and for each group there are 5 payoff relevant rounds, so there were 15 rounds in all. The experiment reveal that showing information on everyone's payoffs to subjects has powerful effects: the hub chooses low effort in the majority of the rounds. Indeed, in 40% out of the 20 rounds the hub chooses 0 information purchase, giving rise to the pure connector outcome. This is

in sharp contrast to the pure influencer outcome observed in all the rounds in the baseline information treatment discussed above. Complexity of the environment may be an explanation for the excessive information purchases by the hub in the baseline treatment. Figures 11.13 and 11.13 present a representative instance of the dynamic leading to the pure connector outcome.

To summarize, we find that subjects make choices that lead to extreme specialization in purchase of information and in linking. This is very much in line with the law of the few. However, the experiment draws attention to the dynamics of competition and the role of informational complexity in shaping behaviour; these factors go beyond the arguments we used to prove the equilibrium properties in the static model.

## 11.5 Monetizing network status

So far, in our examination of social networks we have taken the view that individuals form links and exert efforts (to purchase information or to tweet) solely for purposes of acquiring information. In real world networks like Twitter or Facebook ‘links’ and followers may be used to generate monetary returns. This section explores the implications of such monetary returns for the structure and functioning of communication networks. The discussion is based on Galeotti and Goyal [2010] and van Leeuwen et al. [2020].

In the model of information purchase and linking presented in section 11.4, we may interpret the cost incurred in the formation of a link as a payment that the player forming the link makes to the person receiving the link. In this case,  $k$  becomes a transfer and the payoffs to player  $i$  in a strategy profile  $s = (x, g)$  are given by:

$$\Pi_i(s) = f \left( x_i + \sum_{j \in N_i(g)} x_j \right) - cx_i - d_i(g)k + \sum_{j \in N} g_{jik}. \quad (11.10)$$

Observe that the last term involving transfers is independent of the strategy of  $i$ . It then follows that for all  $s_{-i} \in S_{-i}$ , and  $s_i, s'_i \in S_i$ ,  $\hat{\Pi}_i(s_i, s_{-i}) \geq \hat{\Pi}_i(s'_i, s_{-i})$ , if and only if  $\Pi_i(s_i, s_{-i}) \geq \Pi_i(s'_i, s_{-i})$ . Therefore our methods of analysis and our findings from section 11.4 carry over to the alternative model where link formation costs are transfers from one individual to another. Note that the payoff in 11.7 corresponds to the case with no indirect information communication. This means that the equilibrium outcomes will be as described in Proposition 11.3.

While the profile of information purchase and the network remain unchanged there is a profound difference in the distribution of payoffs. The active individuals in the core

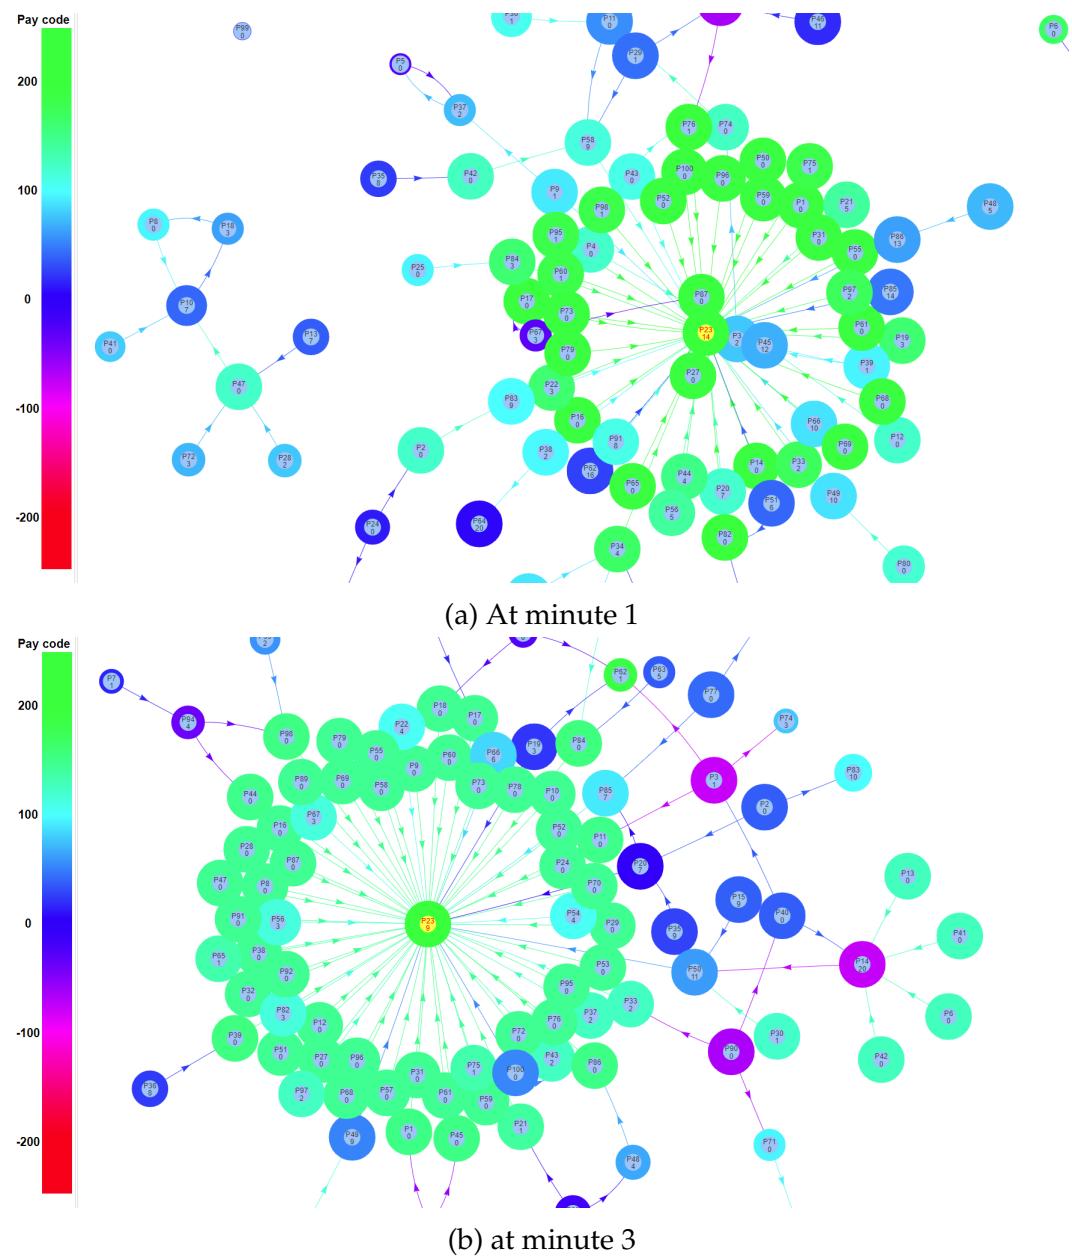

Figure 11.12: Snap shots with payoff information. Source: Choi, Goyal, and Moisan [2019].

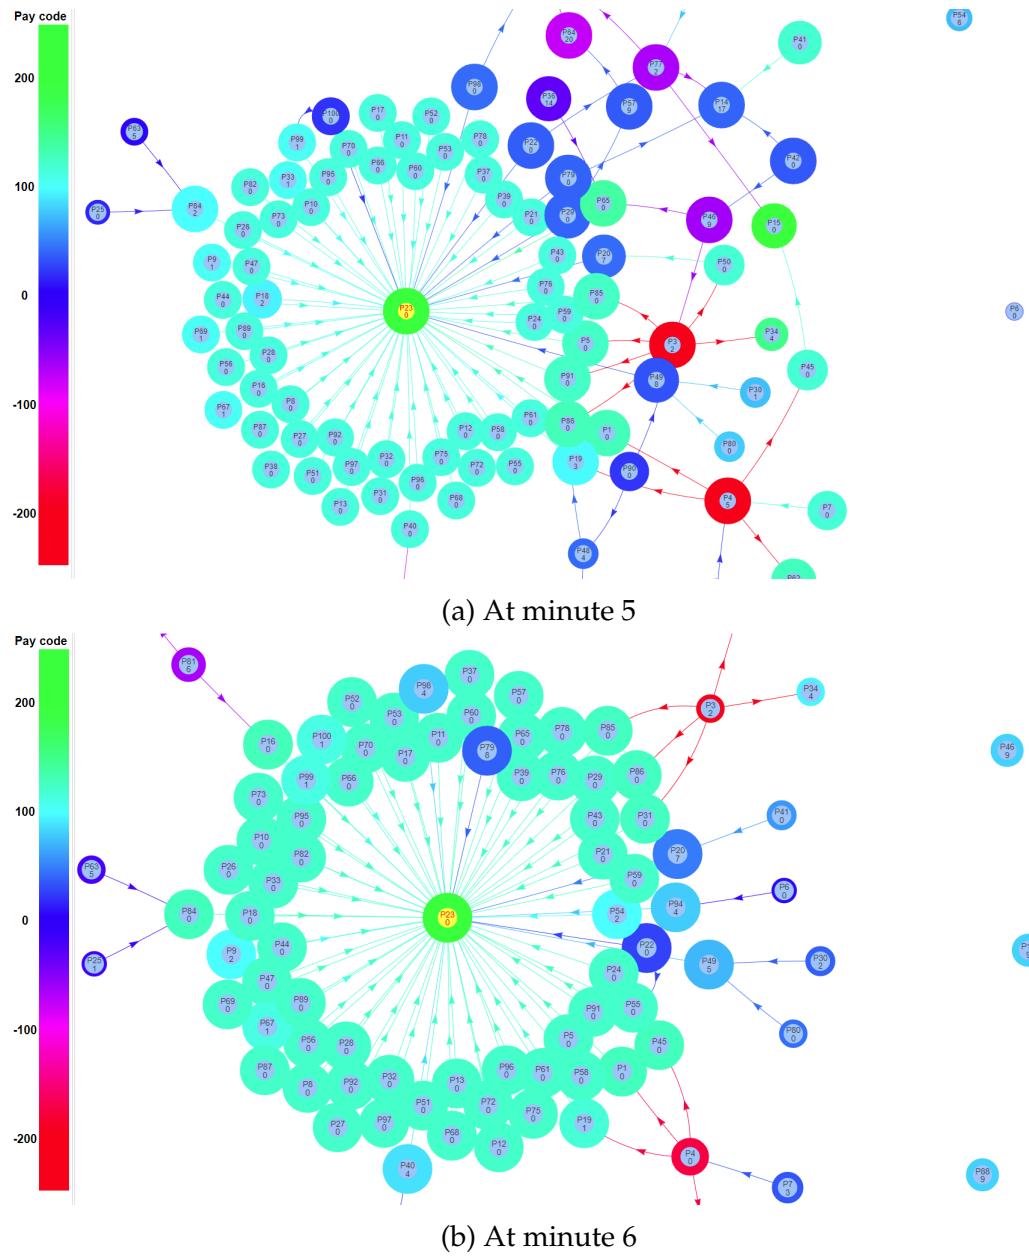

Figure 11.13: Snap shots with payoff information. Source: Choi, Goyal, and Moisan [2019].

will earn link based transfers that will increase linearly in the size of the population. In large populations, there will therefore arise a great gap in payoffs between the core and the periphery (that is quite different from the payoff distribution in the baseline model with no monetary transfers). The argument above tells us that the Nash equilibrium of the static game are unaffected by this possibility. However, in a more natural and realistic setting, where links are formed and deleted and information purchase evolves over time, we can see that the possibility of large payoffs differences may make a difference. We have seen this dynamic in one form already in the experiments we have presented on the pure linking game in section 11.3 and on information purchase and linking in section 11.4. In both these experiments we see intense competition to become a hub so as to earn (slightly) larger returns than the periphery. We expect that these pressures to be amplified when the payoffs are substantially larger for the hub.

A recent experiment by van Leeuwen, Offerman, and Schram [2020] shows that this is indeed the case. They consider a repeated game setting in which at each stage the players play the static game of information purchase and linking. They have a  $2 \times 2$  design: two group sizes (4 and 8) and two payoff models (one without link based payments transfers and one with transfers). Their main results are as follows. In the baseline model without link based payments, there is little specialization in information purchase or linking in both the group sizes. Link based transfers have a dramatic impact and these effects interact with size. Subjects specialize in efforts and a star network emerges. Moreover, the efforts of the hub are much larger in the larger group as compared to the smaller group. This is in line with the intuitions we spelled out: a larger group means a larger payoff for the individual who becomes the hub. This leads individuals to compete more vigorously to become the hub and this is reflected in larger information purchase by them. Indeed, the hub subjects choose efforts that are close to the first best level of effort (and thus significantly greater than the equilibrium level). In this experiment, the efforts of the hubs are so high that the net earnings of the hub are not very different from those of the peripheral individuals. This similarity in payoffs between peripheral individuals and hubs lends stability to the outcome: there is no great incentive for the different individuals to switch places.

Putting together the models and experiments reported in this chapter we are led to the view that individual attempts to economise on costs of linking and information purchase and to effectively access information from others leads to a law of the few. The theory also points to an important welfare problem in these networks: individual efforts possess ‘public good’ features so that equilibrium efforts will be smaller than what is in their collective interest. In small societies, monetizing network connections can circumvent this public good problem by inducing hubs to exert large efforts. However, as the scale of the society

grows, there appear to be large initial mover advantages and an individual who becomes a hub can, over time, retain her status despite lowering her personal efforts to zero. This pure connector hub earns much more than the peripheral individuals.

## 11.6 Reading Notes

The chapter starts with a brief empirical overview of the empirical structure of communication networks. The interest on influencers and the importance of social communication dates from the early work of Katz and Lazarsfeld [1966] and Lazarsfeld, Berelson, and Gaudet [1948]. For more recent research on the role of influencers in social communication, see Feick and Price [1987] and Beck et al. [2002] and Zhang, Ackerman, and Adamic [2007]. For a engaging popular introduction to the subject of personal influence in social networks see Gladwell [2006]. The title of this chapter, ‘the law of the few’ is taken from Gladwell [2006].

This chapter uses the economic theory of network formation to explore the law of the few for information and communication in social networks. For a general introduction to the economic theory of network formation see chapter 3 in the book. Earlier surveys inclue Goyal [2007b] and Jackson [2008]. For a recent overview of the research in this field see Mauleon and Vannetelbosch [2016].

The chapter presents models of network formation in which individuals can unilaterally decide to form links. Unilateral link formation has the advantage that it allows us to use the tools of non-cooperative game theory to analyze the games of linking. This facilitates a study of a number of questions using familiar methods. We start with an exposition of the two-way flow model in Bala and Goyal [2000a]. The model yields simple and intuitive results on network structure and on relation between equilibrium and efficient networks. It also shows that there typically exist multiple equilibrium in this model that reflect the complementarity of links. The two-way flow model has been developed along different dimensions over the years. Researchers have examined richer models of benefits, different link formation protocols, bounded rationality of individuals, and heterogeneity across individuals in costs and in benefits (see e.g., Galeotti, Goyal, and Kamphorst [2006], Ferri [2007], Hojman and Szeidl [2008]); for surveys of the research in this line of work see Goyal [2007b], Jackson [2008] and Mauleon and Vannetelbosch [2016].

The chapter then turns to an experimental test of the theory. Building on a suggestion of Goeree, Riedl, and Ule [2009], we take the view that in realistic group sizes, it is more natural to study networks that have the same broad properties as the equilibrium rather than focusing on the creation of an exact equilibrium network. So, for a star, we look

for sparseness, inequality of connections and small average distance. The experimental findings are taken from Choi, Goyal, and Moisan [2020].

There is by now a large body of experimental work on networks; for surveys see Choi, Gallo, and Kariv [2016] and Breza [2016]. In particular, the pure linking game has been the subject of extensive experimental work: papers by Callander and Plott [2005], Falk and Kosfeld [2012] and Goeree, Riedl, and Ule [2009] present experiments on the same model with small groups (four and six subjects and simultaneous moves in discrete time). They consider a parametric setting in which the star network is an equilibrium and it is also the efficient network and find that subjects fail to converge to this network. The experimental findings reported in the chapter support the equilibrium prediction. We covered only large groups of 100, but the authors of the experiment show that they also hold in small group settings. Choi, Goyal, and Moisan [2020] suggest that the difference in results is due to the flexibility afforded by asynchronous choice in continuous time. Network formation with asynchronous choice and continuous time was studied in an early paper by Berninghaus, Ehrhart, and Ott [2006] and more recently by Goyal, Rosenkranz, Weitzel, and Buskens [2017]. The use of continuous time in repeated game experiments has been explored in a number of recent papers, see e.g., Friedman and Oprea [2012]; Calford and Oprea [2017].

With a view to studying specialization in effort – purchase – levels and in linking, the chapter then considers a richer theoretical model that adds effort level choice to the linking choice. The presentation is based on a model from Galeotti and Goyal [2010]. A number of subsequent papers have explored this framework, see e.g., Kinateder and Merlino [2017], Baetz [2015], Perego and Yuksel [2016], Sethi and Yildiz [2016], and Herskovic and Ramos [2020]. These models may be seen as combining the two-way linking model of Bala and Goyal [2000a] with the public goods model in networks model of Bramouille and Kranton [2007].

Let us make a general point about the game studied in the chapter: the reward function  $f$  is increasing and concave. This means that marginal return to increasing personal effort is falling with the total effort of the neighbors. In other words, efforts of neighbours are strategic substitutes. Several steps in the analysis exploit this feature of the reward function. In follow up work Baetz [2015] and Hiller [2017] study a model in which efforts of neighbours are strategic complements. Complementarity can give rise to a multi-layered network in which more highly linked subsets of individuals exert higher effort as compared to less well connected individuals. For an overview on games of linking and actions see Vega-Redondo [2016].

We present a large scale experiment of this richer model on information purchase and linking. The presentation of the experiment is taken from Choi, Goyal, and Moisan [2020].

This experiment offers strong support for specialization in purchase and linking, in line with the law of the few. However, the experiment also reveals dynamics that go well beyond the arguments invoked in the static model. We then present a related experimental paper by van Leeuwen, Offerman, and Schram [2020] who consider a finitely repeated version of Galeotti and Goyal [2010] in which they include monetary transfers based on incoming links.

We would also like to also mention the strand of research in which players choose partners and then play a coordination game (Riedl, Rohde, and Strobel [2015], Kearns, Judd, and Vorobeychik [2012], Goyal, Hernandez, Martinez, Moisan, Munoz, and Sanchez [forthcoming], and Leider, Mobius, Rosenblat, and Do [2009]. The interest is in how networks affect behavior and in how allowing for endogenous networks affects behavior.

The models in this chapter focus on individuals in social networks and do not consider the role of profit making firms. In practice large social networks are run by firms that seek to maximize profits. The reader is referred to chapters 8, 15 and 16 for discussions on how firms (and platforms) interact with information networks.

## 11.7 Questions

1. Consider a model in which link creation is unilateral, while benefits flow both ways (as in the chapter). In particular, if A forms a link with B, then both A and B can access each other. Suppose that there is no decay. Define  $\hat{g}_{ij} = \max\{g_{ij}, g_{ji}\}$ . Let  $N_i(\hat{g})$  be the set of individuals that  $i$  can access in network  $\hat{g}$ . The payoff to individual  $i$  in network  $\hat{g}$  is

$$\Pi_i(\hat{g}) = 1 + n_i(\hat{g}) - d_i(\hat{g})c, \quad (11.11)$$

where  $n_i(\hat{g}) = N_i(\hat{g})$  is the number of individuals accessed by  $i$  in network  $\hat{g}$  and  $c$  is the cost of a link.

- (a) Show that an equilibrium network is either connected or empty.
  - (b) Show that the connected equilibrium network is a tree.
  - (c) Describe the efficient networks as a function of  $c$  and  $n$ .
  - (d) Show that strict Nash equilibrium is a hub-spoke network (in which the hub forms all the links) for  $c < 1$  and the empty network for  $c > 1$ .
2. (Hojman and Szeidl [2008]) Suppose the payoffs to individual  $i$  in network  $g$  are given by:

$$\Pi_i(g) = f(a_1 n_i^1(g) + \dots + a_{n-1} n_i^{n-1}(g)) - d_i c \quad (11.12)$$

where  $N_i^k(\hat{g})$  is the number of individuals who are at (geodesic) distance  $k$  from individual  $i$  in (the undirected network associated with) network  $g$ ,  $a_1 \geq a_2 \geq a_3 \geq \dots \geq a_d$  and  $c > 0$ . Assume that  $f(\cdot)$  is an increasing and concave function; communication only takes place within a certain distance (there is a  $D < n$  such that  $a_{d'} = 0$  for all  $d' \geq D$ ); and that there are eventually strongly diminishing returns to communication (there is some  $M$  such that for  $m \geq M$ ,  $f(m) - f(m/2) \leq c$ ). Show that if the number of players is large enough, relative to  $M$  and  $D$ , and if  $a_2 > a_3$ , then the star network in which a peripheral players form link with the hub is the unique equilibrium network.

3. Consider a game of efforts and linking. Every individual chooses an action  $\{0, 1\}$  and chooses unilaterally to connect to a subset of other players. The cost of action 0 is zero and the costs of action 1 is  $c$ . The cost of a link is  $k$  where  $k \in (0, c)$ . Let  $s_i = (a_i, g_i)$  be the strategy of player  $i$ , and  $s = (s_1, \dots, s_n)$  be the strategy profile of all players. Given a directed network  $g$ , define  $\hat{g}_{ij} = \max\{g_{ij}, g_{ji}\}$  and the corresponding network  $\hat{g}$ . Let  $N_i(\hat{g}) = \{j | \hat{g}_{ij} = 1\}$  and let  $y_i = a_i + \sum_{j \in N_i(\hat{g})} a_j$  denote the sum of efforts of player  $i$  and his neighbours in network  $g$ . Suppose that  $f(y_i) = 1$  if  $y_i \geq 1$  and 0 otherwise. The payoff to a player from a strategy profile  $s$  is given by

$$\Pi_i(s) = f(y_i) - a_i.c - d_i.k \quad (11.13)$$

where  $d_i$  is the number of links formed by  $i$  under strategy profile  $s$ . Describe the equilibrium when  $k < c$  and the equilibrium when  $k > c$ .

4. Consider a game of efforts and linking as in previous question. Suppose however that the efforts of neighbours are strategic complements (instead of strategic substitutes). Define  $b_i = \sum_{j \in N_i(\hat{g})} a_j$ . Let the payoff to a player from a strategy profile  $s$  is given by

$$\Pi_i(s) = x_i \times b_i - a_i.c - d_i.k \quad (11.14)$$

where  $d_i$  is the number of links formed by  $i$  under strategy profile  $s$ . Describe the equilibrium of this game. Discuss how moving from substitutes to complements alters equilibrium.

5. Consider the game of information purchase and linking as described in section 11.4. Suppose that the assumptions of Proposition 11.3 hold. Let  $\mathbf{s}^* = (\mathbf{x}^*, \mathbf{g}^*)$  be a Nash equilibrium of the game.
  - (a) If  $\sum_{i \in N} x_i^* = z$  then  $\mathbf{g}^*$  is a core-periphery network, hubs purchase information

personally and spokes purchase no information personally.

(b) If  $\sum_{i \in N} x_i^* > z$  then:

- Every player  $i \in I(\mathbf{s}^*)$  chooses  $x_i^* = \frac{z}{\Delta+1} = \frac{k}{c}$  and has  $\Delta \in \{1, \dots, n-2\}$  links within  $I(\mathbf{s}^*)$ , while every player  $j \notin I(\mathbf{s}^*)$  forms  $\Delta + 1$  links with players in  $I(\mathbf{s}^*)$ .
- High information level players choose  $\bar{x}^* = \frac{k}{c}$ , low information level players have  $\eta$  links with high information level players, they are not neighbors of each other and choose information  $\underline{x}^* = \hat{y} - \eta \frac{k}{c}$ , where  $\frac{\hat{y}c}{k} - 1 < \eta < \frac{\hat{y}c}{k}$ .

6. Consider the game of information purchase and linking as described in section 11.4. Suppose that the cost of purchasing information is  $c_i = c$  for all  $i \neq 1$ , but  $c_1 = c - \epsilon > 0$ , where  $\epsilon > 0$  is a small number. Let  $z_1 = \arg \max_y f(y) - c_1 y$ . Clearly, as long as  $\epsilon > 0$ ,  $z_1 > z$ , and  $z_1 \rightarrow z$  as  $\epsilon \rightarrow 0$ . Suppose  $k < f(z_1) - f(z) + cz$ . Show that in a strict Nash equilibrium  $\mathbf{s}^* = (\mathbf{x}^*, \mathbf{g}^*)$  the following is true

- $\sum_{i \in N} x_i^* = z_1$ ,
- the network is a star and player 1 is the hub, and
- either  $x_1^* = z_1$  and spokes choose  $x^* = 0$ , OR,  $x_1^* = [(n-1)z - z_1]/[n-2]$  and  $x^* = [z_1 - z]/[n-2]$ .

7. Consider the game of information purchase and linking as described in section 11.4. Let  $s = (e_i, g_i)$  be the strategy of individual  $i$ , and let  $s = (s_1, \dots, s_n)$  denote the strategy profile of the individuals. The payoff of an individual  $i$  given a strategy profile  $s$ :

$$\Pi_i(s) = f(x_i + \sum_l^{n-1} a_l \sum_{j \in N_i^l(\hat{s})} x_j) - cx_i - d_i(g)k \quad (11.15)$$

where  $a_l = 1$ , for all  $l \geq 1$ ,  $c > 0$  and  $k > 0$ , and  $d_i$  is the number of links created and paid for by individual  $i$ . Define  $z$ :  $f'(z) = c$ .

- Show that the star network with the hub choosing  $z$  and all others individuals choosing effort 0 and forming a link with the hub is an equilibrium, so long as  $k < cz$ .
- What are the conditions under which a pure connector outcome is an equilibrium?

# Chapter 12: Social Coordination

## 12.1 Introduction

One may view any communication as a form of coordination, one in which the speaker and the listener coordinate on a set of meanings for the words that are being spoken. Indeed, almost all human activity involves coordination: ranging from our use of time, when and how we eat, what to wear, and our use of particular languages and technologies (such as fax machines or telephones). As coordination is so central to our life, it is important for societies to have ‘norms’ or ‘standards’. And once a norm becomes established, any single person would be reluctant to change actions, as mis-coordination is costly. For change to come about, therefore, there must be coordination, and this is one reason why social and cultural change is often so difficult. At the heart of the need for coordination is the fact that it arises out of interaction among different people. In this chapter, we will explore how the patterns of interaction – who interacts with whom – matter as societies work their way toward norms, how they respond to new circumstances and arrive at new norms, and how they navigate the tension between differing personal tastes and the benefits of coordination on common norms.

In the next section, we start by laying out the logic of the coordination problem in a setting with two individuals. We clarify the advantages of coordination and the possibility of more and less risky courses of action. We then locate individuals in their neighbourhoods, that are then embedded in a social network. We study the relation between the structure of the network and the prospects of common and diverse social norms. The simple logic of the coordination problem helps us develop a powerful intuition on this issue: a person will choose A if a high enough fraction of her neighbours choose A. Building on this idea, we say that a subgroup of individuals is *p-cohesive* if everyone in the group has at least fraction *p* of their links within the group. Societies have diverse social norms if they contain multiple cohesive sub-groups.

We turn next to the issue of changing norms. Suppose a society has an established norm and a new superior action becomes available. What are the networks in which the new ac-

tion will be adopted and where will adoption fail? The answer lies in the cohesiveness of societies. Adoption will spread and the new norm will take over the entire network only if there is no suitably cohesive sub-group in the society. How can established norms be changed in cohesive traditional societies? One possibility is to create special insulated conclaves in which new norms can be experimentally tried out and as they succeed, the conclaves can be appropriately integrated with the main network. We discuss Special Economic Zones set up in China (and in other countries) as an instance of a policy in which the network itself is reconfigured.

The possibility that the network changes leads us to develop a framework in which individuals choose links with others and they also choose an action in the coordination game. We study the dynamics of evolving networks and how they interact with choices in the coordination game. Our analysis reveals that the possibility of choosing links has powerful effects on social coordination.

The first part of the chapter studies a setting in which all individuals earn the same payoffs from the different outcomes. We then turn our attention to the setting where everyone prefers to coordinate but individuals have differ on how they view the coordinated outcomes. An important feature of modern societies is that there exist large immigrant communities with a distinct cultural background – differing from the majority on religion, cuisine, and their mother tongue. For instance, while individuals would like to successfully coordinate on a common language, different communities would prefer to coordinate on their own language. Similar considerations arise when we consider dress codes or norms relating to religion, giving rise to a tension between diverse preferences and a desire for a common coordination norm. We study how patterns of interaction shape social norms when such communities interact. The earlier observations on the role of integration within a networks are now reinforced by the differences in preferences.

We develop a framework to study the process of formation of neighbourhoods in a setting where coordination is important but individuals coming from different communities have differing preferences over norms. This allows us to define the tension between diverse norms and social efficiency (that arises when everyone conforms to the same norm). The theoretical analysis shows that a variety of network structures – ranging from full integration and conformism to segregation and diversity are theoretically possible. We test this model in the laboratory and find that when subjects are obliged to interact with everyone they choose to conform on the action preferred by the majority. But if they are allowed to choose their own connections then they create segregated neighbourhoods and settle on diverse norms (even though this is socially sub-optimal).

Elements of the coordination problem appear in a wide variety of concrete and practical

settings. To appreciate the fundamental issues at work it is sometimes easier to work with simple and stylized models. This is the reason why the discussion in this chapter is carried out at an abstract level. For a discussion of the issues of coordination in practical settings the reader is urged to read the chapter on platforms and intermediation. There we take up the many markets in which the benefits of using a product are increasing in the number of adopters of the same product (examples include fax machines, computer operating systems, word processing packages and a variety of online platforms). In the industrial organization of such markets, we are interested in understanding the determinants of successful technology, the processes of standard setting, the introduction of new technologies and the coexistence of incompatible products in the market. The discussion in that chapter focusses on the strategic behaviour of firms and how they grapple with the coordination problem with and without heterogenous preferences.

## 12.2 Coordination in a network

The problem of coordination arises in its simplest form when the optimal course of action is to conform to what others are doing. A well known example is the choice of software to draft documents. As we work with colleagues, we have a preference to choose the software that they are using. In order to bring out the basic elements of the coordination problem, we start with the case of two individuals, 1 and 2, choosing between two actions, A and B. The rewards to a player depend on her own action and the action of the other player. The picture below shows how payoffs are determined as a function of the choices of individuals.

	2	A	B
1			
A	<i>a, a</i>	<i>d, e</i>	
B	<i>e, d</i>	<i>b, b</i>	

Table 1

Choosing the same action is better than choosing different action: the payoff from co-ordinating on either *a* or *b* is thus larger than mis-coordinating, *d* and *e*. It is possible that coordinating on one action is better than coordinating on the other action, so generally *a* and *b* will not be equal. This difference is going to be important when we discuss efficient and inefficient norms (and also when we talk about the introduction of a new superior technology).

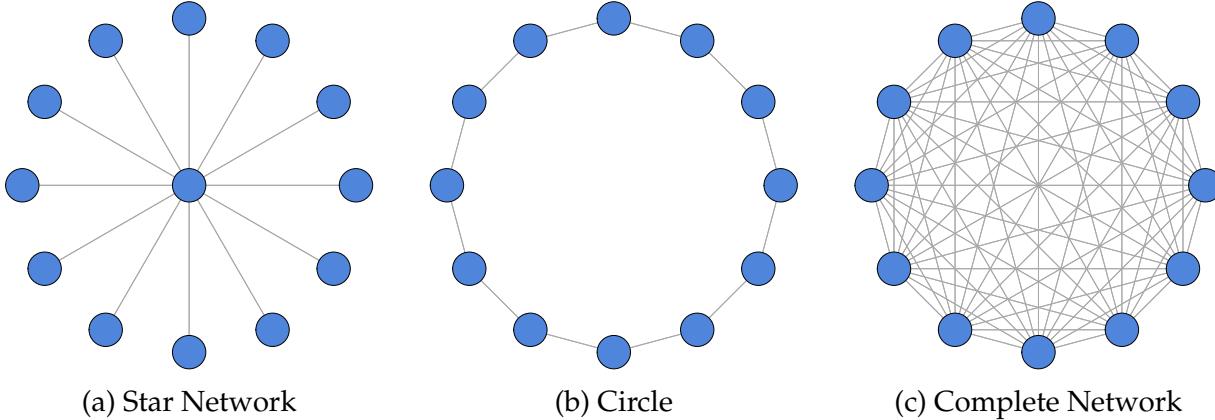

Figure 12.1: Simple networks

A key element in the coordination problem is that individuals make decisions without knowing each other's choices. This uncertainty suggests a natural thought experiment: which action would be best to choose if the other individual is equally likely to choose the other action. the answer to this would depend on the relative values of  $a + d$  versus  $b + e$ . These considerations are summarized in the following restrictions on the values of the payoffs.

$$a > d; \quad b > d; \quad d > e; \quad a + d > b + e. \quad (12.1)$$

Choosing A is optimal when the other individual chooses A. Likewise, for B. In other words, the action combinations  $(A, A)$  and  $(B, B)$  are both Nash equilibria. The assumption that  $a + d > b + e$  means that if a player places equal probability on her opponent playing the two actions then it is strictly better to choose A. Following Harsanyi and Selten [1988], we will say that A is the *risk-dominant* action if  $a + d > b + e$ . Observe that A may be risk-dominant even if  $a$  is smaller than  $b$ , in other words, the efficient and risk-dominant action may not be the same.

As our interest is in social coordination, we extend the above game to allow for several individuals. There are  $N = \{1, 2, \dots, n\}$  with  $n \geq 3$ , individuals located on the nodes of a network  $g \in \mathcal{G}$ . We assume that a player  $i$  plays the coordination game with each of her neighbors,  $N_i(g) = \{j \in N | g_{i,j} = 1\}$ . For concreteness, consider three simple networks – the complete network, the star and local interaction around a circle (Figure 12.1). In the star network, every individual is in the neighbourhood for the hub, while only the hub is in the neighbourhood of each of the spokes. In the complete network, the neighbourhood of every individual includes every other person. In the circle network, the neighbourhood of any person consists of the individuals on her either side.

Individual  $i$  chooses an action,  $s_i$ , from the set  $\{A, B\}$ . Let  $s = (s_1, \dots, s_n)$  be the profile of actions chosen by individuals and  $S = \{A, B\}^n$  be the set of all possible strategy profiles. In a two player game, let  $\pi(x, y)$  denote the payoffs to player  $i$  when this player chooses action  $x$ , while her opponent chooses action  $y$ . The payoffs to an individual in a network are the sum of payoffs that she earns from each of the bilateral interactions in her neighbourhood. Assuming that individuals choose the same action on all interactions, given a network  $g$ , the payoffs to individual  $i$  from a strategy profile  $s$  are:

$$\Pi_i(s|g) = \sum_{j \in N_i(g)} \pi(s_i, s_j) \quad (12.2)$$

To develop an understanding of coordination in networks, it is useful to start with the three networks in Figure 12.1. A preliminary observation is that in all three networks, everyone choosing the same action – A or B – is an equilibrium. This is a direct implication of the payoffs we have assumed: it is always optimal to choose the action that everyone in your neighbourhood chooses. This suggests that global conformism is always an outcome.

We turn next to a study of the circumstances under which different parts of a network adopt different actions? In these simple networks global conformism is the *only* possible equilibrium. This is easiest to see in the star network: clearly every spoke will choose the action chosen by the hub. Next consider the complete network: no two individuals can choose different actions. Label the individuals 1 to  $n$ . Suppose that 1 chooses A and  $n$  chooses B. The payoff of 1 is given by  $[n(A) - 1]a + n(B)d$ , where  $n(A)$  is the number of individuals who are choosing action A and  $n(B)$  is the number of individuals who choose B. Similarly the payoff to individual  $n$  is  $[n(B) - 1]b + n(A)e$ . As 1 is happy with his action it must be that choosing A is better than choosing B:  $[n(A) - 1]a + n(B)d$  must be at least as large as  $n(B)b + [n(A) - 1]e$ . Similarly, for individual  $n$  to be happy with her choice it must be the case that payoff from choosing A,  $n(A)a + (n(B) - 1)d$ , is less than what she earns with action B,  $[n(B) - 1]b + n(A)e$ . Putting together these implications we get the requirement:

$$[n(A) - 1]a + n(B)d \geq n(B)b + [n(A) - 1]e > [n(B) - 1]b + n(A)e \geq n(A)a + [n(B) - 1]d$$

The strict inequality obtains because we have assumed that equation 12.1 holds and so  $b > e$ . Comparing the first and the last expressions in the above equation yields an impossibility, as  $a > d$ , by assumption. Let us spell this out in words: if 1 chooses A and  $n$  chooses B, even though 1 has more neighbors choosing B and fewer neighbors choosing A

than  $n$  does (by 1), this cannot be optimal.

The argument for global conformity on the circle relies on a similar construction: for there to be diversity, there must exist a boundary between an A and a B region: on one side of the boundary, an individual chooses A, while on the other side an individual chooses B. As the individuals at the boundary choosing A and B have one A and one B neighbour each, they must earn  $a + d$  and  $b + e$  respectively. But given our assumption on payoffs given by equation 12.1, choosing A is strictly better than choosing B, so diversity is not sustainable.

This raises the question: what are the networks for which diversity is possible? To develop a first impression of how networks sustain diversity we consider a class of societies in which there are multiple communities and intra-community interaction is stronger as compared to inter-community interaction. Figure 12.2 presents network structures with two communities that reflect this idea. The number of cross community links reflect the level of integration in this society.

To develop an understanding of the relation between integration and diversity consider some payoff parametric values. Suppose  $d = e = 0$ . First suppose that  $a = 4$ ,  $b = 2$ . It can be checked that the community of individuals 1-4 choosing A and the community of individuals 5-8 choosing B is an equilibrium in network I, but not in networks II and III. Next suppose  $a = 4$  and  $b = 3$ : as we have raised the value of coordinating on action B, diversity is now an equilibrium in both networks I and II (but not in III).

For two actions to emerge as social norms in different neighbourhoods of a social network, it suffices that every individual in each of the neighbourhoods is content with their choice. This would hold if, for everyone in a community, a sufficient fraction of connections were within the community choosing the same action. To make this concrete, fix a network  $g$  and the parameters  $a, b$  and set  $d = e = 0$ . Diversity of social norms will obtain if there exist two distinct subsets of connected individuals  $C_A$  and  $C_B$  with the following property: for each  $i \in C_A$ , the fraction of contacts within the community  $p_i \geq b/(a+b)$ , and for every  $i \in C_B$ , the fraction of contacts within that community  $p_i$  is greater than  $a/(a+b)$ . Returning to the above example with  $a = 4$  and  $b = 2$ , for the two norms to coexist, we require that  $p_i \geq 1/3$  for individuals in A community and  $p_i \geq 2/3$  for all individuals in B community.

Fix the community  $C_k$ ,  $k = A, B$ , and consider the person  $i$  with the lowest fraction  $p_i$ . The possibility of sustaining action A in community  $C_A$  depends on whether  $p_i \geq b/a + b$  (in what follows we will define  $q = b/(a+b)$ ). And likewise, for community B. The subset of connected individuals  $C_k$  in a network is  $p$ -cohesive if  $p_i \geq p$  for every individual in  $i \in C_k$ .

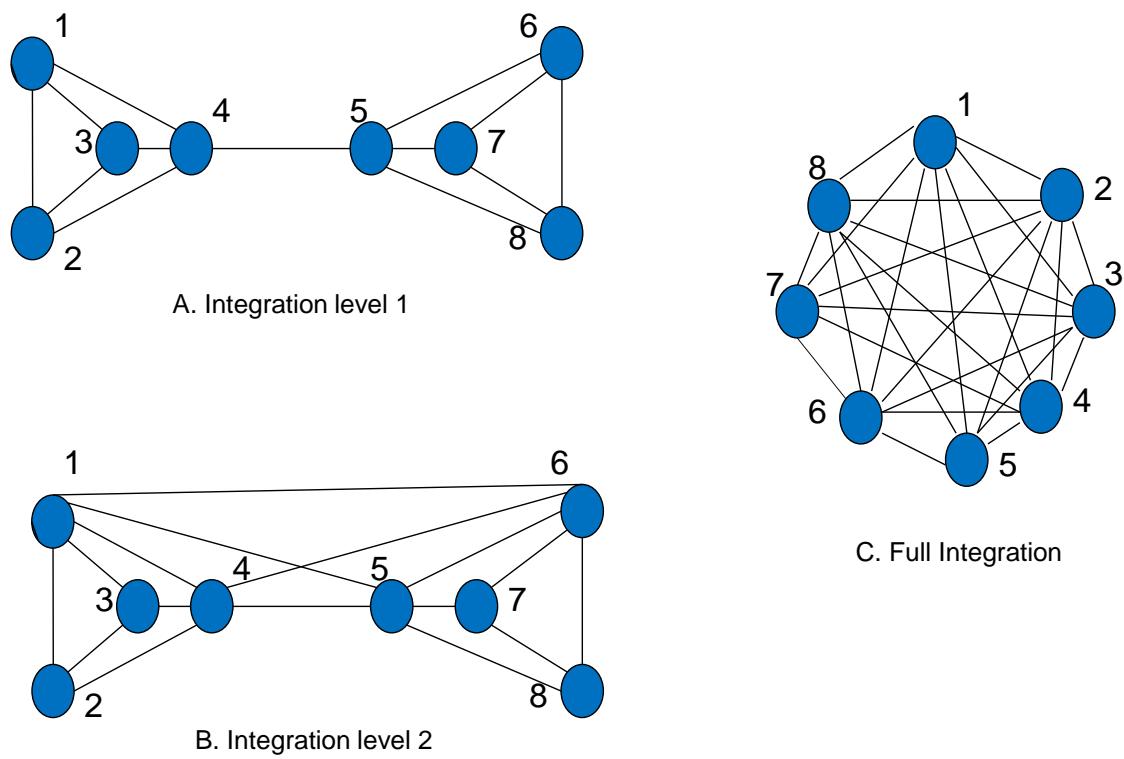

Figure 12.2: Levels of network integration

We summarize this discussion as follows:

**Proposition 12.1.** *Suppose that  $d = e = 0$  and let  $q = b/(a + b)$ . Everyone choosing the same action – conformism – is a Nash equilibrium in every network. Diversity is an outcome if and only if there exist distinct subsets of nodes  $C_A$  and  $C_B$ , with  $C_A$  being  $q$ -cohesive and  $C_B$  being  $1 - q$ -cohesive.*

This result sets the stage for an examination of the process of change from one social norm to another.

## 12.3 Changes in Convention

In this section, we will study a specific type of dynamics: we will suppose that a society has a well established social norm: everyone chooses B. At this point, a new and superior action A becomes available. The actions may refer to a new technology – such as fax machines or telephone or a new software. It may refer to ideas on personal and social hygiene – such as not spitting in public spaces. The social norms can also refer to something much grander – and pertain to entirely different ways of organizing society, as in the case of ‘capitalism’ versus ‘communism’. We study how the network structure determines whether this new norm will be adopted by the society. Our discussion draws on the papers by Goyal [1996] and Morris [2000]; the exposition is based on Easley and Kleinberg [2010].

To focus on the issue of change, we will set  $d = e = 0$  and suppose that  $a > b$  in equation 12.1. Suppose that the dynamics of adoption take place over time that is numbered  $t = 0$ , moving to 1 and 2 and so forth. The process starts at  $t = 0$ : a subset of the society adopts action A. These are the individuals who have been freely offered a new technology. Everyone else is choosing B. At every point from  $t = 1$  onward, an individual who was with action B at time  $t - 1$  chooses between A and B. The choice maximizes their payoff, taking as given the profile of actions of others, i.e, it is a best-response to last-period actions by others. Observe that the process of choice will continue either until everyone has adopted A or there is a moment in time when no new person switches from B to A. It will be useful to define the threshold  $q = b/(a + b)$ . This is the minimum fraction of neighbours choosing A needed for someone to switch from B to A. If an individual has a fraction of neighbours below  $q$  choosing A, then she will persist with B.

To develop a feel for the dynamics of adoption, consider the network given in Figure 12.3. Suppose  $a = 3$  and  $b = 2$ , so the threshold is  $q = 2/5$ . Suppose that at  $t = 0$  we start with  $v$  and  $w$  as the two nodes who switch to A. At  $t=1$ , nodes  $r$  and  $t$  switch as the fraction of A’s in their neighbourhood,  $2/3$ , is greater than the threshold  $q = 2/5$ . But s

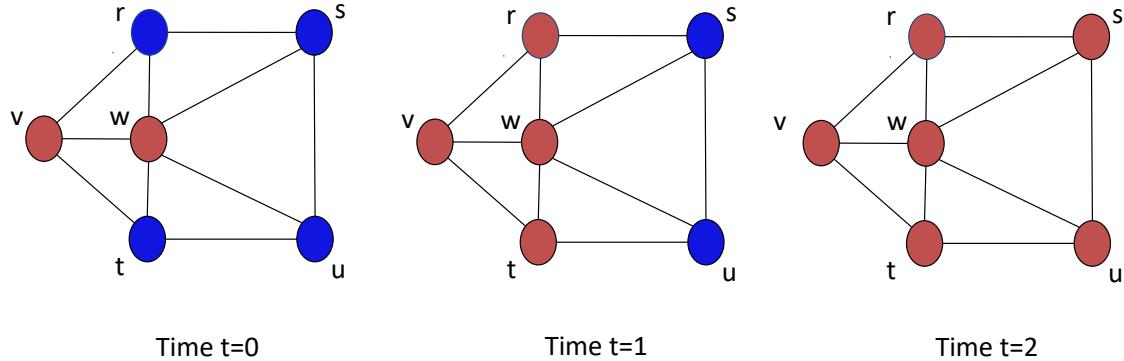

Figure 12.3: Dynamics on a simple network

and  $u$  persist with B as fraction of the fraction of A choosing neighbours,  $1/3$  is less than the threshold  $q = 2/5$ . At  $t=2$ ,  $s$  and  $u$  also switch to A as the fraction of their A neighbours  $2/3$  is now greater than the threshold  $q = 2/5$ . So at  $t=2$ , everyone adopts A. A *complete cascade* happens when everyone switches to action A. Example 1 offers us an instance of a complete cascade.

We next examine barriers – in the network structure – to a complete cascade. Our discussion in the previous section has already given us some ideas of when a cascade will be blocked – this could happen if there is a sufficiently cohesive community of individuals who choose B. To develop this point a little further, consider the network given in Figure 19.10. The process starts with nodes 7 and 8 choosing A. In this network there are two subsets of nodes in the residual network that are tight knit: nodes 1-3 and nodes 11-17. In particular, each of them are  $2/3$  cohesive. So the maximum exposure to A would be  $1/3$  and this is smaller than the threshold  $2/5$ . This means that every individual in either of these groups will find it optimal to persist with B. This simple example paves the way for a general remark on adoption dynamics in networks.

**Proposition 12.2.** Consider a set of initial adopters of behaviour A. Let the threshold be  $q$  for nodes in the remaining network. Then

1. If the remaining network contains a group of nodes with greater than  $1 - q$  cohesiveness then a complete cascade does not occur.

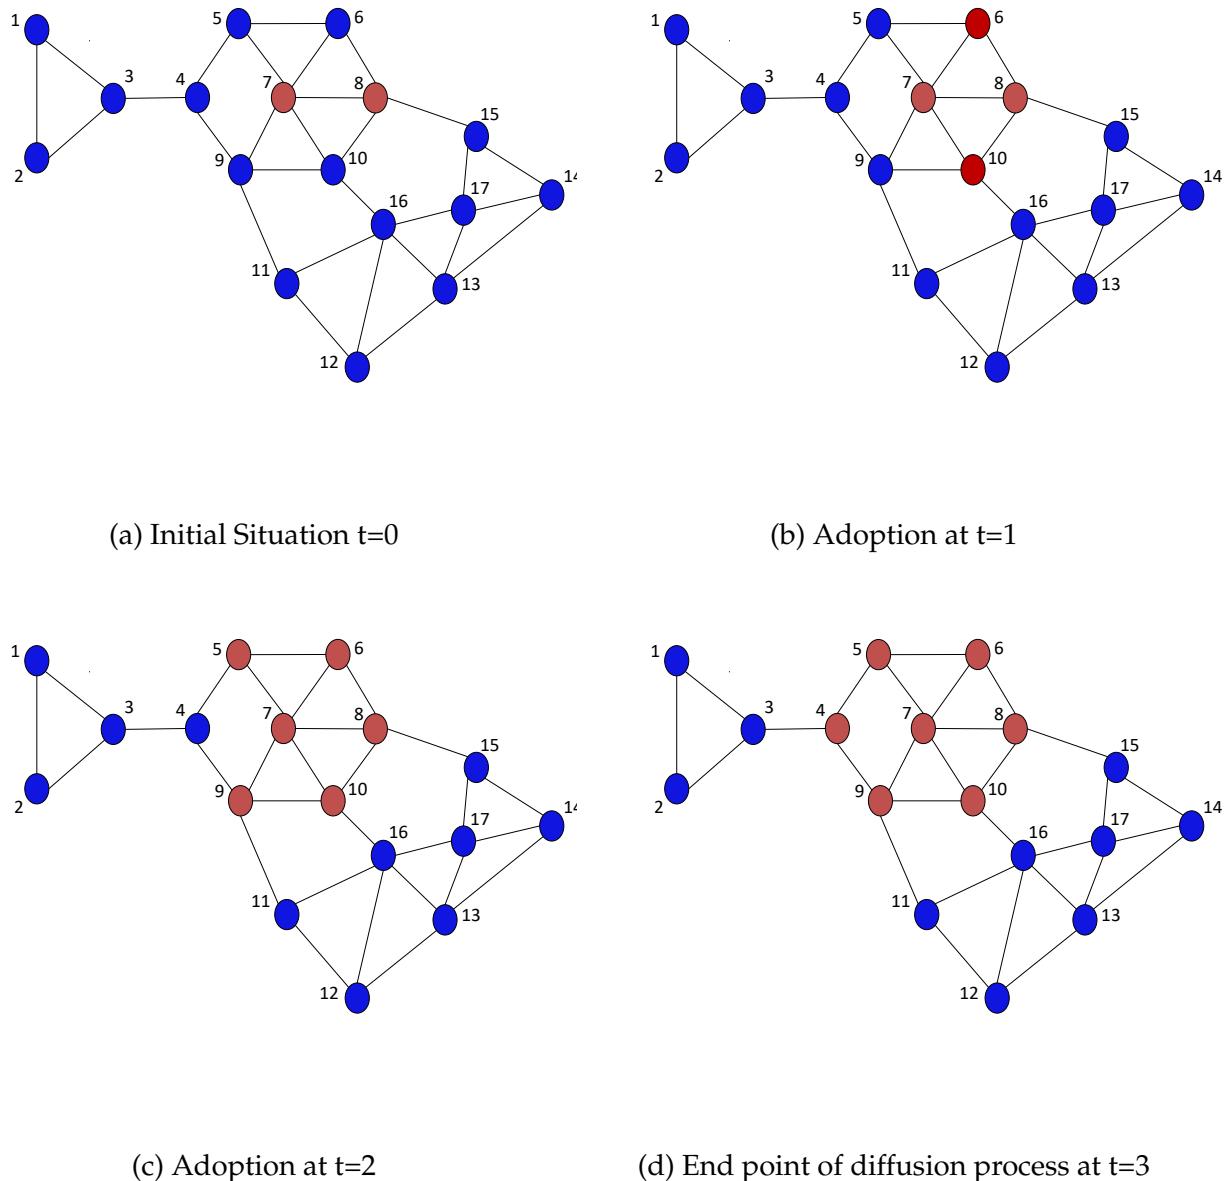

Figure 12.4: Cohesive Groups Blocking Contagion

2. Moreover, whenever a set of initial adopters does not cause a complete cascade the remaining network must contain a group that has cohesiveness greater than  $1 - q$ .

Consider part 1: Suppose the remaining network contains a group that is greater than  $1 - q$  cohesive,  $X$ . If a complete cascade occurs then there must be a time at which the first node in the group  $X$  switches from B to A. We know that this node has greater than  $1 - q$  fraction of neighbours within  $X$  who all choose B. But then it is optimal for the node to choose B. This is a contradiction. So it cannot be case that a complete cascade occurs. Next consider part 2: Suppose the cascade stops before complete adoption. Let the set of action B choosers at the end point of the process be given by  $Y$ . Consider a node  $y \in Y$ . Since  $y$  does not adopt A, it must be the case that her fraction of neighbours within  $Y$  must exceed  $1 - q$ . Indeed, this must be true for all nodes in  $Y$ . So  $Y$  has cohesiveness greater than  $1 - q$ .

So a new norm will permeate a society if and only if it contains no suitably ‘cohesive’ sub-groups. This discussion naturally suggests the following question: what is the maximal receptiveness of a society? More precisely, we can ask: given a network, what is the largest threshold  $q$  that will support a complete cascade?

To study this problem it is helpful to consider large societies, networks with an infinite set of nodes. At the start everyone chooses B. A finite set of nodes change to A. The *cascade capacity* of a network is the largest value of the threshold  $q$  for which there is a complete cascade.

We discuss some examples to bring out the issues. Consider a cycle network in which everyone has degree 2. Working through the computations, as in the earlier examples, it is easy to verify that there is complete cascade for any  $q < 1/2$ . Moreover, there is no switching to A, and hence no cascade at all for  $q > 1/2$ . So the cascade capacity of a line is  $q = 1/2$ . Next consider a ‘grid’ with degree 8: everyone is connected to all their neighbors to the top, bottom, left, right, and on each diagonal. Suppose there is a square of 9 nodes that adopt A. Consider the neighbours of this square. The most receptive person would be someone who has the (maximal) 3 neighbours in the square. So it follows that an action A with  $q > 3/8$  will not spread. Arguing analogously, it can be seen that any  $q < 3/8$  will lead to a complete cascade. So the cascade capacity of the grid is  $3/8$ . Observe that for  $q \in (3/8, 1/2)$ , action A fails to spread. In other words, an action that yields superior payoffs may fail to spread, due to the cohesiveness of the existing network.

With these observations in hand, we can state the following general result on cascade capacity.

**Proposition 12.3.** *There is no network for which cascade capacity exceeds  $1/2$*

The argument underlying this proposition goes as follows. Take a new action with

some  $q > 1/2$ . At any point  $t$ , some individuals are choosing A and others are choosing B. Label an edge in the network as AA if it connects two nodes that are choosing A, AB if the edge connects two nodes that choose A and B, and BB if the edge connects two nodes that both choose B. Observe that expansion of the set of A adopters only happens along edges of type AB. At the start  $t = 0$ , there is a finite set of adopters of A. Let  $I_0$  be number of AB edges that connect these A adopters to non-adopters. We will show that at every point,  $t = 1$  onward, the number of AB edges *falls strictly*. So there are at most  $I_0$  active periods in the dynamics. This means that the cascade is incomplete.

Consider a node  $x$  that switched at time  $t$ . As  $q > 1/2$ , number of AB edges for this node must be strictly greater than the number of BB edges. So it follows, after switch by  $x$ , the number of AB edges for  $x$  falls strictly. This is true for every node that switches at time  $t$ . Hence the number of AB edges falls strictly at time  $t$  as compared to time  $t - 1$ . This completes the argument.

This result has a reassuring implication: a new action A, that is less efficient than the existing action B, can have some success but it can never successfully take over any entire network.

The discussion also draws attention to the difficulties in introducing large scale change in cohesive societies. One way to overcome the resistance to change is to initiate movement from one community to a new location, this helps to erode the cohesiveness of a community. One strand of research explores this route from a theoretical perspective. Let us discuss this approach briefly.

In the line with Ely [2002], Mailath, Samuelson, and Shaked [1994], Bhaskar and Vega-Redondo [2004] and Oechssler [1997] let us consider a world with many islands. Individuals care about average payoffs from interaction and they earn payoffs from interactions with everyone on an island. Moving from an island to another leads to the severing of all ties with the former island and instead playing the game with all the players in the new island. In a sense, then the neighborhood becomes a matter of choice via the choice of an island.

Now imagine that everyone is on one island and playing the inefficient action. Then the possibly experimental move of a few individuals to a new island can lead to the emergence of a location with an efficient convention. Individuals left behind in the old island can now migrate to this newly inhabited island with an efficient convention and this can lead to a transition from a situation where everyone is choosing the inefficient action to one in which everyone is on a new island and choosing the efficient action. Observe that it takes only a few initial experimental individuals to move out to the new island for this transition to take place. Thus the possibility of moving to a new as yet unoccupied location creates

a pathway out of inefficient to efficient outcomes (so long as individuals care only about average payoffs). The basic insight flowing from this work is that if individuals can easily separate/insulate themselves from those who are playing an inefficient action then efficient "enclaves" will be formed and eventually attract the "migration" of others who will adopt the efficient action eventually.

At an abstract level this is a compelling account for the change of coordination norms. To make it a little concrete we discuss one example of a large scale transformation of social norms where immigration has been central. We discuss here the creation of 'special economic zones' in China and in other countries.

Through the 20<sup>th</sup> century, Hong Kong was regarded as one of the great success stories of economic growth. The contrast with the rest of mainland China was specially striking. In 1979, the Chinese leadership introduced Four Special Zones in the neighbourhood of Hong Kong as part of a larger reform of the economic system. These Special Economic Zones included the cities of Shenzhen, Zhuhai and Shantou in Guangdong, and the city of Xiamen in Fujian province. In these zones, private ownership of capital and market oriented labour laws were put in place, in imitation of Hong Kong. These laws were very different from the institutional arrangements in the rest of China. Individuals from the rest of the country could come in with their skills and their savings into these special zones. By 1984, the Chinese leadership expanded the scope of these SEZs by opening 14 other coastal cities – Dalian, Qinhuangdao, Tianjin, Yantai, Qingdao, Lianyungang, Nantong, Shanghai, Ningbo, Wenzhou, Fuzhou, Guangzhou, Zhanjiang, and Beihai. Over the past four decades, these special zones have witnessed extraordinary growth. Some of these cities now have a population over 10 million.

Reasoning in terms of our theoretical framework, the special economic zones and the coastal cities offer individuals an opportunity to move out of the traditional network and to create new relatively insulated conclaves. Once in these conclaves, individuals' interactions are governed by new norms. A new and large collection of networks emerges in these insulated conclaves. At the same time, out-migration has the potential to mitigate the constraints of the old social network. The combination of new networks in the conclaves and the erosion of the old network may create the circumstances for large scale adoption of new social norms across the entire network.

## 12.4 The evolution of conventions

We now revert to the original coordination problem and examine more directly how the dynamics of choice over time can push a society toward one or the other equilibrium.

This discussion will draw attention to decision rules that individuals may use and the importance of evolving networks.

We first study the setting where the network is fixed and exogenously given. The dynamics take place over discrete points in time numbered as  $t = 1, 2, \dots$ . At each point, with probability  $p \in (0, 1)$ , every player gets an opportunity to revise her strategy. Faced with this opportunity, a player chooses an action which maximizes her payoff, under the assumption that the strategy profile of her neighbors remains the same as in the previous period. If more than one action is optimal then the player persists with the current action. Let the action of  $i$  at period  $t$  be  $s_i^t$ , where  $s_i^t \in S$ . The profile of actions at time  $t$  is given by  $s_t$ . Therefore, the strategy for player  $i$  at time  $t$  maps the action profile at time  $t - 1$  into an action at time  $t$ :  $s_i^t : S^{N_i} \rightarrow S$ . If player  $i$  is not active in period  $t$  then set  $s_i^t = s_i^{t-1}$ . This simple best-response strategy revision rule generates, for every network  $g$ , a transition probability function,  $P_g(ss') : S \times S \rightarrow [0, 1]$ , which governs the evolution of the state of the system  $s^t$ . A strategy profile (or state),  $s$ , is said to be absorbing if the dynamic process cannot escape from the state once it reaches it, i.e.,  $P_g(ss) = 1$ . We will study the relation between absorbing states and the structures of local interaction. Our analysis is summarized in the following result.

**Proposition 12.4.** *Given a network,  $g$ , and starting from any initial strategy profile,  $s^0$ , the dynamic process  $s^t$  converges to an absorbing strategy profile in finite time, with probability 1. Moreover, there is a equivalence between the set of absorbing strategy profiles and the set of Nash equilibria of the static social game.*

The arguments underlying these observations are as follows. Let us start at some state  $s_0$ . Consider the set of players who are not playing a best response. If this set is empty then the process is at a Nash equilibrium profile and this is an absorbing state of the process, as no player has an incentive to revise her strategy. Suppose therefore that there are some players who are currently choosing action A but would prefer to choose B. Allow them to choose B, and let  $s_1$  be the new state of the system (this transition occurs with positive probability, given the decision rules used by individuals). Now inspect the players doing A in state  $s_1$  who would like to switch actions. If there are some such players then have them switch to B and define the new state as  $s_2$ . Clearly this process of having the A players switch will end in finite time (since there are a finite number of players in the society). Let the state with this property be  $\hat{s}$ . Either there will be no players left choosing A or there will be some players choosing A in  $\hat{s}$ . In the former case the process is at a Nash equilibrium.

Next consider the latter situation. Consider the second possibility where both actions A and B are chosen. Check if there are any players choosing B in state  $\hat{s}$  who would like to

switch actions. If there are none then the process is at an absorbing state. If there are some A players who would like to switch then follow the process as outlined above to reach a state in which there is no player who wishes to switch from B to A. Let this state be denoted by  $\bar{s}$ . Next observe that no player who was choosing A (and did not want to switch actions) in  $\hat{s}$  would be interested in switching to B. This is true because the game is a coordination game and the set of players choosing A has (weakly) increased in the transition from  $\hat{s}$  to  $\bar{s}$ . Hence the process has arrived (with positive probability) at a state in which no player has any incentive to switch actions. This is an absorbing state of the dynamics; since the initial state was arbitrary, and the above transition occurs with positive probability, the theory of Markov chains says that the transition to an absorbing state will occur in finite time, with probability 1.

We conclude this discussion by noting that for a profile  $s$  to be an absorbing state it must be the case that from some point in time  $t$ , no individual has an incentive to switch actions. But if this is the case then everyone must be playing a best response to the choices of everyone else. But this means that such a strategy profile must be a Nash equilibrium. Similarly, it is easy to see that every Nash equilibrium profile offers no incentives for any one to switch actions, therefore it constitutes an absorbing state of the dynamics. ■

Thus every Nash equilibria can be supported via a natural dynamic process. To select across different equilibria in networks, we therefore need to go beyond these dynamics. We will explore the scope of the following general idea in what follows. Suppose that  $s$  and  $s'$  are the two absorbing states of the best-response dynamics described above. Given that  $s$  is an absorbing state, a movement from  $s$  to  $s'$  requires an error or an experiment on the part of one or more of the players. Similarly, a movement from  $s'$  to  $s$  requires errors on the part of some subset of players. The state  $s$  is said to be *stochastically stable* if it requires relatively more errors/experiments to move from  $s$  to  $s'$  as compared to the other way around. If it takes the same number of mutations to move between the two states, then they are both stochastically stable.

To develop the analysis of stochastically stable states, let us spell out some details of this experiments process. Assume that, conditional on receiving a revision opportunity at any point in time  $t$ , a player chooses her strategy at random with some small probability  $\epsilon > 0$ . Given a network  $g$ , and for any  $\epsilon > 0$ , it follows that in this experimental dynamic process there is a positive probability of transiting from any state  $s$  to any other state  $s'$ . In other words, the experimental dynamics process defines a Markov chain that is aperiodic and irreducible: from standard results it follows that the process has a unique invariant probability distribution on states Kemeny and Snell [1983] and Seneta [2006]. Denote this distribution by  $\mu_g^\epsilon$ . The analysis will study the support of  $\mu_g^\epsilon$  as the probability of experi-

ments becomes very small, i.e. as  $\epsilon$  converges to 0. Define  $\lim_{\epsilon \rightarrow 0} \mu_g^\epsilon = \hat{\mu}_g$ . A state  $s$  is said to be *stochastically stable* if  $\hat{\mu}_g(s) > 0$ .

We present examples that help us appreciate the effects of the network of interaction,  $g$ , on the set of stochastically stable states.

**Example 12.1.** The complete network.

This example considers the complete network in which every player is a neighbor of every other player. Suppose that player 1 is deciding on whether to choose  $A$  or  $B$ . It is easy to verify that at least  $k = (n - 1)(b - d)/[(a - e) + (b - d)]$  players need to choose  $A$ , for  $A$  to be optimal for player 1. Similarly, the minimum number of players needed to induce player 1 to choose  $B$  is  $l = (n - 1)(a - e)/[(a - e) + (b - d)]$ . Given the assumption that  $a + d > b + e$  it follows that  $k < n/2 < l$ . If everyone is choosing  $A$  then it takes  $l$  experiments to transit to a state where everyone is choosing  $B$ ; likewise, if everyone is choosing  $B$  then it takes  $k$  mutations to transit to a state where everyone is choosing  $A$ . It then follows that the risk-dominant action  $B$  is the unique stochastically stable outcome. ■

**Example 12.2.** Local interaction around a circle

Following Ellison [1993], we consider local interaction with immediate neighbors around a circle. Suppose that at time  $t - 1$  every player is choosing  $B$ . Now suppose that two adjacent players  $i$  and  $i + 1$  choose action  $A$  at time  $t$ , due to an experiment in the process. It is now easy to verify that in the next period,  $t + 1$  the immediate neighbors of  $i$  and  $i + 1$ , players  $i - 1$  and  $i + 2$  will find it optimal to switch to action  $A$  (this is due to the assumption that  $A$  is risk-dominant and  $a + d > b + e$ ). Moreover, in period  $t + 2$  the immediate neighbors of  $i - 1$  and  $i + 2$  have a similar incentive, and so there is a process under way which leads to everyone choosing action  $A$ , within finite time. On the other hand, if everyone is choosing  $A$  then  $n - 1$  players must switch to  $B$  to induce a player to switch to action  $B$ . This is true because so long as at least one of the neighbors is choosing  $A$  the optimal action is to choose  $A$ . Thus the risk-dominant action  $A$  is the unique stochastically stable state. ■

The simplicity of the above arguments suggests the following conjecture: the risk-dominant outcome obtains in all networks. This conjecture is false, as the following example illustrates.

**Example 12.3.** The star network.

Following Jackson and Watts [2002b], we consider a star network and suppose that player 1 is the central player. The first point to note about a star network is that there are only two possible equilibrium configurations, both involving social conformism. A study of stochastically stable actions therefore involves a study of the relative stability of these two configurations. However, it is easily verified that in a star network a perturbation which switches the action of player 1 is sufficient to get a switch of all the other players. As this is also the minimum number of mutations possible, it follows that both states are stochastically stable ■

These examples suggest that network structure matters for the stability of different outcomes; the partition of networks where the different equilibria are stochastically stable however appears to be an open problem. We have so far assumed that the network is fixed. In many situations of interest, both social and economic, individuals faced with a coordination problem can orient their network. This is especially true over time. Pupils may pick new friends as they choose new languages or sports activities. Similarly, businesses may pick new partners as they move standards or technologies. We now turn to a study of the co-evolution of networks and actions in the coordination game.

### 12.4.1 Endogenous networks

Following Goyal and Vega-Redondo [2005] we consider a model of links and actions. There is a set of players  $N \in \{1, 2, \dots, n\}$ , where  $n \geq 3$ . A player chooses a links-action pair,  $(g_i, a_i)$ , where  $g_i$  refers to the links that she forms and  $a_i \in \{A, B\}$  refers to the action in the accompanying coordination game. Let  $g = \{g_1, \dots, g_n\}$  be a profile of links chosen by the players. A profile of link decisions defines a directed network. Given a network  $g$ , let us say that  $i$  and  $j$  are directly linked if at least one of them has established a link with the other one i.e. a link between  $i$  and  $j$  exists if  $\max\{g_{ij}, g_{ji}\} = 1$ . Every player who establishes a link with some other player incurs a cost  $c > 0$ . To understand payoffs, we therefore need to keep track of who forms a link and who receives a link: if  $g_{ij} = 1$  and  $g_{ji} = 0$ , then we shall say that  $g_{ij}$  has an active link for player  $i$  and a passive link for player  $j$ . Given a strategy profile  $s = (s_1, \dots, s_n)$ , the payoffs of player  $i$

$$\Pi_i(s) = \sum_{j \in N_i(g)} \pi(a_i, a_j) - \eta_i(g)c \quad (12.3)$$

where  $\pi(a_i, a_j)$  are the payoffs in the bilateral game between two connected players  $i$  and  $j$ , and  $\eta_i(g)$  is the number of links formed by player  $i$  in strategy profile  $g$ . The payoffs  $\pi(a_i, a_j)$  are taken from the matrix in Table 1 above. We start with a brief discussion on the

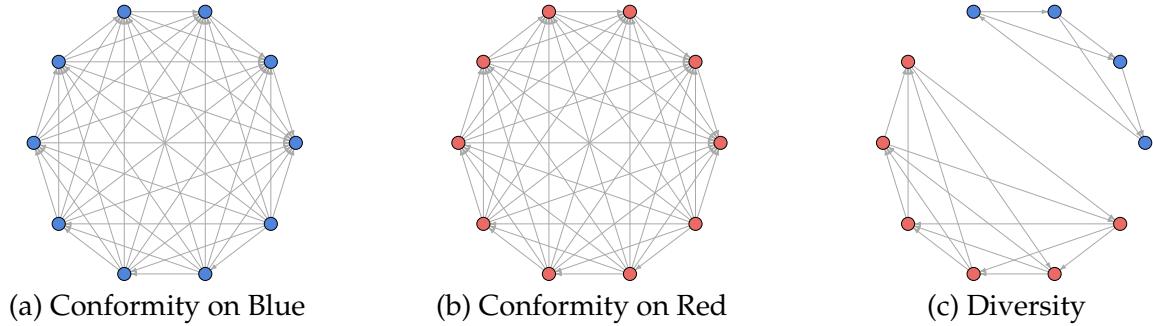

Figure 12.5: Equilibria with Endogenous Networks

equilibrium of the linking and coordination game.

In what follows for concreteness, we will suppose that  $b > a$ , and so there is a tension between risk dominance and efficiency in the coordination game: action  $A$  corresponds to the risk-dominant action, but action  $B$  corresponds to the efficient action. Observe that if costs of linking are greater than the efficient payoffs,  $c > b$  then no links will be worthwhile: the network must be empty. So in what follows we restrict attention to the case  $c < b$ . Our next observation is that if  $c > a$  then two players will be linked in an equilibrium only if they are both playing the efficient action. A final comment pertains to small costs of linking: if  $c < a$  then a complete network with everyone choosing  $A$  or everyone choosing  $B$  are both equilibria. Interestingly, when  $c > e$  then there also exist equilibria with two component networks where players choose a different action across the components. Figure 12.5 presents some equilibria of this game of linking and actions.

Moving to the dynamics, we start by noting an immediate counterpart of Proposition 12.4: there is an equivalence between the set of Nash equilibria of the static game of linking and actions and the best-response dynamics. We examine the role of experiments in selecting across these equilibria. As in the dynamic model with experiments considered above, we suppose that, at regular intervals, individuals choose links and actions to maximize (myopically) their respective payoffs. Occasionally, they may also experiment. Our interest is in the nature of long-run networks and actions, when the probability of these experiments is small.

The perturbed dynamics of actions and endogenous networks lead to very sharp predictions. Define a number  $\bar{c}$ , where  $e < \bar{c} < a$ . Suppose that the probability of experiments is small. If  $0 < c < \bar{c}$ , in the long run, the network is complete and all players choose the risk-dominant action  $A$ . If  $\bar{c} < c < b$  then the long run network is complete and all players choose action  $B$ . Finally, if  $c > b$  then the long run network is empty and actions are undetermined.

So long as the costs of linking are below  $b$ , in the long run the network is complete.

This means that partially connected networks are ephemeral: to see why this is the case, suppose for simplicity that  $b > c > e$ : so players will only maintain links with each other if they are playing the same action. Then note that starting from two components with distinct actions a single experiment will take an individual from one action (say) A to the other action B and with links with the corresponding component. The players in the erstwhile A component will now best respond by disconnecting their links with this experimenting individual. We can iterate this process one experiment at a time and at each point the outcome may be a Nash equilibrium. The process converges to everyone in a complete component choosing B. This suggests that the two component configurations with distinct actions configurations are fragile (it is easy to check that the complete network with conformism is not fragile in this way. As a small exercise, the interested reader may wish to check that a variant of this argument would work for small costs of links also).

Next note that in the complete network players always coordinate on the same action i.e., social conformism obtains. This follows from the discussion in section 12.2. Moreover, recall from 12.1 that if the complete network were to be fixed then the risk-dominant action would be uniquely stochastically stable. Thus it is the dynamics of linking that must account for the sharp transition from all A to all B, as we move  $c$  from under  $\bar{c}$  to above  $\bar{c}$ . Thus it is the interaction of the costs of linking with the dynamics of linking that must be crucial in explaining the different equilibrium actions.

We observe that the threshold  $\bar{c}$  is strictly below  $a$ , i.e., there is some interval of values  $c \in (\bar{c}, a)$  where the complete network with risk-dominant action is a Nash equilibrium and yet it is not stochastically stable, rather the efficient action is uniquely stochastically stable. This interval again shows that the study of the dynamics allow us to go beyond what we could infer simply by examining the Nash equilibrium of the static game.

A complete proof will take us too far afield, but let us try and spell out the main idea informally. Starting from a complete network and everyone choosing (say) A, suppose some players were to experiment with action B. If the costs of linking are very small everyone will maintain the links as they are. In essence, a player must make her fresh choices as if she were in a complete network. In this case, from our arguments in example 12.1 the risk dominant (and inefficient convention) prevails since, under complete connectivity, this convention is harder to destabilize than the efficient but risk-dominated one.

Next suppose the costs of links are higher and that they lie in the range  $c > \bar{c}$ . Now it is no longer profitable for the non-experimenting players to maintain any links with the experimenters. They will delete their links and the network is no longer complete. If there are enough links deleted in this manner, the experimenters are adrift in a new complete component that is playing the efficient action. So long as there are enough experimenters,

those left behind will have an incentive to switch actions and form links with the experimenters. Let the minimum number of experimenters be  $M_{AB}$ . We could similarly contemplate a transition from a complete network with everyone choosing  $B$  to a complete network where everyone chooses  $A$  and compute the minimum number of experimenters needed for this transition; let us denote it  $M_{BA}$ . Recalling that the key comparison is how do the two numbers compare, we compare  $M_{AB}$  and  $M_{BA}$ . It turns out that  $M_{AB} > M_{BA}$  for  $c < \bar{c}$  and that  $M_{AB} < M_{BA}$  for  $c > \bar{c}$ . The details of the computations are fairly involved so we omit them. The interested reader is referred to Goyal and Vega-Redondo [2005] for a complete proof.

We conclude this section with two remarks. First we discuss the connection between the changing locations approach, that was outlined in the previous section, and the evolving networks approach presented in this section. The basic insight flowing from the changing location approach is that if individuals can easily separate/insulate themselves from those who are playing an inefficient action then efficient "enclaves" will be formed and eventually attract the "migration" of others who will adopt the efficient action. One may be tempted to identify easy mobility with low costs of forming links. However, the considerations involved in the two approaches turn out to be very different. Let us elaborate on this point briefly.

Recall, from our discussion of the coordination dynamics in the endogenous networks case that, in the network formation approach, the risk-dominant outcome prevails if the costs of forming links are small. There are two main reasons for this contrast. First, in the network formation approach, players do not indirectly choose their pattern of interaction with others by moving across a pre-specified network of locations (as in the case of player mobility). Rather, they construct directly their interaction network (with no exogenous restrictions) by choosing those agents with whom they want to play the game. Second, the cost of link formation is paid per link formed and thus becomes truly effective only if it is high enough. Thus it is precisely the restricted "mobility" of high costs that helps insulate (and thus protect) the individuals who are choosing the efficient action. If the costs of link formation are low, then the extensive interaction this facilitates may have the unfortunate consequence of rendering risk-dominance considerations decisive.

Our second remark concerns the number of actions in the game of coordination. In the problems we have studied so far, individuals choose between two actions,  $A$  and  $B$ . It is easy to extend the problem so as to have  $k \geq 2$  actions. A variant of this game is the *weakest-link* or the *minimum effort* game. We follow Riedl, Rohde, and Strobel [2016] in describing the game. Let  $N = \{1, \dots, n\}$  be a group of players and  $S = \{1, \dots, k\}$  be the set of effort levels available to every player. Players simultaneously choose an effort level

$s_i \in S$ . Let  $s = (s_1, \dots, s_n)$  be the strategy profile of players,  $b$  the marginal cost of effort, and  $a$  the marginal return from the effort in the group, with  $a > b > 0$ . The payoff of player  $i$  facing strategy profile  $s$  is

$$\Pi_i(s) = a \min_{j \in N} \{s_j\} - bs_i + c \quad (12.4)$$

where  $c > 0$  ensures non-negative payoffs for all strategy profiles. The restriction  $a > b > 0$  implies that every player has a monetary incentive to align her effort level with the minimum level chosen by the other players. Therefore, any strategy profile in which all players choose the same effort level constitutes a Nash equilibria. These equilibria are Pareto-ranked, from the highest to the lowest effort equilibrium. Also observe that the strategy profile in which everyone chooses the lowest effort pairwise risk-dominates every other equilibrium.

In this game individuals choose from among a finite set of actions  $\{1, \dots, k\}$ , where  $k \geq 2$ . The gross payoffs to an individual from an action profile are given by the minimum action chosen among all players while a higher action is costlier. The structure is such that rewards of higher action more than compensate for this cost. Thus there exist  $k$  coordination game equilibria each corresponding to a different action chosen by everyone (for a binary version of this game see the chapter on network structure and human behaviour). Therefore, there are  $k$  Nash equilibrium and they are Pareto-ranked: with a higher matched action profile payoff dominating a lower action profile.

There is a large experimental literature on this game: a robust finding is that subjects generally choose the lowest action as the group of players grows, i.e., they chose the worst equilibrium of the game. For weakest-link games played in fixed groups the seminal papers by Harrison and Hirshleifer [1989] and Van Huyck, Battalio, and Beil [1990] indicated that when played in pairs substantial coordination on the Pareto-dominant equilibrium occurs, whereas efficient coordination breaks down completely when groups grow large (typically beyond size 8). This result has been replicated by a number of experimental studies over the years; for an overview of the literature see Riedl, Rohde, and Strobel [2016].

Our interest is in understanding how the possibility of partner choice will shape the nature of social coordination. Here are some examples of this option of actions and partners. For instance, in the global public good of preventing the outbreak and spread of infectious diseases the country with the poorest preventive measures determines the likelihood of an outbreak. Governments with higher standards can respond not only by lowering their own costly preventive measures but also by restricting trade or traveling to and from countries with low standards. Here is a second example: in groups of co-authors the slow-

est/lowest effort member determines how the speed of progress of the paper. In response to poor effort by a researcher, his co-authors may lower their own efforts or terminate the collaboration.

With these examples in mind, let us consider a variant of this game in which players choose links with each other and also play the weakest-link game. Observe that, as in our discussion above of the baseline coordination game, there exist equilibria with a complete network and with everyone playing any one of the actions. We discuss experimental evidence on this game that is taken from a recent paper by Riedl, Rohde, and Strobel [2016].

Riedl, Rohde, and Strobel [2016] examine the behaviour of subjects in versions of the repeated weakest-link games, with and without link choice. They consider two group sizes: 8 and 24. In their Baseline Treatment (BT), 8 players are located in a complete network and simultaneously choose an integer number (that they interpret as effort) from the set  $\{1, \dots, 8\}$ . Everyone choosing 1 is the least efficient and everyone choosing 7 is the most efficient Nash equilibrium. They have a Neighbourhood Treatment (NT) that adds a link decision to the BT treatment: interaction between any two players is endogenous and requires mutual consent. Recall that a player's payoff is determined by the minimum effort in her neighbourhood. Further, in line with our field examples, which exhibit returns from increasing interaction neighbourhood size, we provide incentives to endogenously form larger neighbourhoods. The treatments are designed in such a way that when each player chooses to connect with everyone else – i.e., create a complete network – the incentives on actions in weakest-link game under NT coincide with those of BT.

The main results are as follows. In the first round, there is little difference between treatments. The average effort level is 5.66 in BT and 5.99 in NT. However, the subsequent evolution of efforts is very different across the rounds. In the BT treatment, the frequency of the lowest effort (11% in round 1) increases strongly and this effort level is the main choice from round 19 onward. The frequency of the highest effort level deteriorates over time from 64% to about 30% in the last few rounds. By contrast, in the NT treatment, the frequency of the lowest effort is never above 4%, and the frequency of the highest effort – 7 – increases strongly from about 60% in the first round to above 94% (and mostly remains there) after round 4.

More generally, efficient coordination is rarely observed in groups of size 8 and never in groups of size 24. This echoes the classical findings of Van Huyck, Battalio, and Beil [1990] and Harrison and Hirshleifer [1989]. Matters are very different with endogenous links: under NT, subjects quickly coordinate on the fully efficient equilibrium and virtually all subjects form links with everyone else (thereby creating a complete network).

Riedl, Rohde, and Strobel [2016] suggest the following mechanism as an explanation for

this result: subjects who face link deletion from individuals who have high effort respond by raising their effort. Over time, this leads almost all individuals to choose high effort and this encourages all individuals to form links with each other, resulting in a complete network with almost universal high efforts. We see that the link dynamics play a central role in the emergence of the high effort outcome.

## 12.5 Coordination with different preferences

In this chapter, so far we have assumed that all individuals have the same preferences over the outcomes (this is reflected in equal payoffs of the row and column players in the outcomes  $(A, A)$  and  $(B, B)$ ). It is easy to see, however, that sometimes we may wish to coordinate with each other but one of us prefers the  $A$  outcome while the other person prefers the  $B$  outcome. Let us take up some examples to bring this out.

In 2017, in a widely publicized incident in the Netherlands, the coach company Qbuzz refused to interview an immigrant who had applied for a job because he refused to shake hand with female clients (on account of his religious beliefs). The coach company felt that the behaviour of the driver went against social norms in the Netherlands (and would probably put off potential customers). This is a simple instance that brings out the point that individuals may have very different ranking over norms. This is an instance of norms on greeting: physical contact between a man and woman is the accepted norm in some communities, while it is entirely prohibited in other communities.

A relatively common tension also arises in the context of language: members of different communities each prefer their mother tongue to be the common language of communication. Language is a central concern in knowledge based and communication intensive societies. These differences in preferences on norms create the following tension: individuals would like to coordinate on actions with others, but their preferences over these actions may be different.

A more standard ‘textbook’ example concerns a couple who want to be together one evening, however, the husband prefers to watch a football game and his spouse prefers to listen to a music concert. These examples motivate the study of the relation between networks and coordination in a setting where individuals prefer coordination but differ on their preferred outcome.

To clarify the key considerations, consider the following simple modification of the model discussed in the previous section. There is a group of individuals who each choose between two actions  $A$  and  $B$ . Everyone prefers to coordinate on one action but some individuals prefer to coordinate on action  $A$  while others prefer to coordinate on action  $B$ . To

develop an understanding for how this difference can have a large impact on individual decisions consider the simple setting of a complete network. Recall, that in section 3, we showed that in a setting where individuals interact with everyone, conformism must obtain. Now consider the modified situation in which some individuals prefer action A over B, while others prefer B over A.

Suppose there are 15 individuals in all and 8 prefer A, while 7 prefer B. This preference is reflected in payoffs: in the two person game, individuals of type A earn 4 from coordinating on action A, and they earn 2 from coordinating on action B. The payoffs of the type B go the other way: B types earn 4 from coordinating on B and only earn 2 from coordinating on A. Now it is easy to see that with these preferences, conformism on either action remains an outcome. But there is also an outcome in which the A types choose action A, while the B types choose action B that is a Nash equilibrium. The wedge in payoffs between actions across types of agents thus gives rise to the possibility of diverse norms, even in a complete network.

Observe however that for diversity to be an equilibrium, it must be the case that the minority is not too small. So, for example, if there were 3 type B individuals in a society with 15 members, then it is no longer possible to sustain an outcome in which the type B's choose B, and the type A's choose action A. A type B individual earns  $2 \times 4 = 8$  in such an outcome, and could earn  $12 \times 2 = 24$  if she were to switch to action A. The prospects of diversity will depend on the values of payoffs and the relative size of minority.

An important point to note is that these prospects are considerably brighter if we move away from the complete network. So, for instance, take the society with 15 members, where 12 are of type A and 3 are of type B but partition them into two distinct cliques corresponding to the types of individual. Now it is easy to see that diversity is a Nash equilibrium: the clique with type A individuals chooses A, while the clique with type B individuals chooses B. This simple example brings out the role of interaction structure in shaping the prospects of diversity and motivates the study of coordination problems in which individuals have heterogenous preferences. The discussion in this section will draw on a literature in economics and sociology and in game theory (see e.g, Schelling [2006], Kearns, Judd, Tan, and Wortman [2009] and Goyal et al. [2021a]).

To develop the arguments formally, we extend the coordination game presented in section 12.2 by assigning different payoffs to players upon successful coordination. This leads us to the ‘battle of the sexes’ game. For ease of exposition, let us write down the payoffs in the battle of the sexes game as played on a network. There are two actions in the game: A and B. Every individual  $i$  has a type,  $\theta_i \in \{A, B\}$ . Individuals are located on a network  $g$ . Individual  $i$  chooses action  $s_i \in \{A, B\}$ . Recall payoffs of coordination game in equation

12.1: for simplicity, set  $d = e = 0$ . The payoff to individual  $i$  from strategy profile  $s$  is

$$u_i(\theta_i, s, g) = \lambda_{s_i}^{\theta_i} \left( 1 + \sum_{j \in N_i(g)} I_{s_j=s_i} \right) \quad (12.5)$$

where  $I_{s_j=s_i}$  is the indicator function for  $i$ 's neighbour  $j$  who chooses the same action as  $i$ . We set  $\lambda_{s_i}^{\theta_i} = \alpha$  if  $s_i = \theta_i$  and  $\lambda_{s_i}^{\theta_i} = \beta$  if  $s_i \neq \theta_i$ . Let  $\alpha > \beta > 0$ .

We note that conformism on either action A or B remains an equilibrium for all networks, as in the baseline coordination game with aligned preferences. Moreover, diversity in actions too can arise, and we expect that it should be easier to sustain in the battle of the sexes as compared to the baseline coordination game. Thus we will face the problem of multiple equilibrium as in the basic coordination problem. But differences in preferences now raise a new issue: how does the location in networks of individuals with particular preferences shape coordination in the group? We present an experiment taken from Kearns, Judd, Tan, and Wortman [2009] to develop a feel for how networks matter.

The setting of the experiment is as follows: there are 36 individuals located on a network. Every individual inhabits a node in the network and can choose one of 2 colors, Red or Blue; moreover, the colours can be asynchronously updated as often as desired during a one minute interval. Subjects are able to view the current color choices of their immediate neighbors in the network at all times but otherwise have no information on the network or the current choices of others in the network. There is no other communication between subjects permitted.

The experiment offers payoffs to individuals only if all 36 subjects arrive at the same colour choice before the end of the one minute (in this sense the pressure to coordinate is even greater than in the battle of the sexes game, where payoffs depended on the extent of local coordination only). For concreteness, we will suppose that there are two types of players: Blue players who are paid \$1.25 for Blue consensus and \$0.75 for Red consensus. There are Red players who are paid \$1.25 for Red consensus and \$0.75 for Blue consensus. To reiterate, payments are made only if (red or blue) global unanimity is reached. This requirement of unanimity is extreme but it helps us develop the main points in a simple way.

There are three design variables underlying the experiment: the number of individuals with different preferences, their placement in the network and the structure of the network. There are two broad categories of experiments: the Cohesion experiments and the Minority Power experiments. The networks used have roughly the same number of edges (roughly 100) but we consider two networks: an Erdos-Renyi network and a preferential attachment network.

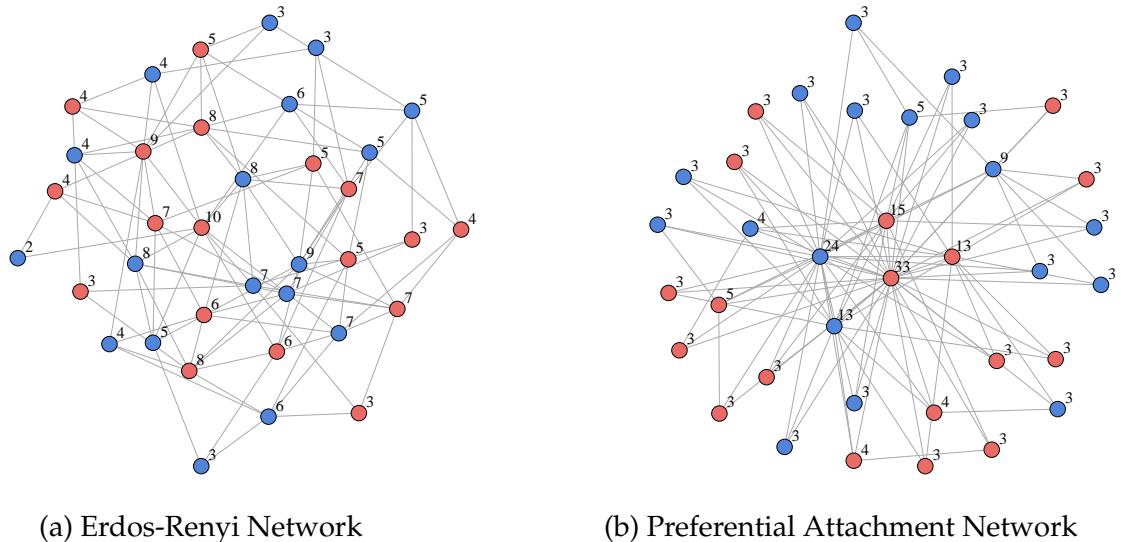

Figure 12.6: Cohesion Experiment Configurations: Two Equal Groups of 18

In the Cohesion experiments, vertices were divided into two equal groups corresponding to their colour preferences. One goal of the experiment was to examine how variation in the network structure – from Erdos-Renyi to Preferential Attachment – could alter social coordination choices. Figure 12.6 presents examples of networks with these features.

In the Minority Power experiments, all networks were generated via preferential attachment. A minority of the vertices with the highest degrees (number of neighbors) were then assigned incentives preferring Red to Blue (the size of the minority varied between 6, 9, and 14), the remaining majority of subjects were Blue types. One objective of the Minority experiment was to examine the influence of a small but well connected group of individuals on collective behaviour. Figure 12.7 presents networks and locates players with colour preferences in the networks.

The authors ran experiments with a variety of payoff configurations but here we will restrict ourselves to discussing the symmetric case: the Blue subjects and the Red subjects exhibited the same payoff differences (\$1.25 versus \$0.75).

At any instant in time, a subject sees the current color choices of the neighbours. The subject's payoffs for the experiment are shown, there is a bar that shows the time that has elapsed in the experiment and there is a 'game progress,' indicator that measures the fraction of edges in the network which choose the same color on each end.

Let us summarize the main findings. On the issue of whether groups arrived at consensus, there was a significant difference in success rate between the Cohesion experiments

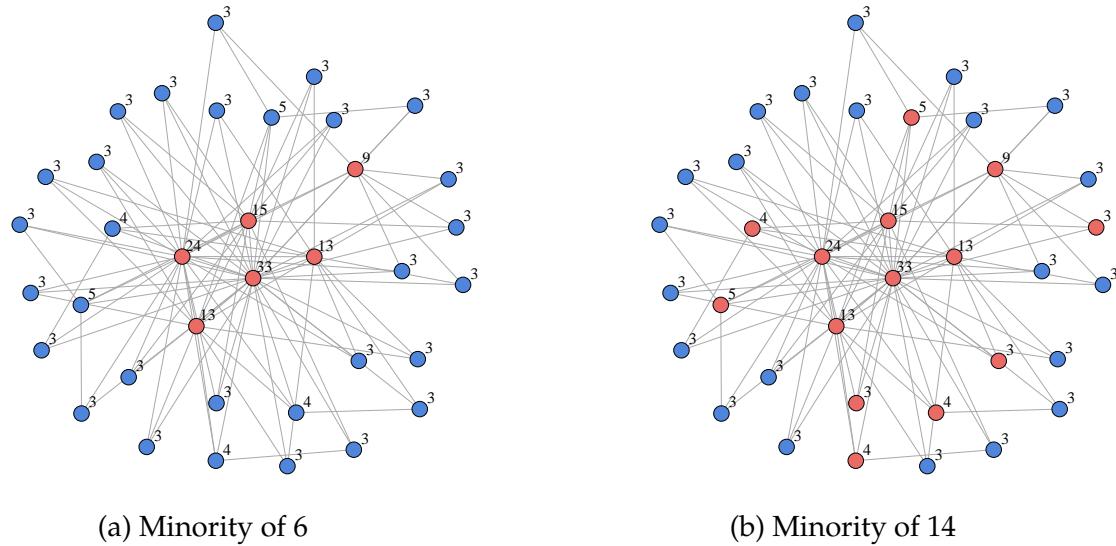

Figure 12.7: Minority Power Configurations: Preferential Attachment Networks

and the Minority Power experiments: subjects found it significantly easier to reach consensus in the Minority Power experiments. A second observation is that in all the cases where the group was successful in the Minority Power experiment, the global consensus was reached on the colour preferred by the well-connected minority. Together these results suggest that not only can an influentially positioned minority group reliably override the majority preference, but that such a group can in fact facilitate global unity.

Our next observation is that within the Cohesion experiments, unanimity was much more likely in the preferential attachment network as compared to the Erdos–Renyi network. When we combine this with the high success rate of the preferential attachment Minority Power experiments we are led to the view that for this class of consensus problems, preferential attachment networks are easier for subjects as compared to the Erdos–Renyi networks.

### 12.5.1 Endogenous Networks

Modern societies experience large scale migration of people from rural to urban areas and from one country to another. Diversity of preferences on issues of shared interest arise naturally and as examples in the previous section illustrate this can give rise to a tension between preference for diversity and the need for common standards or norms. This tension raises the following possibility. A community may sustain its preferred way of doing things – on dress or diet or religion – through social segregation and that this would come

at the cost of social coordination. Our discussion draws on Advani and Reich [2015] and Goyal, Hernández, Martínez-Cánovas, Moisan, Muñoz-Herrera, and Sánchez [2021a].

There are  $N = \{1, 2, \dots, n\}$  with  $n \geq 3$  individuals. There are two actions in the coordination game: A and B. Every individual  $i$  has a type,  $\theta_i \in \{A, B\}$ . Individuals first choose links with others and then they choose between actions A and B. Links are binary,  $g_{ij} \in \{0, 1\}$ : a link is formed between  $i$  and  $j$  if they both wish to form a link. After the network is created, individual  $i$  chooses action  $x_i : g \rightarrow \{A, B\}$ . In equation 12.1, we will suppose that  $d = e = 0$ . The payoff to individual  $i$  from strategy profile  $s = (x, g) = (x_1, \dots, x_n, g_1, \dots, g_n)$  is

$$u_i(\theta_i, x, g) = \lambda_{x_i(g)}^{\theta_i} (1 + \sum_{j \in N_i(g)} I_{\{x_i(g) = x_j(g)\}}) - |N_i(g)|k \quad (12.6)$$

$I_{x_j=x_i}$  is the indicator function for  $i$ 's neighbour  $j$  who choose same action as  $i$ . We will denote  $\bar{g}_{ij}$  as reflecting the situation where  $i$  and  $j$  have proposed with a link with each other, and therefore the link has actually been formed. We set  $\lambda_{x_i(\bar{g})}^{\theta_i} = \alpha$  if  $x_i(\bar{g}) = \theta_i$  and  $\lambda_{x_i(\bar{g})}^{\theta_i} = \beta$  if  $x_i(\bar{g}) \neq \theta_i$ . To focus attention on the interesting case, we will assume  $\beta > k$

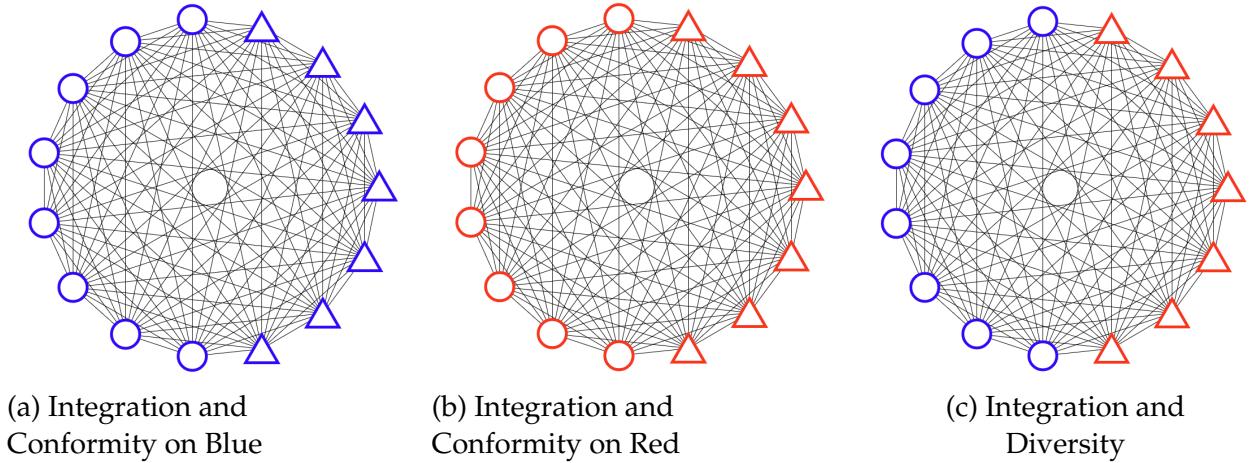

To understand strategic behaviour in our setting, we adapt the pairwise stability notion from Jackson and Wolinsky [1996b] presented in chapter 3 to our setting. In the spirit of their definition, we say that a network and corresponding equilibrium action profile is stable if no individual can profitably deviate either unilaterally or with one other individual. Given a network action pair  $(\bar{g}, x(\bar{g}))$ ,  $x_{-ij}(\bar{g})$  refers to the choices of all players, other than players  $i$  and  $j$ .

**Definition 12.1.** A network-action pair  $(\bar{g}, x(\bar{g}))$  is pairwise stable if:

1.  $x(\bar{g})$  is an equilibrium action profile given network  $\bar{g}$ .
2. for every  $\bar{g}_{ij} = 1$ ,  $u_i(x, \bar{g}) \geq u_i(x', \bar{g} - \bar{g}_{ij})$  and  $u_j(x, \bar{g}) \geq u_j(x'', \bar{g} - \bar{g}_{ij})$ , where  $x'(\bar{g} - \bar{g}_{ij})$  and  $x''(\bar{g} - \bar{g}_{ij})$  are some equilibrium action profiles given network  $\bar{g} - \bar{g}_{ij}$ .
3. for every  $\bar{g}_{ij} = 0$ ,  $u_i(x, \bar{g}) \geq u_i(x', \bar{g} + \bar{g}_{ij})$  or  $u_j(x, \bar{g}) \geq u_j(x', \bar{g} + \bar{g}_{ij})$  where  $x'(\bar{g} + \bar{g}_{ij})$  is some equilibrium action profile given network  $\bar{g} + \bar{g}_{ij}$ .

Figures 12.8 and 12.9 illustrate the pairwise stable network and action profiles (a *circle* node represents a player in the majority and a *triangle* a player in the minority. Majority players prefer action A represented by color blue, while minority players prefer action B represented by color red. The border color of a node displays its chosen action.)

Individual decisions on linking create the possibility of fruitful interaction and the choices in the coordination game determine the actual payoffs. It is possible then to study

Figure 12.8: Pairwise Stable outcomes for  $k = 0$ .

how well individuals do and the group does as a result of the choices that individuals make. We will say that an outcome is efficient if it maximizes the sum of payoffs of all individuals.

An interesting general property is the following: individuals creating the complete network and everyone choosing the majority's preferred action maximizes sum of individual utilities. To develop some intuition for the property, let us consider the complete network. Fixing the behavior of one group, observe that the total aggregate payoffs can only decrease when the other group mixes actions. We therefore only need to compare the two outcomes: one, where everyone conforms to action *up*, and two, where everyone conforms to action *down*. The concluding step shows that conformity on *up* is better if and only if the group that prefers *up* constitutes a majority. Observe that this argument holds for arbitrary values of  $\alpha$  and  $\beta$ . Thus conformity is preferred even if  $\alpha$  is much larger than  $\beta$ : this is because the minority collectively gains less than what the majority losses when the minority switches away from conformism to diversity. We note that the socially efficient outcome is invariant with respect to value of the linking cost  $k$  (so long as it is below  $\beta$ ). A question at the end of the chapter works through the details of the argument.

As the theory is permissive – allowing for both connected and partially connected networks and for both conformism as well as diversity – we turn to experiments to help us develop a better understanding of the problem. The focus of the experiment is on the effects of endogenous linking: we first consider a treatment in which the complete network is given and subjects choose an action and then take up the treatment in which individuals choose links as well as actions.

We will focus on groups of 15 subjects with a majority of 8 (that prefers 'up') and a minority of 7 (that prefers 'down'). There are three groups in a session and two sessions

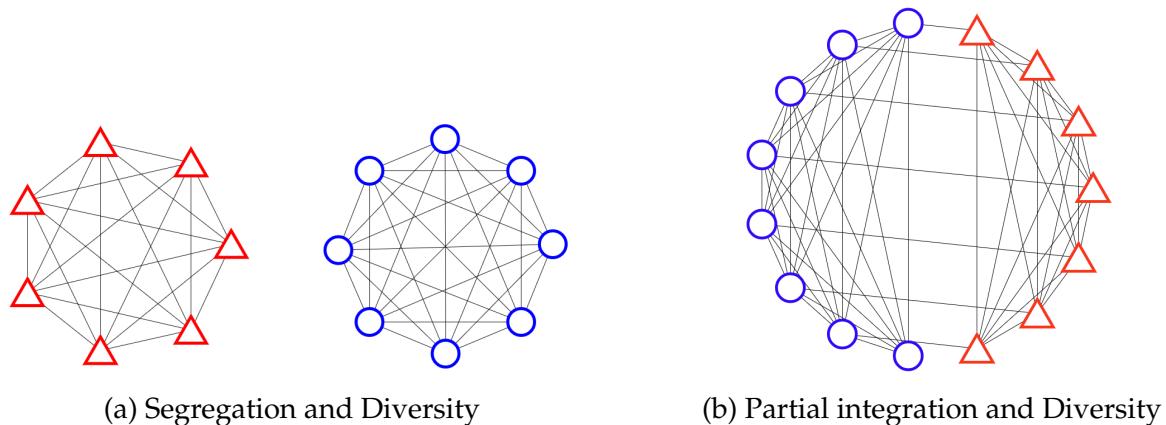

Figure 12.9: Pairwise Stable outcomes for  $k = 0$ .

per treatment (six groups per treatment). Every group plays the game 25 times. The first 5 (rounds) are for trial, subjects are paid based on their actions in the last twenty rounds.

The parameters of payoffs are as follows: coordinating on preferred action brings 4, coordinating on the less preferred action brings 2. The cost of link,  $k$ , is set equal to 0, to facilitate comparison across the exogenous and endogenous link treatments. The theoretical predictions are set out in the Table below.

Player type	Equilibrium Payoffs			
	Endogenous	Exogenous	Endogenous	Exogenous
Minority ( $\Delta$ )	30	28	30	28
Majority (O)	60	32	60	32

Turning to the experimental findings, we start by describing the linking patterns. Subjects create roughly 94.5 links (out of a possible 105), individual average degree is 12.59 (out of a maximum possible 14). There are no differences in connectivity between majority and minority players. The interesting point is that practically all subjects are fully connected to everyone of their own type: almost all the missing links are those between subjects who prefer different actions.

Next we turn to choice of actions in the two treatments with exogenous and endogenous links. Figure 12.10 shows that the average number of subjects choosing the majority's action are 12.68 and 8.18, respectively. This difference is entirely due to choices of the minority.

One reason for why this outcome is surprising is that minority could be earning more by conforming with the majority's preferred action. With this payoff loss in mind, let us

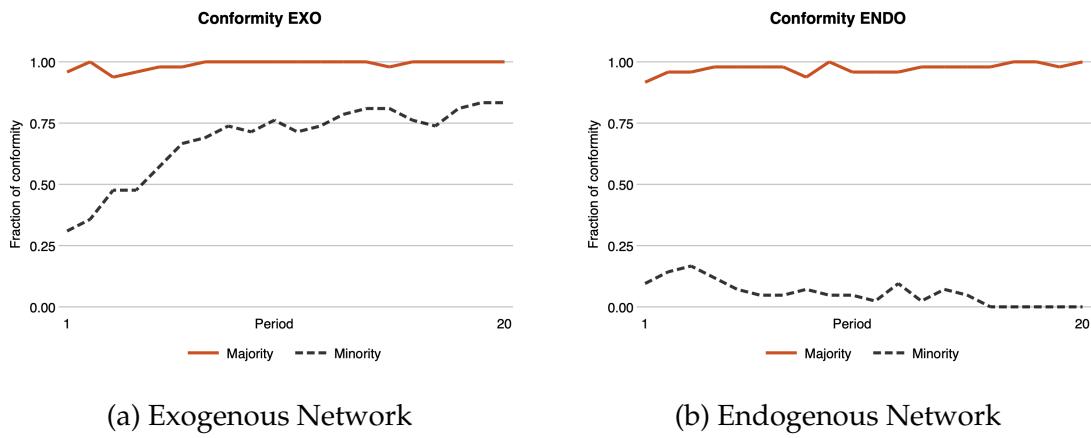

Figure 12.10: Coordination Game Choices

compare the payoffs of the minority subjects in the two treatments. It turns out that the average minority payoffs under the exogenous complete network are *not* significantly different from the average payoffs obtained with the diversity outcome under the endogenous treatment. This is due to slower rate of convergence under exogenous networks.

This leads us to the following tentative explanation: due to the large number of individuals and the different preferences, subjects face a very complex coordination problem. They use cues from the environment and any instruments that they have available to simplify the coordination problem. In the experiment, relatively greater linking with own types correlates strongly with rapid convergence to choosing preferred actions, i.e., to diversity in actions.

## 12.6 Appendix

### 12.6.1 Potential Functions and Stochastic Stability

In the discussion in section 12.4, we started with a myopic best response decision rule and supplemented it with small but persistent mutations and looked at what happens as the probability of mutations becomes small. The key assumption was that errors take place independently of the payoffs. We now explore the issue of payoff sensitive experiments. Following the work of Blume [1993] and Young [1998], one strand of the literature has studied the log-linear best response. We will present the dynamics under this rule and develop the formal arguments in detail as they involve the use of potential functions, a concept that is general interest for the study of games on networks (a point we also made in chapter 4 above).

Let us suppose that in any period  $t$ , an individual  $i$  located in network  $g$  is drawn at random and chooses (say)  $\alpha$  according to a probability distribution,  $p_i^\gamma(\alpha|s^t, g)$ , where  $\gamma > 0$  and  $s^t$  is the strategy profile at time  $t$ .

$$p_i^\gamma(\alpha|s^t, g) = \frac{e^{\gamma\Pi_i(\alpha, s_{-i}^t|g)}}{e^{\gamma\Pi_i(\alpha, s_{-i}^t|g)} + e^{\gamma\Pi_i(\beta, s_{-i}^t|g)}} \quad (12.7)$$

For large values of  $\gamma$  the probability distribution will place most of the probability mass on the best response action. Define  $\Delta_i(s|g) = \Pi_i(\beta, s_{-i}|g) - \Pi_i(\alpha, s_{-i}|g)$ . Then for large  $\gamma$  the probability of action  $\alpha$  is:

$$p_i^\gamma(\alpha|s^t, g) = \frac{e^{-\gamma\Delta_i(s^t|g)}}{1 + e^{-\gamma\Delta_i(s^t|g)}} \cong e^{-\gamma\Delta_i(s^t|g)}. \quad (12.8)$$

The probability of not choosing the best response is exponentially declining in the payoff loss from the deviation. It turns out that dynamics of the log-linear decision rule are extremely well behaved. To develop some intuition for the dynamics let us return to the star network example. In that network, the simplest way to implement a transition is via a switch in the action of the central player. In the standard model, with payoff insensitive mutations, the probability of the central player making a switch from  $A$  to  $B$  is the same as the other way around. Matters are very different under the log-linear response rule. If there are many peripheral players then there is a significant difference in the payoff losses involved and the probability of switching from  $A$  to  $B$  is significantly smaller than the probability of switching from  $B$  to  $A$ .

Our main result with log-linear decision rule says that the long run in network invariant: in all networks, the risk-dominant outcome prevails. As the proof builds on the ideas of potential functions a concept that is of general interest for the study of games on networks more generally, we present a complete proof.

A game has a *potential* if there exists a real valued function  $F(x, y)$  and a re-scaling of the utility functions such that whenever a player deviates unilaterally, the change in payoff equals the change in the potential. For a symmetric two-player game, this means that there exists a symmetric function  $F(x, y) = F(y, x)$ , such that for some re-scaling of utilities,  $\pi_i$ , and for all  $x, x', y \in S_i$ ,

$$\pi_i(x, y) - \pi_i(x', y) = F(x, y) - F(x', y) \quad (12.9)$$

Next note that if a symmetric two-player game admits a potential, then so does the corresponding social game on a network  $g$ . To see this let  $x$  be a profile of actions in the social game, and suppose that player  $i$  deviates by choosing  $x'_i$ . Let  $x' = (x'_i, x_{-i})$ . Then

$$\begin{aligned}
\Pi_i(x|g) - \Pi_i(x'|g) &= \sum_{j \in N_i(g)} [\pi_i(x_i, x_j) - \pi_i(x'_i, x_j)] \\
&= \sum_{j \in N_i(g)} [F(x_i, x_j) - F(x'_i, x_j)] \\
&= \sum_{g_{h,k}=1} F(x_h, x_k) - \sum_{g_{h,k}=1} F(x'_h, x'_k)
\end{aligned}$$

where  $g_{h,k} = 1$  refers to all links that are present in network  $g$ . It follows that a potential for the social game is

$$F^*(x|g) = \sum_{g_{h,k}=1} F(x_h, x_k)$$

Given a network  $g$ , let  $P_g^\gamma$  be the probability transition matrix corresponding to the dynamic process and the log-linear decision rule with some  $\gamma > 0$ . The following result on long run behavior of the system, due to Young [1998], can now be stated and proved.

**Proposition 12.5.** *Consider a symmetric two person game with potential function  $F$ . Let  $g$  be an undirected graph. For every  $\gamma > 0$ , the adaptive process  $P_g^\gamma$  has the unique stationary distribution:*

$$\mu_g^\gamma = \frac{e^{\gamma F^*(x|g)}}{\sum_{z \in S} e^{\gamma F^*(z|g)}} \quad (12.10)$$

and the stochastically stable states of the social game are those that maximize  $F^*(x)$ .

The proof of this result is as follows: For simplicity write  $\mu$  instead of  $\mu_g^\gamma$  and  $P$  instead of  $P_g^\gamma$ . The detailed balanced condition states:

$$\mu(x)P(xy) = \mu(y)P(yx) \text{ for all } x, y \in S. \quad (12.11)$$

Let us begin by showing that  $\mu$  satisfies this detailed balance condition. First observe that  $P(xy) > 0$  only if either  $x = y$  or  $x$  and  $y$  differ for exactly one player. Note that any player is chosen with probability  $1/n$ . This means that:

$$\begin{aligned}
\mu(x)P(xy) &= \frac{1}{n} \left[ \frac{\exp(\gamma F^*(x))}{\sum_{z \in S} \exp(\gamma F^*(z))} \right] \\
&\times \left[ \frac{\exp(\gamma \sum_{j \in N_i} \pi_i(y_i, x_j))}{\sum_{z_i \in S_i} \exp(\gamma \sum_{j \in N_i} \pi_i(z_i, x_j))} \right]
\end{aligned} \quad (12.12)$$

Define

$$\lambda = \frac{1}{n} \left[ \frac{1}{\sum_{z \in S} \exp(\gamma F^*(z))} \right] \left[ \frac{1}{\sum_{z_i \in S_i} \exp(\gamma \sum_{j \in N_i} \pi_i(z_i, x_j))} \right] \quad (12.13)$$

This allows us to rewrite equation (12.12) as

$$\begin{aligned} \mu(x)P(xy) &= \lambda \exp \left[ \gamma \left[ \sum_{g_{h,k}=1} F(x_h, x_k) + \sum_{j \in N_i(g)} \pi_i(y_i, x_j) \right] \right] \\ &= \lambda \exp \left[ \gamma \left[ \sum_{g_{h,k}=1} F(x_h, x_k) + \sum_{j \in N_i(g)} [\pi_i(x_i, x_j) - F(x_i, x_j) + F(y_i, x_j)] \right] \right] \\ &= \lambda \exp \left[ \gamma \left[ \sum_{g_{h,k}=1} F(y_h, y_k) + \sum_{j \in N_i(g)} \pi_i(x_i, x_j) \right] \right] \\ &= \mu(y)P(yx) \end{aligned}$$

This proves that  $\mu(\cdot)$  satisfies the detailed balanced condition. Given that the detailed balance condition holds, it then follows that

$$\sum_{x \in S} \mu(x)P(xy) = \sum_{x \in S} \mu(y)P(yx) = \mu(y) \sum_{x \in S} P(yx) = \mu(y). \quad (12.14)$$

Thus  $\mu$  is an invariant distribution, and since the process is irreducible it is the unique invariant distribution. The claim on stochastically stable states now follows from the behavior of  $\mu$  as  $\gamma \rightarrow \infty$ .

Note next that there exists a potential function in the coordination game:  $F(\alpha, \alpha) = a - e$ ,  $F(\alpha, \beta) = F(\beta, \alpha) = 0$ ,  $F(\beta, \beta) = b - d$ . Next define  $w_\alpha(x)$  ( $w_\beta(x)$ ) as the total number of player pairs who choose  $\alpha$  ( $\beta$ ) in profile  $x$ . Then it follows that probability of profile  $x$  in the invariant distribution  $\mu(x)$  is proportional to  $e^{(a-e)w_\alpha + (b-d)w_\beta}$ . If  $\alpha$  is risk-dominant then  $a - e > b - d$  and it follows that  $\mu(\cdot)$  places all probability mass on the state where everyone chooses the risk dominant action. ■

### 12.6.2 Thresholds, Networks and Common Knowledge

In the models so far we have been concerned with coordination problems played on networks and in which individuals earn payoffs out of interactions that occur locally on links in a network. In this section, we very briefly touch upon a rather different class of situations: let us suppose that people are aware that a demonstration against the government

is being planned for tomorrow. If a large number of people show up then the protest will be successful (for instance the government may be forced to change its stance) and everyone in society – including the demonstrators – will benefit. But if only a few people show up then the demonstrators may be dispersed or arrested and it would have been better to not turn up for the protest. This is an example of a situation in which benefits from an action are contingent on how many others do likewise. It is therefore reminiscent of the examples we considered in the chapter on platforms and intermediation. However, there is an added layer of difficulty: there may not be enough time to collect information on how many people are planning to turn up and so individuals may have to make decisions based on knowledge gathered over time from their existing social networks. Alternatively, the collective action may be an uprising against a repressive regime and so individuals can only trust their immediate neighbours with any information.

We would like to understand what features of a network facilitate the organization of such collective actions. Our discussion outlines a model of collective action of thresholds in networks; this model draws on the work of Chwe [2000] and Granovetter [1978]. The exposition in this section draws on the discussion in Easley and Kleinberg [2010].

Suppose that everyone knows about an upcoming protest against the government. Individuals differ in their willingness to take risk that is captured by a threshold: a threshold of 4 for instance means that this person will show up if for the protest if she is sure that at least 4 people will show up. These individuals are located in a network. A link in this network indicates that the two connected individuals know each other's threshold. Therefore, every person knows the thresholds of all her neighbors in the network. Who will turn up for protest and who will stay at home? Will a protest take place if there are enough people with thresholds that support the protest?

We will discuss some examples of small networks to address these points. Let us assume that everyone knows the social network. Consider the network given in Figure 12.11a. Suppose that  $w$  would only join the protest if at least 4 people (in all) do. Since there are only three people in total, this means she will never turn up for protest. Node  $v$  has a threshold of 3. She knows that  $w$ 's threshold is 4, so she knows that  $w$  will not turn up. Since  $v$  requires 3 people in order to be willing to join,  $v$  knows there will not be enough people joining the protest, and so she will not turn up either. Finally,  $u$  only requires 2 people in order to participate, but she knows the thresholds of both  $w$  and  $v$  and therefore knows that no one else will join. Hence she too will not join.

We next take up a slightly more interesting network as in Figure 12.11b. Let us consider the situation from  $u$ 's perspective; suppose that  $u$ 's threshold is  $x$ . She knows that  $v$  and  $w$  each have a threshold of 3, and she knows that  $u$ ,  $v$ , and  $w$  will individually feel safe taking

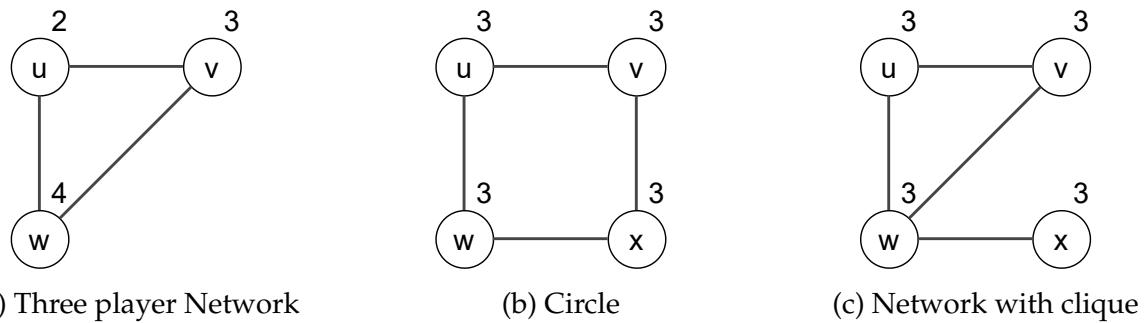

Figure 12.11: Thresholds, Networks, and Protest. Taken from Easley and Kleinberg [2010].

part in a protest that contained all three of them. However, as she knows the network, she can infer that  $v$  and  $w$  do not know each other's thresholds. This means that they are not sure there are enough people going to turn up for the protest and so they will not choose to protest either. How about  $u$ ? Observe that in this network  $u$  does not know  $x$ 's threshold: it could be very high like 5. In that case, node  $v$ , seeing neighbours with 3 and a high threshold like 5, would not join the protest. Similarly for  $w$ . So if  $u$  joined the protest, she would be the only one. Therefore it is not safe for  $u$  to join. As  $u$ 's situation is the same as for all four nodes it follows that no protest happens. Observe that in this example, every node knows that there are three nodes with thresholds of 3 and this number is enough for a protest to form. Each of the nodes holds back from joining the protest because they cannot be sure that the other node knows this fact.

Things would turn out very differently if the link from  $v$  to  $x$  were moved and if it connected  $v$  and  $w$  instead. This yields us the network as in Figure 12.11c. In this new network observe that each of  $u$ ,  $v$ , and  $w$  knows that there are three nodes with threshold 3, and each of them also know that each of the others know this fact, and so forth. In other words, this fact is common knowledge among the three of them. This suffices for them to have the confidence to choose the protest action.

This simple example points to a general insight: for a given set of individuals with protest thresholds that are compatible for protest to actually go on protest the network that connects them must have the ability to generate common knowledge about this fact. In the example we have explored we have shown that the clique structure among individuals with appropriate thresholds is useful in generating common knowledge. This logic can be extended to the case of individuals with different thresholds: these groups of individuals with different thresholds can be located in a hierarchy of cliques with the smallest thresholds being located at the top of the hierarchy.

Figure 12.12 presents an example of such a network. In this network, there are individuals with thresholds 1, 3, 4, 6 and 9. The two individuals with threshold 3 are connected to

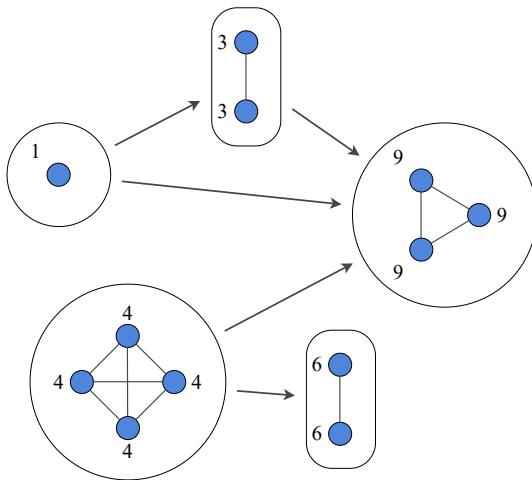

Figure 12.12: Hierarchy of cliques. Taken from Chwe [2000]

each other and commonly observe an individual with threshold thereby establishing common knowledge of 3 individuals with 3 or lower thresholds. The 4 individuals with threshold 4 constitute a clique among themselves; similarly the two individuals with threshold 6 observe each other and commonly observe all the individuals with threshold 4, thereby ensuring common knowledge that 6 individuals have appropriate threshold. Finally the three individuals with threshold 9 are connected to each other and in addition commonly observe all individuals with thresholds 1, 3 and 4 thereby establishing common knowledge that at least 9 individuals have 9 or lower threshold.

The reader will recall that overlapping neighbourhoods were also a factor in coordination on a the risky action in our study of games on networks in chapter 4. For further elaborations on this connection between networks and common knowledge and real world illustrations see Chwe [2000].

## 12.7 Reading Notes

The literature on coordination problems goes back a long way. One may reason from introspection and seek to arrive at a solution. In this spirit, Thomas Schelling offers an excellent introduction to the notion of focal points as a solution to the coordination problem in his book, *The Strategy of Conflict* (Schelling [1960]). The idea of a risk-dominant action is due to Harsanyi and Selten [1988]. For recent work in this tradition, see Bacharach [1999], and Sugden et al. [2004]. David Lewis offers a philosopher's perspective on how conventions help resolve problems of social coordination in his book, *Convention: A Philosophical Study* (Lewis [1969]). The dynamics of choice offer an alternative perspective where societies

solve coordination problems through the gradual accumulation of precedent. In his book *The Civilizing Process* Norbert Elias (Elias [1978]) offers an early historical and conceptual contribution on this subject. For a more recent theoretical perspective on the evolution of conventions, see Peyton Young's *Individual Strategy and Social Structure* (Young [1998]). In this chapter, we have presented the latter, dynamic, perspective to the emergence of social conventions and we have focused on the role of networks in that context.

The study of games on networks has been an active field of study for close to three decades. In the early 1990's, Blume [1993] and Ellison [1993] introduced the study of binary action coordination problems among players located on simple networks (like the cycle and lattices). The exposition in Sections 2 and 3 draws on Goyal [2007a]. The section focusses on the static problem of coordination. A number of authors have explored dynamics of learning and coordination, and some of this work studies the role of network structure.

Blume [1993] studied coordination games on lattices and showed convergence of behaviour to the risk-dominant action. An early result on convergence of dynamics to Nash equilibrium in regular networks (where every player has the same number of neighbors) is presented in Anderlini and Ianni [1996]. Ellison [1993] showed that local interaction has implications for speed of convergence – specifically that local interaction among neighbours on a cycle facilitates faster convergence as compared to random (or global) interaction. Cassar [2007] provides evidence in support of faster convergence under local interaction. On the issue of equilibrium selection – Pareto-dominant versus risk-dominant equilibrium – Blume [1993] and Ellison [1993] show that learning dynamics under local interaction lead to the risk dominant outcome. However, Berninghaus, Ehrhart, and Keser [2002] and Cassar [2007] present experimental evidence that local interaction with high clustering – as in the small world network of Watts and Strogatz [1998] – leads to the Pareto-dominant outcome.

The material on the introduction of a new norm in a society with an existing norms in section 4 is taken from Goyal [1996] and Morris [2000]; our exposition draws on exposition on Easley and Kleinberg [2010].

The existence of multiple strict Nash equilibria in simple games of coordination had motivated a very large body of literature that explores equilibrium selection/refinement criteria. One strand of this work that has been very fruitful examines the role of perturbations (trials or experiments). A number of different models of experiments have been proposed. In this chapter, we discussed stochastic stability at some length. The notion of stochastic stability was introduced by Foster and Young [1990], Kandori et al. [1993] and Young [1993]. The basic model of stochastic stability says that experiments are made

independently of the costs. This assumption has been explored by a number of authors.

Following on Blume [1993] and Young [1998] we present one possible elaboration on this formulation – the log-linear best response – in which the probability of experiments declines exponentially in the payoff losses. We show that the log linear best response rule has a powerful implication: players select the risk-dominant equilibrium in all networks. As the proof uses the notion of potential functions a concept of wider interest in the study of games on networks, we present the formal definitions and the details of the proof. The material is more advanced and it is presented in an Appendix. We mention one other rule here to further draw out the importance of decision rules for the dynamics and the selection of equilibrium. This is the imitate the best payoff action. Robson and Vega-Redondo [1996] study this rule in the context of social coordination games, and show that, taken together with random matching, it leads to the efficient action being the unique stochastically stable action. The study of imitation dynamics in a model with local interaction and suitable informational constraints appears to be an open problem.

The discussion on coordination games in networks suggests that the interaction structure has important effects on social coordination. These networks of interaction evolve over time, as individuals reconfigure their network. We present a theoretical model in which individuals choose links and also an action in the coordination game. This framework draws on the work of Goyal and Vega-Redondo [2005], Jackson and Watts [2002b] and Gilles and Johnson [2000]. The minimum effort game (also referred to as the weakest-link game) allows for a more general treatment of risk versus efficiency and it has been the subject of extensive study, important contributions include Van Huyck et al. [1990], Crawford [1995] and Weber [2006]; for an overview of the literature see Riedl, Rohde, and Strobel [2016]. Experiments on the weakest link game show that as group size grows subjects tend toward the minimum effort equilibrium. We discuss the recent work of Riedl, Rohde, and Strobel [2016] that shows how endogenous linking can dramatically alter subject behaviour leading them to select the efficient equilibrium.

The final part of the chapter takes up the study of coordination problems in a setting where individuals differ in their preferred equilibrium. The study of identity, tastes, and its impact on coordination is spread across several disciplines. The dynamics of how preferences on neighbourhoods can give rise to sharp patterns of segregation was highlighted by Thomas Schelling in his influential work *Micromotives and Macrobbehaviour* [2006]. For a general introduction to contemporary debates surrounding identity, see Fukuyama [2018]. For an introduction to the study of identity in economics see Akerlof and Kranton [2000].

Game theory offers us a natural formulation of coordination games with conflicting

preferences: the ‘battle of the sexes’ game. The chapter presents this game and discusses how network structure can affect social coordination. Section 6 draws on the work of Advani and Reich [2015], Kearns, Judd, Tan, and Wortman [2009] and Goyal, Hernández, Martínez-Cánovas, Moisan, Muñoz-Herrera, and Sánchez [2021a]. In a closely related paper Kearns et al. [2012] study endogenous linking in a game of voting with biased voters. In this game, players must coordinate on the *same* vote to earn a payoff. They find that with endogenous linking, subjects form rich networks but fail to reach coordination. This finding is consistent with the findings of the experiment in Goyal et al. [2021a] that are presented in section 12.5.1. In recent years, the co-evolution of networks and behaviour has been studied in a broader range of contexts. The interested reader is urged to consult Vega-Redondo [2016] for an overview of this research.

The study of thresholds in social action has a distinguished history, see e.g., Granovetter [1978] and Schelling [2006]. We presented a model taken from Chwe [2000] in which social structure serves to locally communicate the thresholds of individuals. The role of communication networks in facilitating protest movements has been highlighted in the context of the Arab Spring movements; see for example the discussion in Acemoglu, Hassan, and Tahoun [2018].

## 12.8 Questions

1. Discuss the relation between the  $q$  – core of a network (discussed in the chapter on network structure and human behaviour) and a  $p$  – cohesive set of nodes in a network (discussed in this chapter).
2. Consider the model of myopic best response dynamics studied in the chapter. Suppose that the network is as in Figure 12.13. At the start everyone is choosing action  $B$ . Suppose that every node has threshold  $q = 2/5$  for switching to action  $A$ . Now, let  $e$  and  $f$  and  $k$  form a three-node set  $S$  that initially chooses action  $A$ .
  - (a) Which other nodes will eventually switch to  $A$ ?
  - (b) Find a subset of nodes outside  $S$  that blocks behavior  $A$  from spreading to all nodes.
  - (c) Suppose we can add one node to the set  $S$  of initial adopters. Is it possible to do it in such a way that the new 4-node set causes a cascade at threshold  $q = 2/5$ ?
3. (Goyal and Janssen [1997] In some contexts, we can choose a ‘flexible’ option in addition to the two actions  $A$  and  $B$ . We can learn two languages or carry two credit cards.

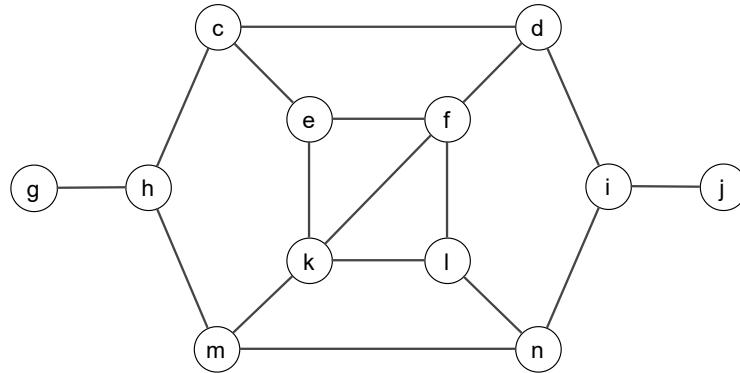

Figure 12.13: Network Example

Someone who is flexible can effectively engage with individuals who choose either one of the two actions. Suppose the cost of choosing the flexible action is  $c > 0$ . Then the matrix of payoffs with actions  $A, B$  and  $(A, B)$  can be written as follows.

	2	$A$	$B$	$B$
1				
$A$		$a, a$	$d, e$	$a, a - c$
$B$		$e, d$	$b, b$	$b, b - c$
$(A, B)$		$a - c, a$	$b - c, b$	$a - c, a - c$

Table 1

where  $a > d$ ;  $b > d$ ;  $d > e$ ;  $a + d > b + e$ ;  $a < b$ ;  $a > c > 0$ .

- (a) Compute the Nash equilibrium of this two-person game.
- (b) Suppose there are  $n$  players that are located around a circle. Every player interacts with one neighbour on either side. Payoffs of a player are the sum of earnings from the games with the two neighbours. Describe some of the Nash equilibria of this local interaction game.
- (c) Suppose that  $n$  is large. Consider the myopic best-response dynamic process. At the start there is an interval of players that chooses  $A$  and that the rest of the players choose  $B$ . What are the circumstances – on the costs of the flexible action – under which the dynamics will lead to efficient action and risk-dominant action taking over the entire population?
- (d) Develop examples of networks in which the flexible action is played in equilibrium.

4. Consider the two stage game of linking and actions in the coordination game studied in section 12.5.1. Show that if  $k < \beta$  then a complete network with everyone coordinating on the majority's preferred action maximizes sum of individual utilities.

# **Chapter 13: Communication and Social Learning**

## **13.1 Introduction**

In these democratic days, any investigation into the trustworthiness and peculiarities of popular judgements is of interest. The material about to be discussed refers to a small matter, but it is much to the point. *Galton 1907, pages 450-451.*

In his piece '*Voice of the People*', Francis Galton (1907) discusses the merits of estimating the weight of an ox by asking individuals. Eight hundred persons submitted a guess, the guesses ranged from 1074 (fifth percentile) to a bit over 1293 pounds (ninety fifth percentile). The median guess was 1207, while the correct weight was 1198 pounds. The median weight was thus less than one percent off the correct weight and he also found that more than 50% of the guesses lay within roughly 3% of the true weight. This weight-competition gives us a first feel for the 'wisdom of the crowd': individuals typically hold a variety of views – reflecting their different experiences and their expertise. However, if we were to take an average of their opinions – by identifying the median or the mean – then we could arrive at something close to the truth.

A hundred years later, democratic politics has become more common across the world, and as the scale of social media has grown, our opinions and beliefs matter for an ever widening range of subjects. For instance, we decide on who to hire, where to work, which computer or car to buy, what to eat to remain healthy, which fruit or vegetable to plant, what combination of inputs to use to grow a crop, where to go for a holiday, how real is global warming and what should we do about it. New goods and services and new ideas are regularly being added to existing options. In this world of change and ever expanding choice, we try to inform ourselves of the alternatives and then make decisions. As there are often many aspects to the decisions and it is costly to invest time and effort, we necessarily seek out the opinions and thoughts of others. The sharing of information via mass

media and personal interaction is therefore a central feature of our day-to-day life. This chapter studies the role of patterns of communication in shaping individual opinions and behaviour.

To set the stage we begin by presenting a number of case studies on opinions and choices and on the role of social interaction. These case studies cover a wide range of empirical contexts ranging across medicine, agriculture, climate change, fishing, and all the way to domestic and international politics. Taken along side our earlier discussions on social networks and communication in chapters 1 and 11, they motivate an enquiry into general principles that govern social influence in networks of communication.

We lay out a theoretical framework in which individuals carry out activities that generate information and they share this information with others. The information sharing shapes opinions and these opinions then lead to new actions that generate new information, and so forth. Our goal is to understand how the information sharing connections among individuals affect the generation and the flow of information. This allows us to understand the circumstances under which information is adequately generated and successfully aggregated and the determinants of the rate at which this aggregation takes place. Motivated by the our case study of Twitter in chapter 1 and the case studies in this chapter, in our theoretical studies we devote special attention to networks with unequal connections and on the role of homophily.

We explore models with fully rational individuals as well as bounded rational individuals. We will use the DeGroot approach as a model of bounded rational individuals. It turns out that on some of the fundamental questions (such as whether opinions converge and whether they are correct) – the theoretical predictions of a fully rational and a bounded rational model are similar. But there are questions on which the DeGroot approach allows us to obtain more complete answers. For instance take the question of wisdom of crowds: when is a large group going to have correct beliefs and choose the right action? The Bayesian model helps us develop the intuition that influential individuals may interfere with information aggregation and social learning and offers us sufficient conditions on networks for correct consensus. The DeGroot approach yields us a complete answer to this question: a large group of individuals learns the truth if and only if there are no overly influential individuals in it. In other words, absence of influential individuals is both necessary and sufficient for wisdom of crowds. Similarly, on the role of homophily: the Bayesian model provides us examples with diversity of beliefs and choices, while the DeGroot model shows that homophily slows down learning and this sustains diversity of opinions for much longer. The final section of the chapter presents experimental evidence that offers strong support for these theoretical predictions on the role of network inequality

and homophily.

## 13.2 Evidence on Social Influence

This section starts with a discussion of the classical early studies on social influence carried out by sociologists in the middle of the twentieth century. It then presents studies on innovation in agriculture. This is followed by a discussion of the role of social influence in shaping views and behaviour on climate change and the environment. Finally, we present an experiment on the effects of network structure on the accuracy of guesses in a numerical estimation problem.

### EARLY STUDIES

In the early twentieth century, with the coming of radio, television and newspapers, it was felt that the views and the decisions of individuals would be largely shaped by mass media. In *People's Choice*, Lazarsfeld, Berelson, and Gaudet [1948] studied the determinants of voting behavior in the American Presidential Election of 1940 in the small midwest town of Erie, Ohio. The study involved repeated interviews of a sample of 2400 voters from May to October 1940. It showed that individual voters identified personal interactions and specific individuals as critical to a change in how they voted.

Building on this study, in a subsequent book, *Personal Influence*, Katz and Lazarsfeld [1966] studied marketing, fashion, film viewing and public affairs. They conducted a survey of 800 female residents of Decatur, Illinois in 1945-46. In this survey they identified a fraction of their sample as potential 'opinion leaders' – these individuals were instrumental in the respondent changing their opinion and their choice. This work also highlighted another feature of the nature of social influence – the opinion leaders are 'not a group apart'; that opinion leadership is not a trait possessed by some and not by others. Rather, opinion leaders are scattered across the different strata of society – and that the leadership arises out of day-to-day personal relationships.

The spread of modern medicines is a major factor in explaining the remarkable improvements in the longevity and the quality and human life over the past hundred years. There is considerable uncertainty when a new drug or a new treatment is introduced – this uncertainty arises partly out the differences in the ways in which different patients respond. Thus information about efficacy of the treatment is vital in facilitating its adoption. A early study on medical innovation pertains to the adoption of the antibiotic, *tetracycline*, in four midwestern towns of the United States in the 1950's. Coleman, Katz, and Menzel [1966] examine the timing of first prescription by a physician. The timing ranged widely – some doctors adopted within the first four months while many others had not adopted the

drug even after a year.

Physicians were asked to fill a survey with questions concerning information about their personal characteristics and their social contacts. 125 general practitioners, internists, and pediatricians were studied – they constituted 85% of the doctors in these fields practising in the four towns. The doctors were asked three questions: To whom did he most often turn for advice and information? With whom did he most often discuss his cases in the course of an ordinary week? Who were the friends, among his colleagues, whom he saw most often socially? Physicians could nominate up to 3 doctors in response to each of these questions.

The *main finding* is that there is a positive correlation between the number of social connections and the speed of adoption. Consider the 36 doctors who were mentioned as friends by no one: at the six months point, only 30% of these doctors had prescribed the drug; at the 8 months point, only 42% of these doctors had prescribed the drug. By contrast, consider the 33 doctors who were mentioned as friends by 3 or more other doctors: at the six month point, 70% of them had prescribed the drug, and by the eight month point, over 91% of these doctors had prescribed the drug.

#### INNOVATION IN AGRICULTURE

The adoption of new technologies is central to change in agriculture and to the process of economic development. For a new technology to be adopted by a farmer its fit with the local circumstances must be understood. This usually calls for experimentation with different input combinations. As neighbouring farmers face similar circumstances, it is natural that they should learn from each other's experience. We present two studies that document the importance of such social learning.

*High Yielding Variety (HYV) Seeds in the Green Revolution in India in the 1960's:* Foster and Rosenzweig [1995] collected data on 4,118 households for the crop years 1968-69, 1969-70, and 1970-71. This data covered information on area planted with the new high-yielding seed varieties (for wheat and rice). Farmers' adoption of HYVs occurred at an accelerated rate over this 3-year period: consider villages where there was some adoption of HVV seeds by 1970: in this set of villages only 19 percent were using HYV seeds in 1968, 29 percent had used the new seeds by 1969, and 42 percent had used them by 1970. Moreover, among farmers using HYV seeds in the 1970-71 crop year, acreage under HYV seeds grew from only 4 percent of their cultivated land in the 1968-69 crop year to over 20 percent of cultivated land in 1970-71.

The *main finding* was that imperfect information about the appropriate input combination was a key obstacle to the adoption of HYV seeds. In particular, they found that farmers

with experienced neighbors were significantly more profitable and devoted more of their land to new technologies than those with inexperienced neighbors.

*Pineapple in Ghana in 1990's:* In this period, an established system of maize and cassava intercropping was transformed into intensive production of pineapple for export to European markets. This is taken from. The interest is in how farmers learnt about the appropriate level of input use.

Conley and Udry [2010] collected data in three villages of southern Ghana for the 1996-1998 period. In the sample villages, pineapple was grown by less than 10 percent of farmers in 1990 and it was grown by over 46 percent of farmers in 1997. In all, 180 households were drawn from a population of 550 households. The focus was on 132 farmers who cultivated pineapple on 406 plots in all. Of these plots, 288 were planted during the survey period and the study focuses on the determinants of 113 observed changes in fertilizer use.

The information network of every farmer was plotted; spatial proximity was a contributing factor to information links, but farmers often held ties with further away farmers too. A farmer used his own experience with inputs and profits and combines it with the experience of his information neighbours to decide on input use in subsequent periods. The *main finding* was that changes in fertilizer use by a farmer were affected by the experience of his information neighbours – if the experience of neighbours using the same fertilizer mix was negative, then that led to a change in the farmer's behaviour. Moreover, the responsiveness to news in the information neighbourhood was inversely related to the level of own experience: veteran pineapple farmers responded less to news from their neighbours than novice farmers.

#### CLIMATE CHANGE AND ENVIRONMENT

We now present studies on the role of social networks in shaping beliefs about climate change and fishing behaviour.

*Opinions on Climate Change:* There is robust evidence that temperature has increased over the past hundred years and there is wide agreement among scientists that human activity has played an important role in bringing about this increase. Yet there are exist significant differences in popular opinion on both issues. In a 2019 Pew Survey of (a sample of) Americans one half believed that human activity contributes a great deal to climate change, thirty percent felt that human actions have some role in climate change, and twenty percent believe that human activity does not play a role or plays no role at all in climate change (Funk and Hefferon [2019]). These differences were strongly correlated with the political position of the respondents. For instance, among liberal Democrats 84% felt that human

activity contributes a great deal to climate change, while among conservative Republicans only 14% felt that way. In the latter group, 45% believed that humans play not too much or no role at all in climate change.

*Fishing and Sharks:* Hawaii's longline fishery is a limited-entry industry supplying domestic and international markets with fresh tuna and swordfish. It is the largest commercial fishing sector in the Hawaiian Islands. From 2008 to 2012, there were 122–129 active vessels that completed between 1,205 and 1,381 annual fishing trips. They generated revenues of 65 to 94 million USD per year. A major concern for these fisheries is that they encounter sharks while fishing for tuna and swordfish. This can lead to the capture of a species of sharks (that is under threat).

Barnes, Lynham, Kalberg, and Leung [2016] collect data on the social network among fishers and how that relates to the number of sharks captured. The fisher group is composed of three distinct ethnic groups: Vietnamese Americans (VA), European Americans (EA), and Korean Americans (KA). The social network of fishers – who shares information with whom – exhibits strong homophily: fishers organize themselves into three distinct communities that overlap strongly with ethnicity. Out of 159 fishers, only 6 have a majority of ties outside their ethnic group, while 1 fisher has an equal proportion of intra-ethnic and inter-ethnic group ties. We will refer to these 6 as outliers. The network is shown in Figure 13.1. The figure reports mean ( $\mu$ ) and standard deviation ( $\sigma$ ) in shark bycatch (per 1,000 hooks) in Hawaii's tuna fishery for the years 2008 to 2012: there is a big difference across the three communities.

To examine the role of networks, the authors focus on the behaviour of the outliers whose connections span groups with very different rates of shark bycatch. They find that the behaviour of these outliers is closer to the behaviour of their respective information neighbourhoods than with their own ethnic group. The effect of information networks can be very large: if, for instance, all the three ethnic communities were to catch sharks at the same rate as the EA ethnic group then roughly 46,339 sharks might have been avoided (leading to a 12% reduction in overall shark bycatch for Hawaii).

#### DOMESTIC AND INTERNATIONAL POLITICS

We present two case studies taken from the United States.

*Weapons of Mass Destruction (WMD) in Iraq:* The case for the invasion of Iraq in 2003 centred on the argument that Saddam Hussein's regime had WMD and that these were a threat to regional stability and international peace. In a poll conducted in October 2004, Americans held very different views on this issue: 47% of Republican respondents believed that Iraq had weapons of mass destruction and only 9% of Democrats thought so. Over a year

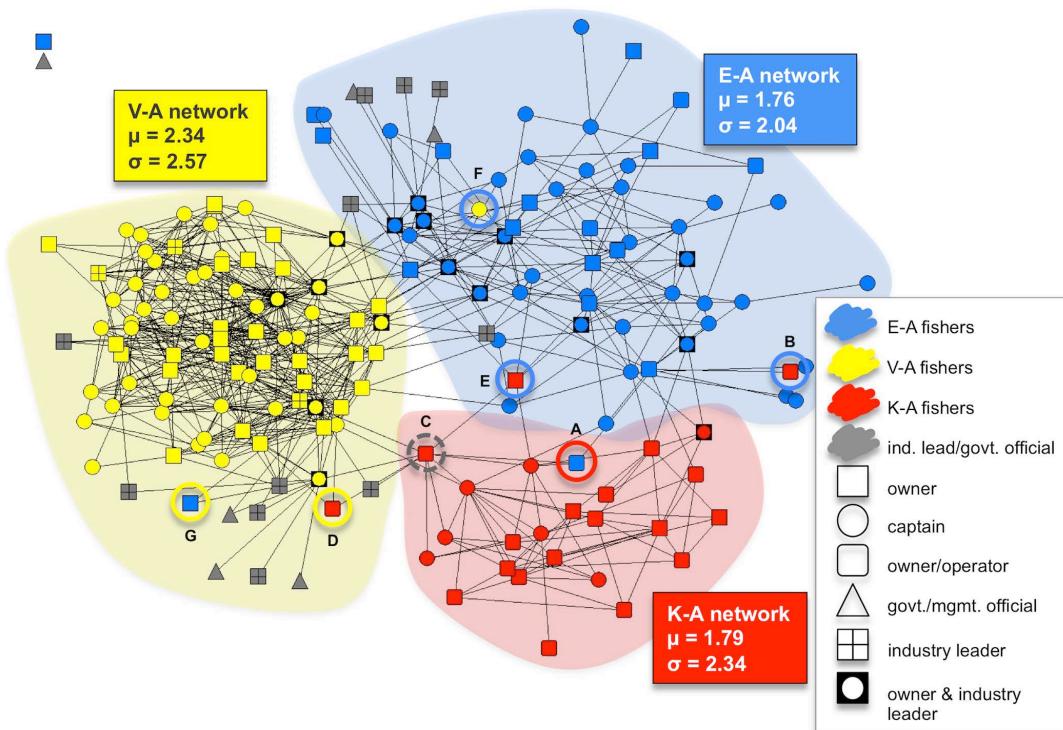

Figure 13.1: Social Networks and sharks bycatch. Each node corresponds to an individual fisher color coded by ethnicity or an actor deemed important for information sharing by respondents (i.e., industry leader, government, or management official). Information sharing groups are delimited by color. Two isolates not connected to anyone are located in the top left corner. Circled nodes denote outliers. Those with solid lines represent fishers who have a majority of ties outside their ethnic group, with the color of the circle corresponding to the group they have a majority of ties to. Those with gray dashed lines denote nodes with an equal proportion of ties both within and outside their ethnic group. Picture courtesy of Michele L. Barnes

later a poll conducted in March 2006 found that, in spite of new information releases and continued communication and the passage of time, the percentages had barely changed: the numbers stood at 41% for Republicans and 7% for Democrats (Golub and Jackson [2012] and 'Iraq: The Separate Realities of Republicans and Democrats', the document is available on World Public Opinion web page: [www.worldpublicopinion.org](http://www.worldpublicopinion.org))

*2020 US Presidential Election:* This election was fought between Joseph Biden (Democrat) and Donald Trump (Republican). Biden won the election by a margin of over 7m votes. US federal and state officials have repeatedly said that they have no evidence that votes were compromised during this election. In the period since then election, a number of legal challenges were filed against the result and they have been turned down by courts. We discuss popular opinion on two issues: one, whether the election was fair and two, whether Biden was the actual winner. We draw on two polls conducted by Reuter/Ipsos in November 2020 and in May 2021 (Ipsos: <https://www.ipsos.com/>).

The poll conducted in November 2020 surveyed a nationally representative sample of 1346 American adults (including 598 Democrats, 496 Republicans and 149 independents). The poll found that 28% of Americans and 59% of (registered) Republicans believed that Donald Trump had won the election. More than six months after the election and after the many court decisions, little had changed. In a poll conducted in May 2021 with a sample of 2,007 adults (909 Democrats, 754 Republicans and 196 Independents), 25% of all Americans believe that Donald Trump was the winner. There was a big divide on this question across party lines: 53% of Republican and only 3% (registered) Democrats held this view.

These two studies suggest that differences on factual matters can persist in spite of communication and the accumulation of evidence over time. These differences appear to be highly correlated with political positions of those surveyed.

Our case study on Twitter in chapter 1 drew attention to its extraordinary size and the great inequality in connections across individuals (recall the plot of millionaires). The case studies in this section draw attention to the role of social interaction in shaping opinions and behaviour. In the next two sections we develop theoretical models to explore the role of social communication in shaping social learning and human behaviour.

### 13.3 Learning about a New Technology

A common theme in the case studies is that individuals have incomplete information on the different alternatives. A second feature of some of the cases studies – such as innovation

in agriculture – is that individuals may be able to learn from experience – their own as well as that of their neighbours. This learning has the capacity for shaping future actions. These considerations motivate the following model that is taken from Bala and Goyal [1998] and Bala and Goyal [2001]. The exposition draws on Goyal [2011] and Golub and Sadler [2016].

There is a set of individuals  $N = \{1, \dots, n\}$  with  $n \geq 2$  who choose between two actions  $a_0$  and  $a_1$ . The action  $a_0$  may be thought of as a known technology – it yields 1 and 0 with equal probability. Action  $a_1$  is the unknown technology – it may be a high quality or low quality. If it is high quality it yields 1 and 0 with probabilities  $\pi$  and  $1 - \pi$ , where  $\pi \in (1/2, 1)$ . If it is low quality then it yields 1 and 0 with probabilities  $(1 - \pi)$  and  $\pi$ , respectively. Individuals have a prior  $\mu_i \in (0, 1)$  that the true quality of technology  $a_1$  is high.

The expected utility from action  $a_0$  is

$$U(a_0, \mu_i) = \frac{1}{2} \cdot 1 + \frac{1}{2} \cdot 0 = \frac{1}{2} \quad (13.1)$$

For an individual with belief  $\mu_i$ , the expected utility from action  $a_1$  is

$$U(a_1, \mu_i) = \mu_i[\pi 1 + (1 - \pi)0] + (1 - \mu_i)[(1 - \pi)1 + \pi 0] = \mu \quad (13.2)$$

An individual who seeks to maximize utility will choose the new technology,  $a_1$  if  $\mu_i > 1/2$  and will choose action  $a_0$  if  $\mu_i < 1/2$ .

We now consider the individual learning problem. Suppose that an individuals choose actions repeatedly. Trials with the known technology  $a_0$  do not reveal any new information on its quality or the quality of  $a_1$ . However, when she tries the unknown technology  $a_1$  the outcomes yield information about its quality. If the action yields outcome 1, then the individual will update her belief about the quality of the action upwards, while if the outcome is negative than she will lower her belief about the quality of the action. Formally, new information is incorporated through an application of Bayes rule. Starting with some belief  $\mu_i > 1/2$ , suppose the individual tries action  $a_1$ , and the outcome is 1. Then the posterior belief that  $a_1$  is high quality is

$$\mu'_i(1) = \frac{\mu_i \pi}{\mu_i \pi + (1 - \mu_i)(1 - \pi)} \quad (13.3)$$

On the other hand, if the outcome is 0, the posterior belief is

$$\mu'_i(0) = \frac{\mu_i(1 - \pi)}{(\mu_i(1 - \pi) + (1 - \mu_i)\pi)} \quad (13.4)$$

As  $\pi > 1/2$ ,  $\mu'_i(1) > \mu_i$ , and  $\mu'_i(0) < \mu_i$ : this is the sense in which the experience with

action  $a_1$  yields information and shapes the evolution of beliefs over time.

We can now consider the learning dynamics if an individual chooses actions repeatedly. Let time be indexed  $t = 1, 2, \dots$ . In period 1, an individual chooses an action that maximizes her payoff for that period, in other words she chooses  $a_1$  if  $\mu_{i,1} > 1/2$  and chooses  $a_0$  if  $\mu_{i,1} < 1/2$ . At the end of the period, she observes the outcome of their own actions. At the start of the next period, she updates her prior  $\mu_{i,1}$ , and arrives at the belief  $\mu_{i,2}$ . She then makes a decision in period 2, and so forth.

Let us briefly comment on the long run outcomes of learning. Suppose an individual starts with an optimistic prior concerning action  $a_1$ , i.e.,  $\mu_{i,1} > 1/2$ . A simple computation on equation 13.4 tells us that there exists a sequence of 0's that would lead her to a posterior below the threshold 1/2. The probability of such a sequence is positive, irrespective of whether the action is high or low quality. Hence, the individual will stop trying out action  $a_1$  with positive probability. Once she stops she will persist with action  $a_0$  forever, as there is no further information revealed by trials with that action and so her beliefs dictate choosing  $a_0$ . Thus an individual can fail to learn that action  $a_1$  is optimal with positive probability.

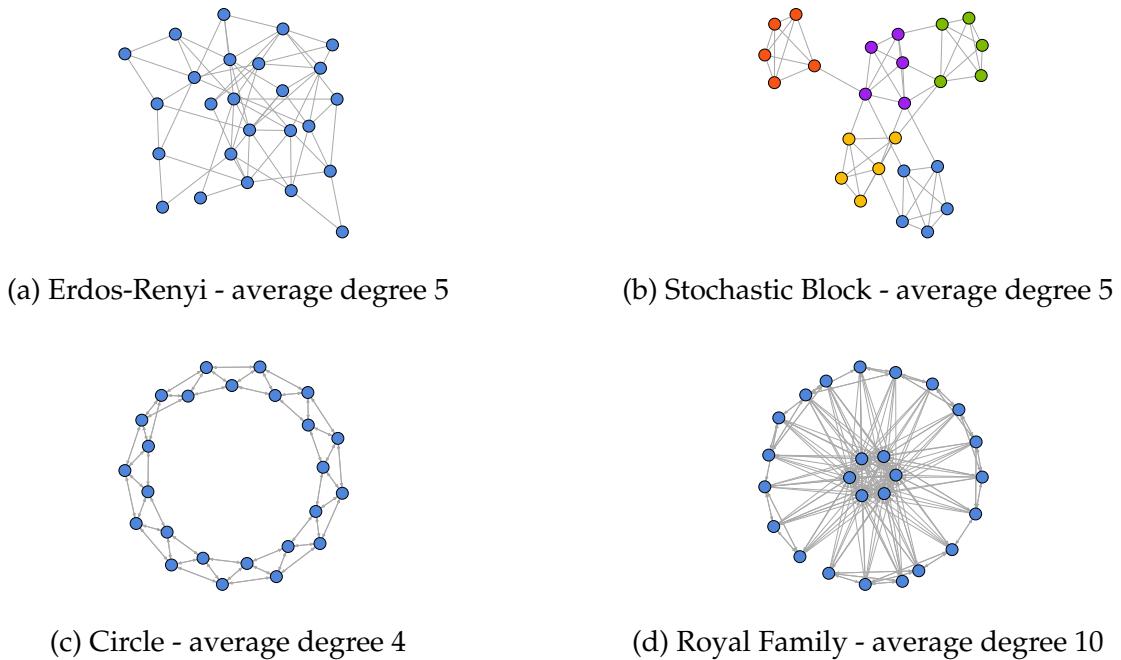

We now locate this individual in a (directed) social network where she can also observe the trials of her neighbours. What are the prospects of learning in a network?

Consider a directed network  $g$ : a link  $g_{ij} \in \{0, 1\}$  represents information access: if  $g_{ij} = 1$  then individual  $i$  observes the actions and outcomes of the actions of individual  $j$ . The set of neighbours of individual  $i$  is given by  $N_i(g) = \{k \in N | g_{ik} = 1\}$ ; let  $\eta_i(g) \equiv |N_i(g)|$  be the *out-degree* of individual  $i$ . Define  $N_{-i}(g) = \{k \in N | g_{ki} = 1\}$  as the individuals who observe  $i$ ; set  $\eta_{-i}(g) \equiv |N_{-i}(g)|$  as the *in-degree* of individual  $i$ .

Figure 13.2 presents examples of information networks (that build on our discussion in chapter 1). In the Erdos-Renyi network and the Stochastic Block network for all  $i, j$ ,  $g_{ij} = g_{ji}$ . In the circle network, every person has a local neighbourhood consisting of four individuals. Prominent social networks like Twitter combine two key elements: local neighbourhoods (that reflect homophily) and extreme inequality in degree. We accommodate them by moving from a circle network to a network with a *royal family*. This is accomplished as follows: we create a directed link from everyone to six selected individuals. This gives rise to a network with (essentially) two types of individuals: the royal family each of whom have  $n - 1$  links and those outside the royal family (with 10 links).

Recall that there is a (directed) path from  $j$  to  $i$  in  $g$  if  $g_{ij} = 1$  or if there exist distinct players  $j_1, \dots, j_m$  different from  $i$  and  $j$  such that  $g_{i,j_1} = g_{j_1,j_2} = \dots = g_{j_m,j} = 1$ . A network  $g$  is said to be *strongly connected* if there exists a path between any pair of players  $i$  and  $j$ . All four networks in Figure 13.2 are strongly connected.

So an individual  $i$  located in a network  $g$  observes her own actions and their outcomes

Figure 13.2: Simple Networks:  $n=25$ 

and the actions and outcomes of her neighbours  $N_i(g)$ . She uses these ‘experiments’ with the actions to update her beliefs over time.

We note that in principle, the choices of a neighbour reveal something about her priors and that over time they may also reveal something about the actions and experience of the neighbours of her neighbor. So, for instance, if a neighbour having chosen action  $a_0$  for several periods switches to action  $a_1$  this probably means that she has learnt something about action  $a_1$  by observing her neighbours. For simplicity, we will first assume that an individual makes no inferences from the choice of actions of her neighbours. We then return to the issue of indirect inferences about neighbours of neighbours subsequently.

All the ingredients of the learning from neighbours model are now in place. We will explore the influence of the network,  $g$ , on the evolution of individual actions, beliefs, and utilities,  $(a_{i,t}, \mu_{i,t}, U_{i,t})_{i \in N}$ , over time.

### 13.3.1 Information Aggregation

Individual actions are an optimal response to beliefs, which in turn evolve in response to the information generated by actions. Thus the dynamics of actions and beliefs feed back on each other. Over time, as an individual observes the outcomes of own actions and the actions and outcomes of neighbors, his beliefs will evolve depending on the particularities

of his experience. However, it seems intuitive that as time goes by, and his experience grows, additional information should have a smaller and smaller effect on his beliefs about action  $a_1$ . As actions respond to beliefs, we would expect that as beliefs settle down, so should actions and utilities. Moreover, as an individual observes his neighbours period after period, we would expect that she should be able to do as well as them. Iterating on this improvement principle, we note that individual A should do as well as her neighbours who do as well as their neighbours. Putting together these points yields the following result on learning and information aggregation.

**Proposition 13.1.** *The beliefs, actions and utilities of individuals converge in the long run. If the society is strongly connected then every individual chooses the same action and earns the same utility.*

First, observe that if an individual with belief  $\mu_i$  tries action  $a_1$ , then her expected belief after the action is

$$(\mu_i\pi + (1 - \mu_i)(1 - \pi))\mu'_i(1) + (\mu_i(1 - \pi) + (1 - \mu_i)\pi)\mu'_i(0) = \mu_i. \quad (13.5)$$

This equation says that the expected posterior belief is equal to the current belief: the beliefs are a Martingale. Standard arguments from the theory of martingales tell us that beliefs converge to a limit belief; for an introduction to the study of martingales the interested reader is referred to Williams [1991].

Second, consider actions and utilities: an individual's action is optimal with respect to her beliefs. Thus the long run actions of any individual must be optimal with respect to her long run beliefs. Someone who observes this individual can in principle 'imitate' this action and therefore earn the same payoff. While this observation is intuitively plausible, we need to be careful in the reasoning: the principal complication is that individual  $i$  observes the actions and corresponding outcomes of a neighbor  $j$ , but does not observe the actions and outcomes of the neighbors of  $j$ . The claim that  $i$  does as well as  $j$  if he observes  $j$  then rests on the idea that all payoff relevant information that  $j$  has gathered is 'implicitly' reflected in the choices that he makes, over time. In particular, if  $j$  chooses a certain action in the long run then this action must be the best action for him, conditional on all his information. However, individual  $i$  observes these actions and the corresponding outcomes and can therefore do as well as  $j$  by simply imitating  $j$ .

This 'improvement via imitation' logic extends along paths: in a strongly connected society, every individual has a directed path to every other individual, so it follows that everyone must do as well as everyone else. Thus, all players converge on the same action and earn the same utility. The discussion provides us a high level outline of the arguments

underlying the result; a question at the end of the chapter works through the formal details.

### 13.3.2 Learning optimal actions

We started our examination of learning in networks with the issue of whether an individual located in a social network will eventually learn the optimal action. This section shows that the answer to this depends on the structure of the network.

To see the role of the network in the simplest setting, suppose that action  $a_1$  is of high quality and suppose that all individuals start with prior beliefs  $\mu_{i,0} > 1/2$ . We will also assume that

$$\min_{i \in N} \mu_{i,1} > \frac{1}{2} \quad \max_{i \in N} \mu_{i,1} < \frac{1}{1+x} \quad (13.6)$$

where  $x = (1 - \pi)/\pi \in (0, 1)$ . In period 1, everyone tries action  $a_1$ . Suppose that individuals are located in a royal family network as given by in Figure 13.2. In this example every person observes her four local neighbours and the six members of the royal family (in common)

Suppose that every individual in the royal family is unlucky in the first period and gets an outcome of 0. Any individual on the circle can hope to get at most five positive signals from her local neighborhood. Thus any person in this society will have a minimum residual of one negative signal. Given the assumptions on priors, it is easily checked that this negative information is sufficient to push the posteriors below the critical cut-off level of  $1/2$ . Thus every individual will switch to action  $a_0$  in period 2.

Observe that action  $a_0$  yields no new information in period 2. So beliefs in period 3 will remain as in period 2. Everyone will choose action  $a_0$  in period 3, and this will remain so, for all subsequent periods. Thus the society is locked into (the sub-optimal) action  $a_0$  forever. Finally, observe that this argument holds irrespective of the size of the society. This example provides one illustration of the breakdown of the wisdom of crowds.

The ‘royal family’ plays a crucial role in this breakdown of learning. To see this consider the circle network in which everyone observes their four immediate neighbours (as in panel (c) of Figure 13.2). As action  $a_1$  is high quality, from elementary considerations it follows that if an individual tries this action forever then there is a set of sample paths (with positive probability on which the number of 1’s always remains greater than the number of 0’s. Similar sequences of actions can be constructed for each of the four neighbors of player  $i$ . Exploiting the independence of actions across players, it follows that the probability of the five players  $\{i-2, i-1, i, i+1, i+2\}$  receiving positive information on average is strictly positive. Let this probability be  $q > 0$ . Recalling our assumption of absence of

indirect inference from the neighbours of neighbours, we conclude that the experience of individuals outside her neighborhood cannot lower the beliefs of individual  $i$  (when the outcomes of her neighbours are uniformly positive). Thus the probability of individual  $i$  choosing the suboptimal action  $a_0$ , in the long run, is bounded above by  $1 - q$ .

We can construct a similar set of outcomes for individual  $i + 5$ , whose information neighborhood is  $\{i + 3, i + 4, i + 5, i + 6, i + 7\}$ . From the independent and identical nature of trials by different individuals, the probability of this sample of paths is also  $q > 0$ . As individuals  $i$  and  $i + 5$  do not share any neighbors, the two events,

$$\{i \text{ doesn't try optimal action}\}$$

and

$$\{i + 5 \text{ doesn't try optimal action}\}$$

are independent. The probability of the joint event

$$\{ \text{neither } i \text{ nor } i + 5 \text{ try the optimal action}\}$$

is bounded above by  $(1 - q)^2$ . In a society where the neighbourhood is given by  $N_i = \{i - 2, i - 1, i + 1, i + 2\}$ , the probability of learning can be made arbitrarily close to 1, by raising the number of such individuals. In other words, wisdom of crowds obtains in a (sufficiently large) circle network.

More generally, we can say that two individuals A and B are *locally independent* if their neighbourhoods are disjoint – they share no neighbours in common. Locally independent individuals who start with action  $a_1$  each have a positive probability – that is independent – of persisting with that action forever. The above argument shows us that in a *large* society if enough people start by trying out action  $a_1$ , then some of these players will obtain positive results and continue using the optimal action forever. They will thereby gather sufficient information and learn the true quality of this action. Then, from strong connectedness, it follows that they will also ensure that everyone chooses the optimal action in the long run.

**Proposition 13.2.** *Consider a strongly connected society. The probability that everyone chooses an optimal action in the long run can be made arbitrarily close to 1, by suitably increasing the number of locally independent optimistic players.*

Our discussion provides us a high level idea of the arguments underlying this result; the details of the proof of the result are developed in a question at the end of this chapter.

### 13.3.3 Homophily

Proposition 13.1 says that in a strongly connected society all individuals will obtain the same utility. In our baseline model with two actions there is a unique optimal action in either state of the world. To see the role of homophily in the simplest way imagine that in addition to  $a_0$  and  $a_1$ , there is an action  $a_2$ , which can be of high or low type (with probabilities for outcome 1, given by  $\pi$  or  $1 - \pi$  as for action  $a_1$ ). There are four states of the world corresponding to both  $a_1$  and  $a_2$  being of high or low quality and two states corresponding to the case where one is of high quality and the other of low quality. Now we can apply the arguments of Proposition 13.1 to infer that in a strongly connected society all individuals must earn the same utility in the long run. However, in the state where both  $a_1$  and  $a_2$  are high quality, Proposition 13.1 leaves open the possibility that some individuals choose action  $a_1$  while others choose action  $a_2$ . We examine the role of homophily in this specific situation.

Suppose all individuals start with the same priors on the true state. Let us consider society with two communities and vary the level of integration of the communities. Figure 13.3 presents three network with varying levels of integration: the networks in panels (a) and (b) exhibit imperfect integration (with most individuals linked more within their own group as compared to outside the group), and the network in panel (c) is complete and exhibits full integration. Building in the arguments in the previous section, we can say that it is possible that the individuals in blue start with action  $a_1$  and persist with that action forever, while individuals in the red group start with action  $a_2$  and receive positive signals on that action and persist with that action forever. Crucially, the bridge agents that connect the two communities are more exposed to their own groups and therefore also persist with the group's action. Thus it is the selective exposure of individuals to information that sustains diversity of actions in the long run. In the complete network, everyone receives the same information and therefore must choose the same action (here we are abstracting from the case of indifference). The formal details of the proof of this result are outside the scope of the chapter; the interested reader is urged to consult Bala and Goyal [2001].

### 13.3.4 Variations on the model

In the model above, we assumed that individuals do not make inferences from the choice of actions of their neighbours about the information that the neighbours are accessing from their neighbours. This places a restriction on the rationality of individuals. It is possible to relax this assumption. A rich strand of recent research explores the implications of networks when individuals are fully rational. We consider a model originally proposed by

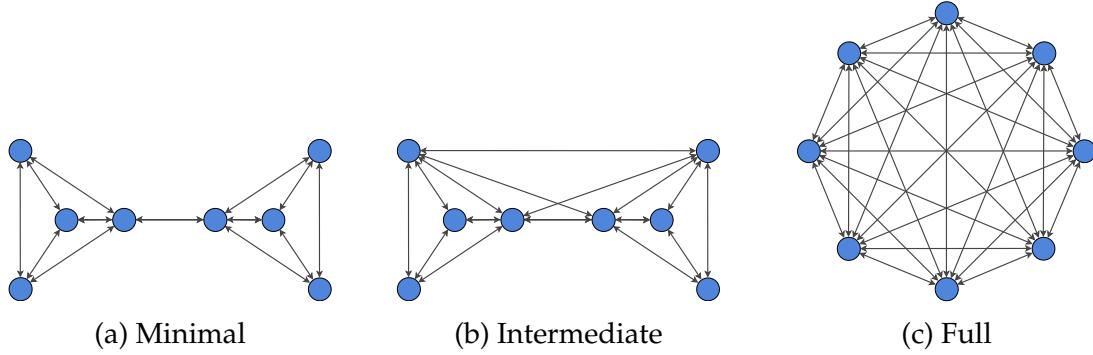

Figure 13.3: Levels of integration:  $n=8$

Gale and Kariv [2003] and that has been subsequently studied by a number of authors, see e.g., Mossel, Sly, and Tamuz [2014], Mossel, Sly, and Tamuz [2015] and Chandrasekhar, Larreguy, and Xandri [2020].

In this model, individuals receive a single informative signal at the beginning of the game. Each player in the game makes a guess about the true state in each period. For simplicity, and to avoid strategic interaction issues, suppose that individuals choose an action that maximizes single period utility. Given this behavior, however, belief updating based on observed neighbors' choices is fully rational: in other words, indirect inferences about signals of the neighbours of neighbours are allowed. In this context, the improvement-through-imitation principle holds: individuals can ensure themselves the same expected utility as a neighbor through imitation, and they may improve based on their other information.

Building on this principle, it is possible to show that the insights of Propositions 13.1 and 13.2 can be generalized and shown to hold when individuals make indirect inferences about neighbours of neighbours through changes in guesses/actions of their neighbours. In particular, strong connectedness ensures that everyone chooses an action that yields the same expected utility. This action is optimal in undirected networks but may fail to be optimal in networks that contain a royal family.

At different points in the section, we have commented on the complexity of making inferences about information that others hold and especially about the information of the neighbours of neighbours. These types of inferences appear to be implausible and especially so when we consider networks with hundreds (or thousands) of individuals. With these concerns in mind, we now turn to a study of information aggregation and opinion formation when individuals follow bounded rational rules.

### 13.4 A model of communication and social Influence

Galton's study of weights draws attention to two central ideas: one, information is diverse and dispersed among different individuals in the community and two, this information, when put together, provides an accurate estimate of the truth of the matter at hand. In his setting, individuals were asked to submit their guesses but in many contexts individuals talk and share ideas. This section presents a model that examines this process of communication: does social communication allow individuals to gain access to all useful information available and how quickly is this accomplished? The material in this section is taken from DeMarzo, Vayanos, and Zwiebel [2003], Golub and Jackson [2010] and Golub and Jackson [2012]. Our exposition draws on Goyal [2011], Jackson [2008] and Golub and Sadler [2016].

There is a set  $N = \{1, 2, \dots, n\}$  with  $n \geq 2$  individuals, each of whom starts with a belief at date 0, a number given by  $p_i(0) \in [0, 1]$ . Individuals are located in a network that reflect the weight that individual  $i$  assigns to the opinions of others: the weight that  $i$  assigns to the opinion of  $j$  is given by  $w_{ij}$ , where  $w_{ij} \geq 0$ . For simplicity, it will be assumed that for every  $i$ , the sum of weights equals 1, i.e.,  $\sum_{j \in N} w_{ij} = 1$ . Let the  $n \times n$  matrix of weights be given by  $\mathbf{W}$ .

In period  $t \geq 1$  an individual  $i$  updates his belief, by taking an average of his own belief  $p_i^0$  and the opinions of others. Thus in period  $t = 1$ :

$$p_i(1) = \sum_{j \in N} w_{ij} p_j(0). \quad (13.7)$$

The belief at time period  $t \geq 1$  is similarly obtained by combining the opinions at time  $p^{t-1}$  with weights  $\mathbf{w}$ .

$$p_i(t) = \sum_{j \in N} w_{ij} p_j(t-1). \quad (13.8)$$

Define for any  $t \geq 0$ , the vector of beliefs at the start of that period

$$\mathbf{p}(t) = (p_1(t), p_2(t), p_3(t), \dots, p_n(t))$$

We study how the dynamics of opinions  $\mathbf{p}(t)$  are shaped by the initial opinions and the network of interaction.

- What are the circumstances under which individual opinions settle down?
- When does consensus obtain, i.e., all individuals settle on the same opinion?

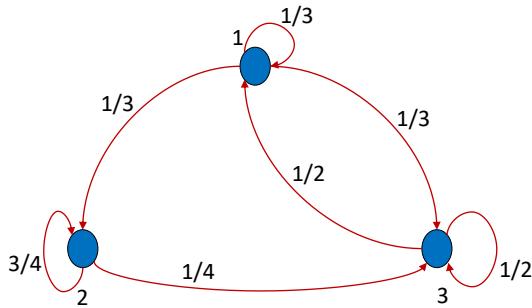

Figure 13.4: Simple Weighted Network

- When does the updating of opinions lead to efficient aggregation of information?
- What are the effects of homophily on opinion dynamics?

It is helpful to begin with some simple examples to appreciate the dynamics of opinion formation. Consider a society with 3 individuals in which the weights are as follows.

$$W = \begin{bmatrix} 1/3 & 1/3 & 1/3 \\ 1/2 & 1/2 & 0 \\ 0 & 1/4 & 3/4 \end{bmatrix} \quad (13.9)$$

Figure 13.4 illustrates this matrix in network form. Suppose we start with initial opinions  $\mathbf{p}(0) = (1, 0, 0)$ . Consider the opinions in periods 1 and 2, respectively:

$$\mathbf{p}(1) = W\mathbf{p}(0) = \begin{bmatrix} 1/3 & 1/3 & 1/3 \\ 1/2 & 1/2 & 0 \\ 0 & 1/4 & 3/4 \end{bmatrix} \times \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} = \begin{bmatrix} 1/3 \\ 1/2 \\ 0 \end{bmatrix} \quad (13.10)$$

$$\mathbf{p}(2) = W\mathbf{p}(1) = \begin{bmatrix} 1/3 & 1/3 & 1/3 \\ 1/2 & 1/2 & 0 \\ 0 & 1/4 & 3/4 \end{bmatrix} \times \begin{bmatrix} 1/3 \\ 1/2 \\ 0 \end{bmatrix} = \begin{bmatrix} 5/18 \\ 5/12 \\ 1/8 \end{bmatrix} \quad (13.11)$$

As individuals communicate and update their opinions, we see that their opinions be-

come more similar: at the start individual 1's opinion was 1, while individuals 2 and 3 held the opinion 0. By period 2, individual 1 has moved to 5/18, individual 2 has moved to 5/12 and individual 3 has moved to 1/8. So individual 1's opinion moves down while the opinions of 2 and 3 move up.

The rate of change of opinion depends on the weights that individuals put on their own opinion and the opinion of others. Observe that individual 1 places equal weight on all three, while individual 3 only places weight on individuals 2 and 3. Nevertheless, as individual 2 places weight on 1, the opinion of 1 has an influence on 3, over time. Indeed, as these individuals communicate further, their opinions will continue to evolve. As weights remain unchanged over time, this evolution is captured in the simple formula:

$$p(t) = Wp(t-1) = W^t p(0). \quad (13.12)$$

To understand the evolution of beliefs, it is therefore sufficient to keep track of the matrix  $W^t$  and the initial opinions  $p(0)$ . In particular,  $W^t$  'converges' to a matrix  $W^*$ :

$$\begin{bmatrix} x & y & z \\ x & y & z \\ x & y & z \end{bmatrix} \quad (13.13)$$

where the row vector  $(x, y, z)$  corresponds to the stationary distribution of WV if we view  $W$  as a Markov matrix.

In our  $3 \times 3$  example,  $W^*$  is given by

$$\begin{bmatrix} 3/11 & 4/11 & 4/11 \\ 3/11 & 4/11 & 4/11 \\ 3/11 & 4/11 & 4/11 \end{bmatrix} \quad (13.14)$$

In the long run an individual influences everyone in equal measure. The existence of  $W^*$  in turn means that long run opinion,  $p(\infty)$ :

$$p(\infty) = W^* p(0) = \begin{bmatrix} 3/11 \\ 3/11 \\ 3/11 \end{bmatrix} \quad (13.15)$$

Thus, repeated communication and updating leads to convergence of all individuals

to the same opinion. Let us examine the conditions for convergence and consensus more systematically.

### 13.4.1 Convergence and Consensus

It is useful to start with a two-person example. Suppose the initial opinion is  $p(0) = (1, 0)$  and that the weighted matrix is

$$W = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \quad (13.16)$$

It is then easy to see that in period 1,  $p(1) = Wp(0) = (0, 1)$  and in period 2,  $p(2) = W^2p(0) = (1, 0)$ . Indeed, the opinions cycle indefinitely, taking on values  $(1, 0)$  in odd periods and  $(0, 1)$  in even periods. In this example, the cycling of beliefs arises because the matrix  $W^t$  alternates every two periods. Observe that the society is *strongly connected* because individuals place all weight on each other. A simple way to avoid a cycle in opinions is to suppose that an individual places some weight on their own opinion, i.e.,  $w_{ii} > 0$ , for some  $i \in N$ . To see this, suppose the weighted matrix is given by:

$$W = \begin{bmatrix} 0.1 & 0.9 \\ 1 & 0 \end{bmatrix} \quad (13.17)$$

It is easy to verify that opinions in periods 1 and 2 are, respectively:

$$p(1) = \begin{bmatrix} 0.1 & 0.9 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} 1 \\ 0 \end{bmatrix} = \begin{bmatrix} .1 \\ 1 \end{bmatrix} \quad p(2) = \begin{bmatrix} 0.1 & 0.9 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} .1 \\ 1 \end{bmatrix} = \begin{bmatrix} .91 \\ .1 \end{bmatrix} \quad (13.18)$$

Indeed, opinions evolve smoothly. In the long run,

$$p(\infty) = \begin{bmatrix} .53 \\ .47 \end{bmatrix} \quad (13.19)$$

The other issue pertains to similarity of opinions of individuals: at an intuitive level, opinions become similar if two individuals are neighbours of each other – they place positive weight on each other. In a network, the opinions of 1 will become similar to the opinion

of 2 if there is a path from 1 to 2. However, it is possible that there is a path from 1 to 2, but that there is no path from 2 to 1. In that case, 1 is influenced by 2, but 2 is immune to the opinion of 1. A simple example of such a society is described in the following weighted matrix:

$$W = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 1/5 & 1/5 & 1/5 & 1/5 & 1/5 \\ 1/5 & 1/5 & 1/5 & 1/5 & 1/5 \\ 1/5 & 1/5 & 1/5 & 1/5 & 1/5 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad (13.20)$$

Suppose  $p(0) = (1, 0, 0, 0, 0)$ . Individual 1 will then not change her views over time, as she places no weight on anyone else; similarly, individual 5 will not change her views over time. However, individuals 2-4 will update their views, and indeed, as they assign equal weight to individuals 1 and 5, their long run opinion will the average of the opinions of 1 and 5: i.e.,  $1/2$ . Observe that the weights that 2-4 place on each other eventually disappear: as a result, in the long run, the opinions will converge to  $p^* = (1, 1/2, 1/2, 1/2, 0)$ . This example brings out the possibility of convergence without consensus. It also highlights the role of stubborn or ‘self-absorbed’ individuals, who are not receptive to the opinions of others (but others are open to them).

Let us develop sufficient conditions on the weighted network matrix for convergence and consensus. Formally, we require that there exists an  $f \geq 1$  such that all entries of the iterated matrix  $\mathbf{W}^f$  are positive, i.e.,  $w_{ij}^f > 0$ . An adjacency matrix that satisfies this property is called *primitive*. To see why ‘primitive’ matrices will exhibit convergence observe that if  $w_{ij}^f \geq \underline{w}$ , for some  $\underline{w}$ , then the range of opinions must shrink over time. Setting  $w_{\max}(t)$  and  $w_{\min}(t)$  as maximum and minimum belief at point of time  $t$ , we can infer that

$$w_{\max}(t + f) - w_{\min}(t + f) \leq (1 - \underline{w})[w_{\max}(t) - w_{\min}(t)] < w_{\max}(t) - w_{\min}(t)$$

Therefore in a society with a primitive matrix  $W$  opinions will converge to a common ‘consensus’ belief. We now turn to the issue of social influence: how much influence does an individual have on the consensus belief of their society?

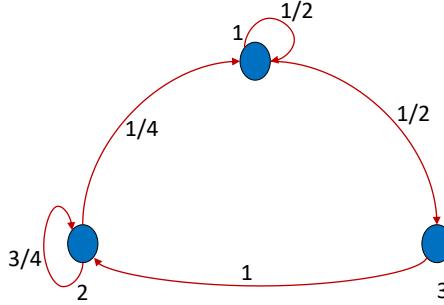

Figure 13.5: Weighted Network 2

### 13.4.2 Social Influence

Let us examine how the influence of an individual 1 on individual 2 evolves in a social network, over time. At time 1, this influence is captured by the number  $w_{21}$  as this is the weight placed by 2 on 1. At time 2, the influence of 1 on 2 is captured by the paths of length 2 that start from 2 and end at 1: this is captured by the term  $w_{21}^2$ . More generally, at time  $t$ , the influence of  $i$  on any individual  $j$  is given by  $w_{ji}^t$ . Therefore, to understand the influence of  $i$  on  $j$  in the long run, we need to examine  $w_{ji}^*$ .

As  $\mathbf{W}^T$  converges to  $\mathbf{W}^*$ ,  $w_{ji}^*$  is well defined for every pair  $i$  and  $j$ . To get a feel for evolving social influence, consider an example with three individuals that satisfies the properties of positive own-weights (1 and 3) and strong connectedness.

$$W = \begin{bmatrix} 1/2 & 1/2 & 0 \\ 0 & 0 & 1 \\ 1/4 & 0 & 3/4 \end{bmatrix} \quad (13.21)$$

Figure 13.5 presents the network corresponding to the weighted matrix. The limit influence  $W^*$  is given by:

$$W = \begin{bmatrix} 2/7 & 1/7 & 4/7 \\ 2/7 & 1/7 & 4/7 \\ 2/7 & 1/7 & 4/7 \end{bmatrix} \quad (13.22)$$

We note that in a strongly connected society, the influence of  $i$  on every individual is the same and we will refer to this as the *social influence* of  $i$  on the society and denote it by a number  $s_i$ . The social influence vector is denoted by  $\mathbf{s} = (s_1, \dots, s_n)$ .

As  $W$  is strongly connected it is easy to see that every individual must have positive social influence. The social influence of an individual may be expressed as a weighted sum of the influence of their neighbours as follows:

$$s_i = \sum_{j \in N} W_{ji} s_j. \quad (13.23)$$

Recalling the recursive nature of centrality as discussed in chapter 1, we will say that the social influence of a node is proportional to its (left) eigenvector centrality. As  $W$  is strongly connected and primitive, and the rows sum to 1, it follows from standard results in the theory of Markov Chains that  $W^*$  always exists and that there exists a unique left-hand unit eigenvector (the eigenvector corresponding to eigenvalue 1); for an overview of the theory of Markov Chains and matrix algebra see Kemeny and Snell [1983] and Seneta [2006].

**Proposition 13.3.** *Suppose that the matrix  $W$  is primitive. Then*

1. *The influence of individual  $j$  on individual  $i$  converges:*

$$\lim_{t \rightarrow \infty} w_{ij}^t = s_j. \quad (13.24)$$

2. *The opinions  $p_i(t)$  converge to  $p(\infty)$ . The limit opinion  $p(\infty) = \mathbf{s}p(0)$ .*
3. *The social influence vector  $\mathbf{s}$  is defined as the (unique) solution to*

$$\mathbf{s} \cdot \mathbf{W} = \mathbf{s}. \quad (13.25)$$

If an individual  $i$  receives more weight than individual  $j$  – i.e.,  $W_{ki} \geq W_{kj}$  for every  $k$  – then  $i$  is more influential than  $j$ . This follows from equation (13.23). This equation also implies that if  $i$  receives the same weight as  $j$  but if  $i$  receives weight from those who have more social influence then  $i$  will in turn have more influence. Next note that if all links are symmetric,  $w_{ij} = w_{ji}$  for all pairs  $i, j$ , then every individual will have the same social influence. A question at the end of the chapter works through the details of this feature of social networks.

To illustrate this result we next consider long run opinions in some well known networks. First consider a set of graphs in which links are binary and undirected, so  $g_{ij} = g_{ji}$

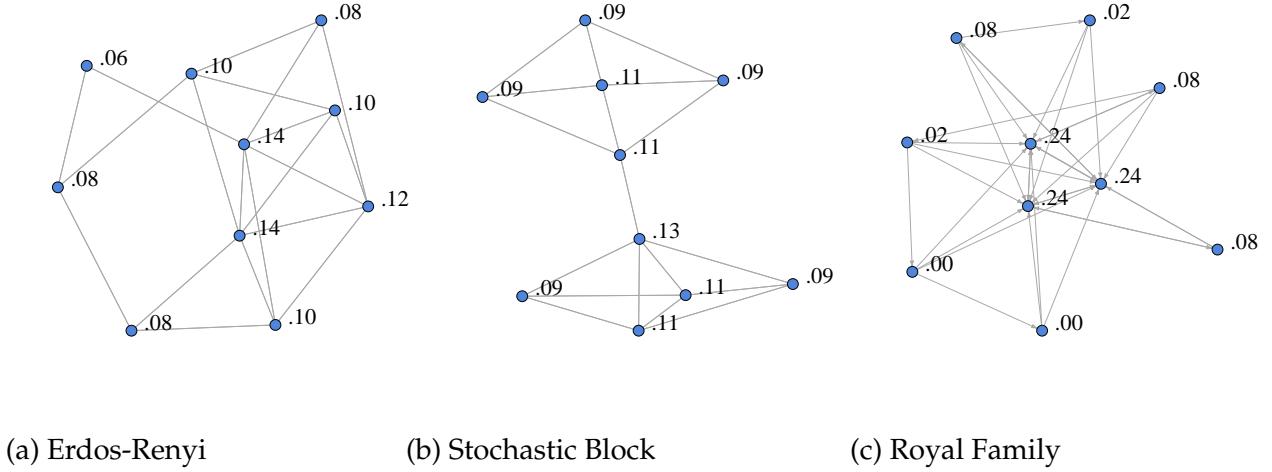

Figure 13.6: Social Influence in Networks:  $n=10$ , average degree=4

and  $g_{ij} \in \{0, 1\}$ . For every person set  $g_{ii} = 1$ , to ensure that the weights matrix is primitive. Then normalize the weights by setting  $w_{ij} = g_{ij}/d_i$ , for every  $i \in N$ . Figure 13.6 presents three networks of a society with ten individuals – an Erdos-Renyi graph, a Stochastic Block random graph, and a Royal Family graph. In all cases, the true state is 0.5. Every individual draws signals that has equal probability on  $\{0.2, 0.5, 0.8\}$ . The signals are drawn independently. So in period 0,  $p_i(0) \in \{0.2, 0.5, 0.8\}$ . Individuals then update their opinions using the weighted matrix defined by the graphs. The numbers next to the nodes presents the social influence of individuals in each of the networks. Observe that the range of social influence is modest in Erdos-Renyi and the Stochastic Block network, while it is large in the case of the Royal Family network. The ratio of maximum social influence to minimum social influence is 2.33, 1.45 and 12 in the Erdos-Renyi, Stochastic Block and Royal Family network, respectively.

### 13.4.3 Complete Learning

We turn to an issue that is at the heart of contemporary discussions: could it be that individuals in a large society hold opinions that are contrary to evidence, over extended periods of time? One way to think about this is to suppose that there is a true state and that individuals acquire impressions about it through personal enquiry or efforts. As individuals come to this issue with their own personal experiences, they may arrive at slightly different beliefs about the true state. A well known story along these lines is the Galton problem that was discussed in the introduction. The conditions under which individual idiosyncrasies cancel out and the average of these ‘views’ corresponds to the ‘truth’ has been studied in

the theory of probability. A well known theorem in probability theory, the ‘strong law of large numbers’, tells us that if individual impressions are independent and unbiased then the average opinion would become a better and better measure for the actual facts, as the number of individuals grows. In other words, a large crowd will be wise. This section examines how this central intuition is affected by the presence of network connections that route social communication.

To fix ideas, it is helpful to suppose that there is a true state given by  $\theta \in \mathbb{R}$ . Individual  $i$ ’s belief about this true state is given by  $p_i(0)$  where  $p_i(0) = \theta + \rho_i$  where  $\rho_i$  reflect some idiosyncratic term. For concreteness suppose that every person draws this  $\rho_i$  from the same distribution, and that the draw is independent. Suppose  $\rho_i \sim \mathcal{N}(0, \sigma^2)$ . In period 0, individual  $i$ ’s opinion or belief about the state of the world is simply  $p_i(0)$ . In period 1, individual  $i$  updates his view of the world upon the observation of others’ signals. Bayes’ Rule then yields:

$$p_i(1) = \sum_{j \in N} w_{ij} p_j(0).$$

where  $w_{ij}$  is a measure of the precision of  $j$ ’s signal.

We start with a consideration of some simple examples. First, consider the simple case where everyone communicates their signal to everyone else: in other words, suppose the social network is complete and every individual places weight  $1/n$  on everyone. In this case, in period 1, everyone will have the same opinion and it will be given by

$$p_i(1) = \frac{1}{n} \sum_{i \in N} p_i(0) = \theta + \frac{1}{n} \sum_{i \in N} \rho_i \quad (13.26)$$

where the first equality holds because everyone places the same weight on everyone, while the second equality holds due to the definition of individual signals. In principle, the sum of  $\rho_i$ ’s is uncertain as they are drawn from a distribution  $F$ . However, a classical result in probability theory – the strong law of large numbers – tells us that the variance of this term becomes negligible as the number of individuals grows (for a classical exposition of this theorem the interested reader is referred to Billingsley [2008]). In other words, the belief in the completely connected egalitarian network will approximate the true value of  $\theta$  in large groups, from period 1 onwards.

We now turn to opinion formation in networks more generally. The principal complication is that repeated updating privileges more connected individuals over less connected individuals. This in turn means that the former come to acquire disproportionate social influence and this influence can bias the opinion of society at large. Let us develop this idea with the help of an example of hub-spoke networks that is given by the following matrix.

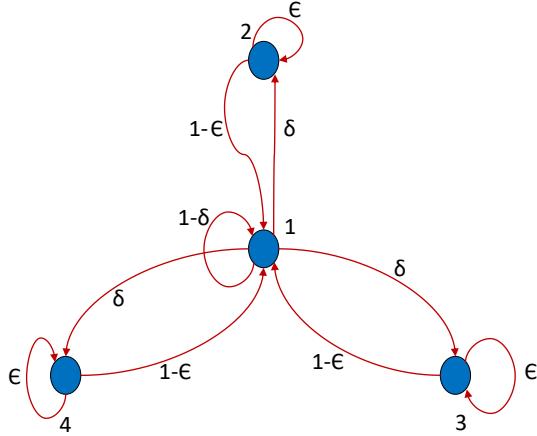

Figure 13.7: Weighted Hub-spoke Network

	1	2	3	4
1	$1-\delta$	$\delta/3$	$\delta/3$	$\delta/3$
2	$1-\epsilon$	$\epsilon$	0	0
3	$1-\epsilon$	0	$\epsilon$	0
4	$1-\epsilon$	0	0	$\epsilon$

Figure 13.7 illustrates the network corresponding to this matrix. It is easy to verify that for general  $n$ , with individual 1 at the center, the social influence vector is:

$$s_1 = \frac{1 - \epsilon}{1 - \epsilon + \delta}; \quad s_j = \frac{\delta}{(n-1)(1 - \epsilon + \delta)}, \quad j \neq 1 \quad (13.27)$$

This means that the long run belief is

$$p^* = \theta + s_1 \rho_1 + \frac{\delta}{(n-1)(1 - \epsilon + \delta)} \sum_{j=2}^n \rho_j. \quad (13.28)$$

We can see that  $p^*$  will not be equal to  $\theta$ , even when  $n$  gets large, because it will be always assign positive weight to the signal of the hub, and this signal will generally not be equal to 0. In other words, a large society organized in a hub-spoke structure will *not* arrive at the truth, through communication. Importantly, observe that in a large society we know from the law of large numbers that there will be sufficient information available to reach the truth. So we can conclude that it is the network structure that prevents information aggregation.

The example also gives us the reason for the breakdown in communication: the hub

individual comes to acquire disproportionate social influence as compared to everyone else. Observe that the influence of all other individuals becomes negligible as the size of the society  $n$  grows, while the social influence of 1 remains unchanged. This means that it is the signal of individual 1 – the  $\rho_1$  – that biases public opinion.

We have seen that influential individuals are sufficient to block correct opinions. It turns out that they are also necessary: in other words, any society where no single individual possesses significant social influence will eventually converge to the correct view (this is a more or less a direct consequence of the strong law of the large numbers).

**Proposition 13.4.** *Fix some initial beliefs  $p^n(0)$  and let  $\mathbf{W}_n$  be a sequence of primitive matrices. Let  $w_i^n$  be the social influence and  $p_i^n$  the limit belief in a network with  $n$  individuals. The limit beliefs converge (in probability) to the truth,  $\theta$ , if and only if individual social influence disappears as the society grows large, i.e,*

$$\lim_{n \rightarrow \infty} \max_i s_i^n \rightarrow 0. \quad (13.29)$$

Our example of the hub-spoke network illustrates the basic intuition underlying this result; a question at the end of the chapter works through the argument for general networks.

Proposition 13.4 is illustrated with the help of Figure 13.8. Here we consider two networks with fifty individuals – the Erdos-Renyi and the Royal Family network. The average degree is the same in the two networks: 3. The left side of the figure illustrates the networks. We generated beliefs at random and then ran the opinion dynamics process. The right side panel presents the limit belief. The true state is  $\theta = 1/2$ . We see that in the Erdos-Renyi network, the limit belief is very close to the true state at 0.48. On the other hand, the limit belief in the Royal Family – 0.40 – is a fair way from the truth. The reason for this breakdown of aggregation is the large social influence of the royal family (that drew a signal lower than the true state).

Our discussion on the persistence of diverse opinions in the case studies on climate change and fishery and on WMD and presidential elections motivates the following question: what features of the social interaction lead to a persistence of diverse opinions and slow down the convergence of opinions? This is the subject of the next section.

### 13.4.4 Homophily

We finally turn to the role of homophily in shaping social learning. Let us start with a simple example to develop some intuition. To begin, consider a Erdos-Renyi graph with  $n$  individuals and probability of linking given by  $p$ . Next consider a variant of the Erdos-Renyi graph, in which the individuals are divided into distinct groups and the probability

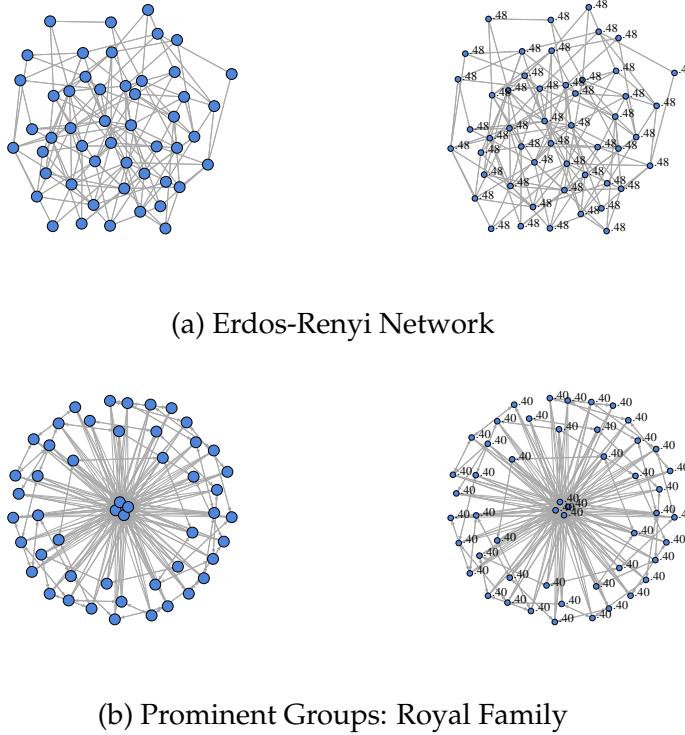

Figure 13.8: Network Structure and Wisdom of Crowds

of linking within a group is higher than the probability of linking across groups. Suppose that there are  $m$  equal groups and for simplicity suppose that the probabilities are perfectly symmetric:  $p_s$  is the probability of a link between two individuals within a group and  $p_d$  is the probability of a link between two individuals who belong to different groups; we assume that  $p_s > p_d$ . This  $p_s, p_d$  model is a special case of the Stochastic Block model in which within group and the cross group probabilities are respectively equal. We will refer to this model as the Islands Model in the rest of this section. Figure 13.9 illustrates networks generated using the islands Model.

Let us draw out a relation between homophily and the Islands Model. In the Islands Model, the average probability of linking is given by:

$$p = \frac{p_s + (m - 1)p_d}{m} \quad (13.30)$$

Recall from chapter 1 that the extent of homophily can be defined as the difference between same and different linking probabilities, with a normalization for dividing by the number of islands,  $m$ :

(a) Erdos-Renyi Network:  $p = 0.25$ (b) Islands Network:  $m = 4, p_s = 1, p_d = 0.05$ .Figure 13.9: Homophily and Networks:  $n = 20$ 

$$IH = \frac{p_s - p_d}{mp} = \frac{\frac{p_s}{mp} - \frac{1}{m}}{1 - \frac{1}{m}} \quad (13.31)$$

The final formula, on the right-hand side, is known as Coleman's Homophily Index (after the sociologist James Coleman): it provides us a measure of how much a group's fraction of own-type links ( $p_s/mp$ ) exceeds its population share ( $1/m$ ), as a ratio how big this difference could be ( $1 - \frac{1}{m}$ ). A positive  $IH$  indicates homophily while a negative  $IH$  indicates heterophily. Observe that this ratio varies between 0 (when  $p_s = p_d$ ) and 1 (when  $p_s > 0$  and  $p_d = 0$ ). We see it is increasing in the ratio  $p_s/p_d$ . And it can be verified that it is equal 0 for the Erdos-Renyi network and it is equal to 0.826 for the Islands Model with  $p_s = 1$  and  $p_d = 0.05$ .

Consider the dynamics of opinion in the Erdos-Renyi Network and the Islands Model. Both networks are strongly connected and egalitarian. As before, the true state is 0.5 and the long run belief in both networks is a good approximation. However the structure of the network has a profound impact on the speed of convergence. In the Erdos-Renyi network, opinions of all individuals are close to 0.5 by period 5. On the other hand, in the Islands Model, there is considerable dispersion of opinions in period 5. In particular, in period 5, the opinions range from 0.41 to 0.6. Indeed, even at time  $t = 15$ , when Erdos-Renyi beliefs have converged to 0.51, there remains considerable dispersion of opinion in the Islands Network: the opinions of three communities are 0.47, 0.47, and 0.48, while members of one community hold the opinion 0.50. Figures 13.10 and 13.11 illustrate the impact of homophily on the pace of social learning and the persistence of diverse beliefs.

These examples provide us a first impression of how the rate of convergence of beliefs may be shaped by homophily. We now develop this idea more systematically.

Figure 13.10: Opinion Dynamics in Erdos-Renyi Networks

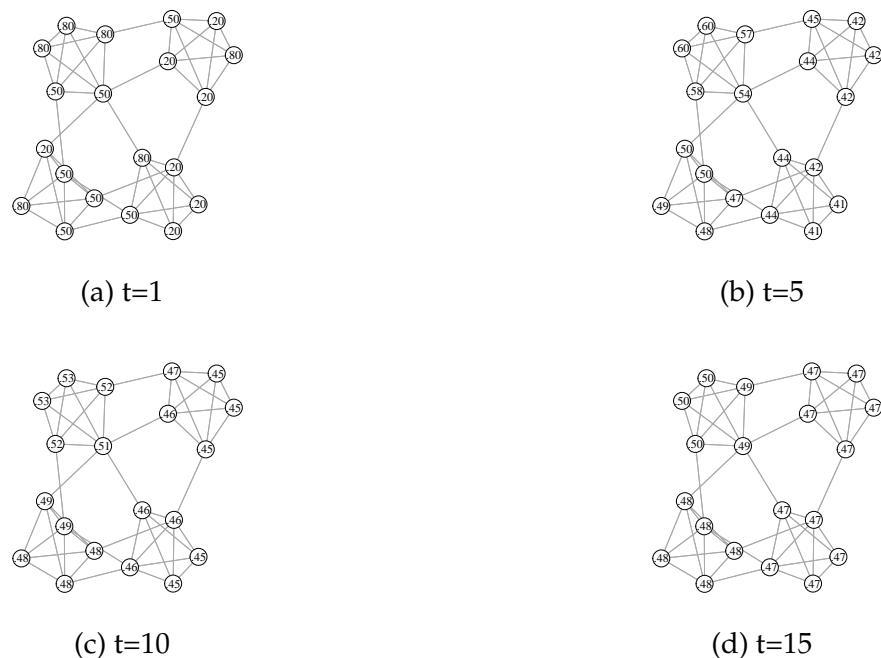

Figure 13.11: Opinion Dynamics in Islands Network

For expositional simplicity, let us consider binary links,  $g_{ij} \in \{0, 1\}$  and define weights of the matrix  $W$  as  $w_{ij} = g_{ij}/d_i$ . We may then diagonalize the matrix  $W$  as follows:

$$W = S \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \lambda_2 & 0 & 0 \\ 0 & 0 & \lambda_3 & 0 \\ \dots & \dots & \dots & \dots \\ 0 & \dots & \dots & \lambda_n \end{bmatrix} S^{-1} \quad (13.32)$$

where the columns in  $S$  are the (right) eigenvectors and the rows in  $S^{-1}$  are the (left) eigenvectors of  $W$ . The eigenvalues are presented in descending order  $\lambda_1, \lambda_2, \dots, \lambda_n$ ; note that as all rows sum to 1 for this matrix, the largest eigenvalue  $\lambda_1 = 1$  (for a discussion of such properties of stochastic matrices, the interested reader is referred to Seneta [2006]).

We have shown that in any society if  $W$  is primitive then opinions converge to a consensus  $p(\infty)$ . It is possible to show that the distance between period  $t$  belief and the long run belief is an increasing function of the second eigenvalue of the matrix  $W$ . This second eigenvalue of the weighted matrix,  $W$ , is closely related to the level of homophily in the society. To see this in the simplest way, let us construct Islands Model with progressively higher levels of homophily (by varying  $p_s$  and  $p_d$ ) and present their second eigenvalues. In all cases, the number of nodes,  $n = 20$ , and the average degree is 5. These networks are presented in Figure 13.12. Our discussion leads to the following result.

These considerations lead to the following observation:

**Proposition 13.5.** *Consider an Islands Network with a primitive  $W$ : the rate of convergence of opinions to consensus is negatively related to the level of homophily.*

A proof of this result lies outside the scope of this chapter; the interested reader is urged to consult Golub and Jackson [2012].

To summarize, we have studied a model of communication in which individuals repeatedly update their opinions by averaging across the opinions of their neighbours. This analysis yields a number of powerful conclusions: one, if society is strongly connected then everyone will hold the same opinions, i.e., consensus obtains. Two, the influence of a person on this consensus opinion is given by their (eigenvector) centrality. Three, the consensus belief in a large society reflects all available information if and only if no one possesses significant social influence. Four, the rate at which a society aggregates the information to arrive at consensus depends on the extent of homophily: greater homophily leads to longer persistence of disagreement.

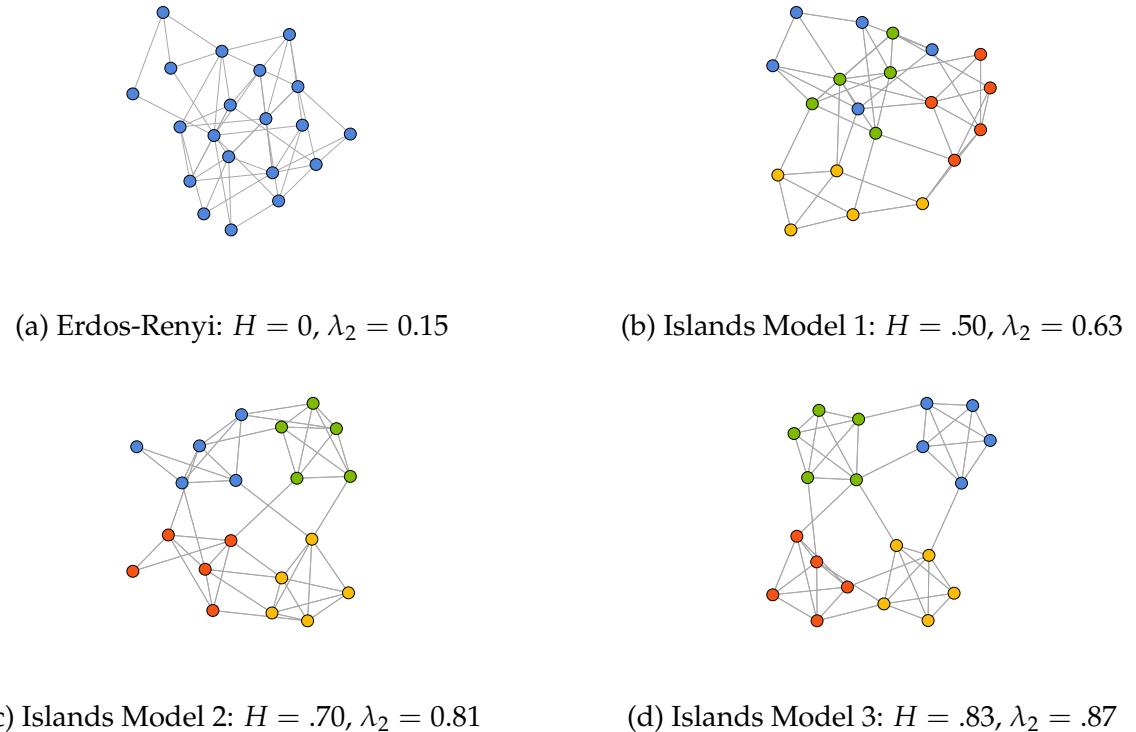

Figure 13.12: Homophily and Second Eigenvalues

## 13.5 Experimental evidence on social learning

In this section, we present experimental evidence on the role of networks in shaping opinions and behaviour. The discussion is based on Choi, Goyal, Moisan, and To [2021].

The theoretical model is a simplified version of the models we have studied in the previous two sections. There is a set of individuals  $N = \{1, \dots, n\}$ , with  $n \geq 2$ , who choose between two actions *Green* and *Red*. There are two states, Green and Red. Action Green yields a payoff of 1 if the true state is Green, and zero otherwise. Likewise, action Red yields a payoff of 1 if the true state is Red and zero otherwise.

Time is discrete and proceeds as  $t = 1, 2, \dots$ . At the start, individuals believe that the two states are equally likely. They observe a noisy but informative signal on the true state: individual  $i$  receives a binary signal  $s_i \in \{\text{Green}, \text{Red}\}$ . The probability of receiving Green (Red) signal conditional on true state being Green (Red) is  $p \in (1/2, 1)$ . Thus upon receiving a Green signal, the expected payoff to an individual from action Green is  $p$  and the payoff is  $1 - p$  from action Red. In period  $t$  an individual chooses action  $a_{i,t} \in \{\text{Green}, \text{Red}\}$ .

Individuals are located in an information network,  $g$ . At time  $t$ , individual  $i$  observes the actions of her neighbours  $N_i(g)$  from period 1 until period  $t - 1$ . The signal at the

start and the observations on neighbours' guesses in subsequent periods are an input into choices at time  $t$ .

In the first period individuals choose an action that mimics their signal  $s_i$ . In periods  $t \geq 2$ , they choose an action  $a_{i,t}$  that corresponds to the majority action in their neighbourhood in the previous period. Let us also suppose that individuals randomize (with equal probability) between the two actions if there is no clear majority.

We consider three archetypal networks: the Erdős-Renyi (ER) network, the Stochastic Block (SB) network, and the Royal Family (RF) network. Figure 13.13A presents examples of these networks. To develop hypothesis, we run simulations under the behavioral rule described above. The signals are randomly drawn i.i.d. for 40 subjects with signal quality  $p = 0.7$ . The group-level variable  $c_t$  measures the extent to which group actions at time  $t$  move toward either correct consensus or incorrect consensus relative to the initial assignment of signals

$$c_t = \begin{cases} (n_t - n_0)/(n - n_0) & \text{if } n_t \geq n_0, \\ (n_t - n_0)/n_0 & \text{if } n_t < n_0, \end{cases} \quad (13.33)$$

where  $n_0$  denote the number of correct signals received by individuals at time 0 and  $n_t$  denote the number of correct actions made at time  $t$ . This variable ranges between -1 (incorrect consensus) and 1 (correct consensus). If the number of individuals choosing a correct action is the same as that of correct signals,  $c_t$  equals to 0.

Using 1000 runs of the DeGroot simulations, Figure 13.13B shows the evolution of consensus, measured by the absolute value of  $c_t$ , and Figure 13.13C shows the fraction of players switching actions between period  $t$  and period  $t - 1$ . We note that learning occurs rapidly: most of the consensus achieved in the simulation happens at the first few periods. Network structure has a significant impact on consensus dynamics: RF network achieves consensus by period 4 in almost all cases; SB network realizes only about 60% of the possible consensus by period 4 and remains at that level afterwards. Learning in ER continues a bit longer and it achieves about 87% of the possible consensus by period 7. Figure 13.13D presents the distribution of  $c_t$  at periods 7-12. It shows that ER network correct consensus obtains in 62% of the cases; in the SB network correct consensus is obtained in 34% of cases. In the RF network consensus obtains in nearly all cases: correct consensus in 79% of the cases and incorrect consensus in 21% of cases.

These simulations motivate three hypotheses:

1. Individual choices converge to a limit action.

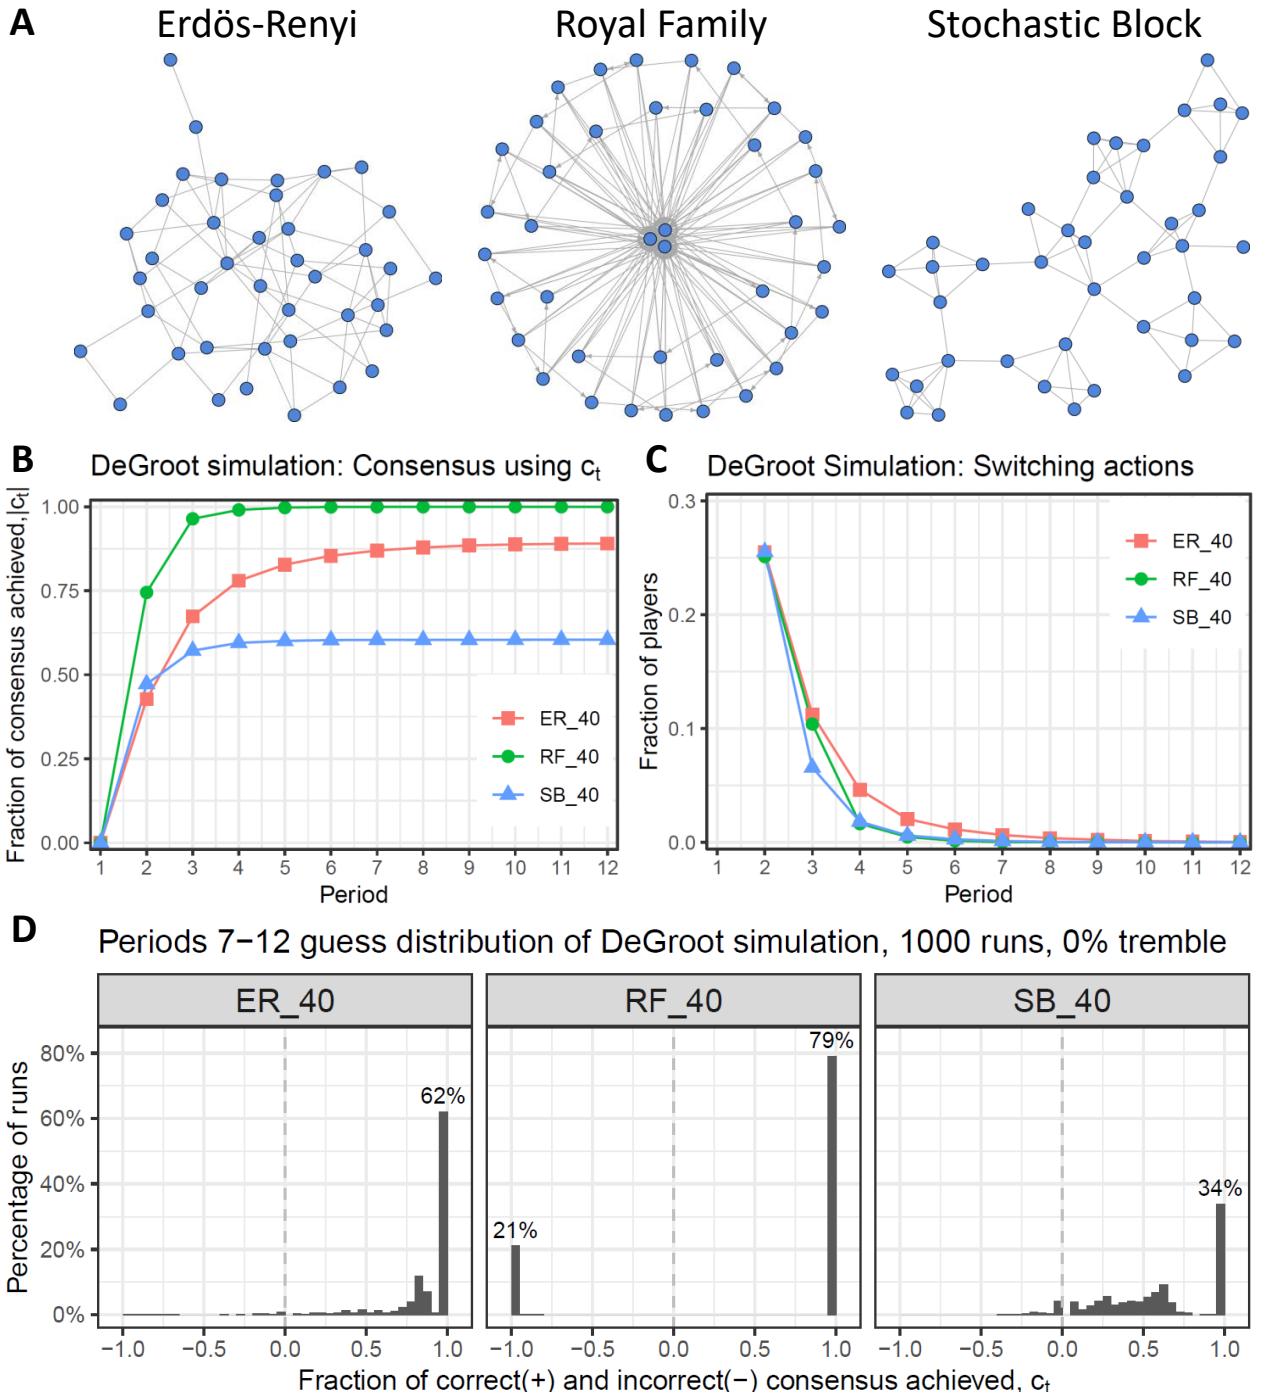

Figure 13.13: Canonical networks and DeGroot simulations of 1000 runs. (A) Average degree is (approximately) equal to 4; diameter in ER, RF, SB is equal to 5, 38, and 9, respectively. (B) By period 4, RF network (green) achieves complete consensus in almost all cases. SB network (blue) realizes 60% of possible consensus. ER network (red) achieves 87% of maximum possible consensus. (C) By period 7, switching frequency is negligible. (D) In periods 7-12, 62% of cases in ER network reach correct consensus, 34% in SB network and 79% in RF network. Almost all remaining cases yield breakdown of consensus (38% in ER, 66% in SB) or incorrect consensus (21% in RF). Source: Choi, Goyal, Moisan, and To [2021].

2. Breakdown of consensus is higher in SB as compared to ER and RF.
3. Incorrect consensus is higher in RF as compared to ER and SB.

Each experimental sessions consisted of a group of 40 subjects who played 6 rounds of the learning game. Groups of subjects were assigned to one of three experimental conditions, each associated with a distinct network structure: ER, SB and RF. Four independent groups of 40 subjects participated in each experimental condition, and no subject participated in more than one experimental session.

At the start of each round, subjects were informed about a bag containing 10 balls. The colour composition of the bag was unknown to the subjects. They were told that the bag contains either 7 Red and 3 Green balls (we will refer to this as the RED bag) or 7 Green and 3 Red balls (the GREEN bag). Each subject drew a ball from the bag and saw its colour. There was a probability 0.7 of getting the ‘correct’ signal. For 12 periods, subjects were asked to make a guess on whether the bag is RED or GREEN. At the end of the round, one period (from 1 to 12) was picked at random to determine actual payoffs in the round: subjects earned 3 euros if their guess matched the colour of bag (GREEN or RED), and 0 euro otherwise. Total earnings for a subject corresponded to the sum of earnings in each round and a 5 euro show up fee. The experiment lasted approximately 1.5 hrs. Average payment per subject was 19.3 euros (including a 5 euro show-up fee).

Figure 13.14 summarizes our experimental findings on network effects. Figure 13.14A shows the evolution of consensus across rounds and groups. Figure 13.14B presents the switching frequency from period  $t - 1$  to period  $t$ . Figure 13.14C presents the distribution of  $c_t$  in the last 6 periods, i.e., between period 7 and period 12, in each network.

We begin by discussing the dynamics of learning in Figure 13.14A and 13.14B. Most of the learning occurs in the early periods; by period 4, the RF network reaches 58% of the maximum margin of consensus and the SB network reaches 22%, while the ER network achieves 35% by period 6. The quick learning is consistent with the simulations. There remains a small amount of switching toward the end: the frequency of switching falls to 10% eventually.

Figure 13.14C shows the distribution of  $c_t$  across the three networks, in the periods 7-12. The distribution of the RF network is bi-modal near the two types of consensus, the SB network has a mode around the value of  $c_t = 0$ , indicating a high likelihood of no learning and the persistence of diverse opinions, while ER network generates a distribution somewhat uniformly spread between 0 and 1.

To consolidate these findings, let us define binary variables of correct consensus (if  $c_t > k$ ), incorrect consensus (if  $c_t < -k$ ), and breakdown of consensus (if  $-k \leq c_t \leq k$ ) based

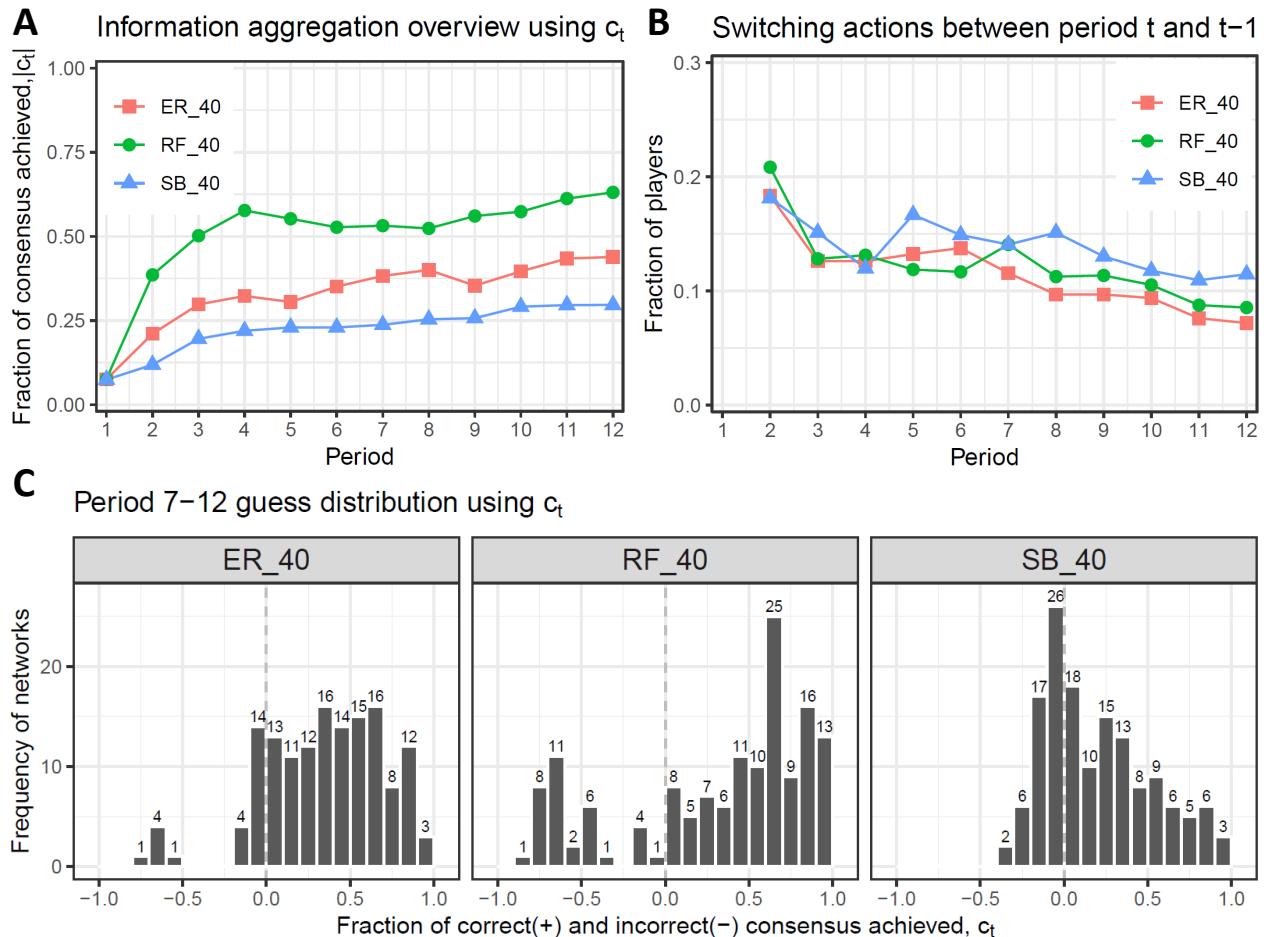

Figure 13.14: Learning and consensus. (A) By period 12, RF, ER, SB reach 63%, 44%, 30% of possible consensus. (B) Switching frequency falls below 10% by period 12. (C) Distribution of  $c_t$  is uniform between 0 and 1 for ER, bimodal around 1 and -1 for RF, and modal around 0 for SB. Source: Choi, Goyal, Moisan, and To [2021].

on the value of  $c_t$ . Let us fix  $k$  to be 0.3. Then, consistent with the second hypothesis, the fraction of breakdown of consensus is highest in the SB network: it is 40% in the ER network, 19% in the RF network, and 65% in the SB network. Finally, consistent with the third hypothesis, the fraction of incorrect consensus is highest in the RF network: it is 4% in the ER network, 20% in the RF network, and 1% in the SB network.

To summarize: the experiment offers strong support for our three hypotheses on the effects of networks on opinions and behaviour.

## 13.6 Appendix: Sequential models of learning

For completeness, we present a canonical model of social learning: there is a single sequence of privately informed individuals who take one action each. Before making his choice an individual gets to observe the actions of all the people who have made a choice earlier. The actions of his predecessors potentially reveal their private information. An individual can therefore use the information revealed via the actions of others (together with his own private information) to make decisions. This model was introduced in Banerjee [1992] and Bikhchandani, Hirshleifer, and Welch [1992]. for a general treatment of this model, see Smith and Sørensen [2000]. An extensive literature has grown around this basic model. The interested reader is referred to Smith and Sørensen [2000] for an elaboration of the general model, and to Golub and Sadler [2016] and Chamley [2004] for comprehensive surveys. The principal question is: do individuals eventually learn and choose the optimal action?

A basic insight is that learning can lead to herding and everyone may choose the wrong action. Consider a setting in which private signals are equally accurate and individuals assign equal weight to their own and the signal of others. To fix ideas suppose that there are two actions and two states. For simplicity, suppose that in state 1 action 1 is optimal, while in state 0 action 0 is optimal. Suppose that initially agents believe that the states are equally likely. At point of entry, agent in period  $t$ , observes a private signal: probability of signal  $x$  when true state is  $x$  is  $q$ , where  $q > 1/2$ . The probability that signal is  $x$  when true state is  $y \neq x$  is  $1 - q < 1/2$ . Assume that signals are drawn independently, conditional on the true state in every period. Now suppose that the first two individuals observe a signal in favor of state (and hence action) 1. They will both choose action 1. Consider agent 3 who observes this sequence of 1's. Given that the information from others is as accurate as his own, two signals in favor of state 1 will overrule his own signal in favor of action 0. So agent 3 will also choose action A, and this is his choice irrespective of his own signal. In that case, his action does not convey any information about his signal. In particular, agents

4 onward are in the same situation as agent 3. So they too will ignore their own private information and choose action 1. Thus the sequence of individuals may herd on action 1.

Observe that this argument is independent of whether 1 is in fact an optimal action. So we have shown that there is a strictly positive probability that society may herd on the wrong action. Finally, observe that private signals arrive independently (and exogenously) over time: so eventually there will always be enough information to infer the optimal action. This illustrates how observational learning may fail to aggregate private information.

One way out of inefficient herding is that agents draw signals that have different levels of accuracy. This will induce private beliefs which vary across agents. In particular, if some agents receive very ‘strong’ signals – signals which make one state much more likely as compared to the other state – then they may choose to ignore past observations and choose an action which reflects their private signal. Suppose that the private belief about state 0, given by  $\mu_t^0$  ranges between  $\underline{\beta}$  and  $\bar{\beta}$ . Let us say that the beliefs are bounded if  $\underline{\beta} > 0$  and  $\bar{\beta} < 1$ . Beliefs are unbounded if  $\underline{\beta} = 1 - \bar{\beta} = 0$ . It is fairly straightforward to verify that if agents have bounded beliefs then inefficient herding may occur, while if beliefs are unbounded then observational learning will lead to efficient choice of actions eventually.

In this model, the social network is very elementary: a person at time  $t$  gets to observe everyone who came before them. Let us briefly consider a variation with a richer network structure. Following Acemoglu, Dahleh, Lobel, and Ozdaglar [2011], we may introduce social networks in this model of sequential learning as follows: suppose that agent at time  $t$  can draw a sample from the past,  $N_t \subset \{1, 2, \dots, t-1\}$ . Let this sample be drawn with some probability distribution  $\mathcal{L}_t$ . Some examples of such distributions are:

- $\mathcal{L}_t(\{1, 2, \dots, t-1\}) = 1$ : this corresponds to the standard model in which every agent observes the entire past history of actions.
- $\mathcal{L}_t(t-1) = 1$ : every agent observes only the immediately preceding agent.
- $\mathcal{L}_t$  assigns equal probability to picking every subset of the past sequence of agents.

We can study the impact of social networks by varying the nature of the distribution  $\mathcal{L}$ .

For expositional simplicity, let us assume that beliefs are unbounded. Recall, that if observation window is the entire past history then the arguments above ensure that actions converge in probability to optimal actions. We examine the network needed to ensure learning.

A simple example illustrates the key idea: suppose that there is a positive probability that for all  $t \geq 2$ ,  $\mathcal{L}_t(1) = p > 0$ . Suppose that Mr. 1 chooses action 1. Under the assumption of unbounded beliefs we know that any point there is a possibility of an agent

with extremal signals (and the corresponding private beliefs) which sharply favor one state over the other. But under our hypothesis there is a strictly positive probability that such an agent observes a single agent, Mr. 1, who has chosen action 1. It is then easy to see that this agent will choose an action that depends solely on his private signal. As beliefs arise independently over time and as observation neighborhoods are independent across agents, it follows that there is a strictly positive probability that agents will choose an action in line with their private belief. This prevents asymptotic learning.

To rule out this problem, Acemoglu, Dahleh, Lobel, and Ozdaglar [2011] develop the property of expanding observations in social networks. A social network is said to satisfy expanding observations if for all  $k \in N$ ,

$$\lim_{t \rightarrow \infty} \mathcal{L}_t(\max_{n \in N_t} < k) = 1. \quad (13.34)$$

If the network does not satisfy this property then it is has non-expanding observations. Expanding observations rules out the example discussed above in which every agent samples agent 1 with strictly positive probability. It is possible to show that *if beliefs satisfy the unbounded beliefs assumption and networks satisfy the expanding observations assumption then actions converge to the optimal action eventually*.

Let us sketch the main ideas underlying the result. First, we establish a generalized ‘improvement’ principal. Suppose every agent  $t$  gets to observe one person from the past: then there is a strict increase in the probability of Mr.  $t$  making the correct choice, as compared to the person he observes. This argument builds on our earlier discussion of the improvement upon ‘imitation’ principle across neighbors in 13.3. The second step is to show that this improvement principle can be extended to allow for multiple observations. The third step exploits expanding observations to infer that later agents will have access to new information and so the expected utilities must converge to the maximum possible value, i.e., actions must converge to the optimal one.

We conclude with a comment on the relation between the expanding assumptions property and royal family network. Note that the key obstacle to complete learning in the repeated action setting is the asymmetry in observation: there is a small group of agents who observe few others but are observed by everyone. In the sequential learning model, the expanding observations property of social networks ensures that agents eventually assign zero probability on any fixed set of early agents. This ensures that new information arrives into the system and ensures long run learning.

## 13.7 Reading Notes

The study of social communication and influence has a long and distinguished history. Pioneering work was carried out by a group of sociologists around the mid-twentieth century. *People's Choice* by Lazarsfeld, Berelson, and Gaudet [1948] presents an early empirical study of social influence on voting behaviour. Katz and Lazarsfeld [1966] expand the scope of this early study to examine the role of social influence in marketing, fashion, movie going and public affairs. *Medical Innovation* by Coleman, Katz, and Menzel [1966] reports on the adoption of a medical drug, tetracycline, among a set physicians in the early 1950's. Rogers [1995b] provides an overview of the early work on communication and innovation.

Economists studying technological change in agriculture have focused on social learning in shaping adoption of new input combinations for a variety of crops. An early contribution is Foster and Rosenzweig [1995] work on High Yielding Variety seeds in India that is discussed in the chapter. More recent work includes Bandiera and Rasul [2006], Munschi [2004] and Duflo, Kremer, and Robinson [2006]. Most of this work presents evidence on social informational spillovers (without paying attention to the details of the network structure). Conley and Udry [2010] takes a step forward in this literature by collecting data on information networks of farmers and present evidence on the role of such information neighbourhoods in shaping the adoption of fertilizers in the cultivation of pineapples.

The case study on fishery in Hawaii is taken from Barnes, Lynham, Kalberg, and Leung [2016]. The case study on climate change is taken from Funk and Hefferon [2019].

Establishing causality in network effects poses a number of challenges; these challenges are greatly exacerbated when the network is endogenous. There is a sophisticated literature that studies these issues; see Manski [1995], Brock and Durlauf [2001], and Bramoullé, Djebbari, and Fortin [2009]. Partly in response to these difficulties, recent research has used experiments to uncover network effects on opinion formation and behaviour. We presented a case study on wisdom of crowds taken from Becker, Brackbill, and Centola [2017]. Christakis and Fowler [2007] and Christakis and Fowler [2013] study different aspects of learning and behaviour in networks using both observational and experimental data.

The theoretical literature on information sharing and learning in networks may be seen as broadly following two approaches. One approach studies choice that generates information and social interaction that spreads this information. As information spreads, it alters beliefs and thereby shapes the choice of subsequent actions. In this way current choice and the network shape the generation of new information. This approach builds on the insights of the statistical literature on bandit-arms (Berry and Fristedt [1985]) and is very close

in spirit to the economic development work on the adoption of new crops (as in Conley and Udry [2010]). The model of learning and choice of bandit-arms in networks presented in section 3 was introduced in Bala and Goyal [1998]. They established that connectedness was sufficient to ensure convergence of actions and utilities. They also identified the role of influential individuals in inhibiting learning and showed that egalitarian networks guarantee complete learning. Bala and Goyal [2001] studied the role of homophily and network integration in sustaining diversity of beliefs and actions. In closely related work, Ellison and Fudenberg [1993] and Ellison and Fudenberg [1995] study social learning and the prospects of long run diversity (their work is less concerned with the network architecture dimensions of the learning process). These models involve collective experimentation but in the interests of tractability abstract of strategic considerations on choice of actions; for an early study of strategic forces in collective experimentation see Bolton and Harris [1999].

A second and more widely studied approach endows individuals with signals and examines the aggregation of this information via social interaction. The simplest model is one in which a sequence of individuals learn from the actions of previous individuals – influential early work in this tradition includes Banerjee [1992] and Bikhchandani, Hirshleifer, and Welch [1992]. This model was elaborated upon by Smith and Sørensen [2000]. For a model of sequential learning in which individuals learn from observing past actions and outcomes of the action, see Bala and Goyal [1995]. Chamley [2004] presents an overview of the first generation of social learning models. This line of work was brought into a ‘network’ setting by Gale and Kariv [2003]. They proposed a model of guesses: individuals guess on the true state of the world and then update their guesses after observing the guesses of their neighbours. An interesting and technically sophisticated line of research explores observational learning in networks, see e.g., Rosenberg, Solan, and Vieille [2009], Acemoglu, Dahleh, Lobel, and Ozdaglar [2011] Mossel, Sly, and Tamuz [2015] and Mueller-Frank [2013]. Mueller-Frank [2013] studies a general setting that goes beyond the case of decision rules that maximize expected utility, and allows for arbitrary choice correspondences; he also permits the decision rules not to be common knowledge. Chen, Mueller-Frank, and Pai [2021] examine general conditions under which an (outside) principal can learn the true state without knowledge of the details of the information structure of individuals.

Within the information aggregation literature, there is also an alternative – bounded rational – approach to information sharing and opinion formation. This approach goes under the name of deGroot updating, as it builds on a model proposed in DeGroot [1974]. Section 4 presents a model of DeGroot learning. Early antecedents of this approach to

updating and consensus-reaching include French Jr [1956] and Harary [1959]. DeMarzo, Vayanos, and Zwiebel [2003] introduced the DeGroot model to economics and obtained a number of key early results, on connectedness, on social influence and on rate of convergence to consensus. In more recent work, Golub and Jackson [2010] and Golub and Jackson [2012] studied correct and incorrect consensus and the effects of homophily on the rate of convergence to consensus.

The binary state/action model was introduced in Gale and Kariv [2003] and has become a workhorse for the study of observational learning and information aggregation in networks; for recent theoretical studies of this model see Mossel et al. [2015] and Mossel et al. [2014].

For more recent surveys of research on social learning in networks see Goyal [2011] and Golub and Sadler [2016].

The dynamics of opinion formation and behaviour have been extensively studied from an experimental perspective. Early contributions in economics include Choi, Gale, and Kariv [2005] and Mobius, Phan, and Szeidl [2015]. For a survey of the research in economics see Choi, Gallo, and Kariv [2016] and Breza [2016] and for recent research that test the binary state, binary action model see Grimm and Mengel [2020], Chandrasekhar, Larreguy, and Xandri [2020] and Choi, Goyal, Moisan, and To [2021]. For experiments on learning in sociology and communications see Centola [2011], Centola and Baronchelli [2015].

We very briefly describe an experiment on wisdom of crowds that examines the effect of networks on information aggregation. The experiment is taken from Becker, Brackbill, and Centola [2017]. Individuals are engaged in an estimation task. Individuals guess once and they can revise their guesses two more times. In the control treatment, individuals are simply asked if they wish to revise their guess. In the social network treatment, after the first guess, they are shown the average of the guesses in their network neighbourhood and asked to guess a second time. At the start of the third round, they get to see the guesses in the second round. Then then make a third guess. Participants are rewarded a monetary prize the value of which depended on the accuracy of their final estimate.

Subjects were allotted either to one of two social networks or to a control condition (with no information sharing). In the decentralized network treatment, participants were placed in a regular network with degree 4, while in the centralized network treatment a single person was connected to everyone else (as in a star network). Subjects were not provided any information about their social networks – this was to ensure that subject experience was similar across the two network conditions. Subjects in the control condition were not placed into social networks, but were instead given the opportunity to answer the same questions without being exposed to social influence.

There were 40 subjects in the three treatments. In total, there were 13 experimental trials in each of the two networks (thus 1040 network subjects in all) plus 8 trials with the control group (comprising 320 subjects). The subjects were recruited from the World Wide Web.

The *principal findings* are as follows: in the control treatment, there was a negligible decrease in dispersion of estimates and a small increase in accuracy of average estimate from round 1 to round 3. By contrast, the dispersion of opinions declined by over 40% in the two network treatments. In the decentralized network, the accuracy of estimate increased by over 20%. In the centralized network, the effects on accuracy of estimate depended on the ‘quality’ of central agent’s signal (relative to others). If the signal neutralized the bias of the signals of the other 39 individuals then social interaction led to much more accurate estimates by everyone. If the signal reinforced the bias then social interaction led to poorer estimates. For instance, if the true value is 100 and the group mean is 90, a central node with an estimate of either 105 (more accurate) or 120 (less accurate) will pull the group toward the truth. On the other hand, if the central node’s initial estimate is 70 that would pull the group away from the truth.

Finally, we note that most of the above literature assumes that individuals can observe the choices and experience of their neighbours. There is also a small but interesting strand of research that examines how networks affect the incentives of individuals to share their information. This work embeds the classical work of Crawford and Sobel [1982] within a network setting. Early contributions in this field include Galeotti, Ghiglino, and Squintani [2013] and Hagenbach and Koessler [2010]. For a recent contribution that combines these two papers with network formation see Goyal, Safranov, and To [2021b].

I thank Ben Golub for helpful discussions and for sharing his lecture notes on social learning. I thank Michelle Barnes for kindly sharing the network figure from her paper with me.

## 13.8 Questions

1. The first three questions help the reader work through the mathematical details of Proposition 1 and Proposition 2 in the chapter. To be able to make the arguments precise, let us describe the probability space in which all actions and realizations take place. The probability space is denoted by  $(\Omega, \mathcal{F}, P^\theta)$ , where  $\Omega$  is the space of all outcomes,  $\mathcal{F}$  is the  $\sigma$  field, and  $P^\theta$  is the probability measure induced over sample paths in  $\Omega$  by the state  $\theta \in \Theta$ . In the two action example discussed in the chapter there are two states:  $\theta_1$  in which action  $a_1$  is optimal, and state  $\theta_0$  where action  $a_0$  is optimal.

Let  $\Theta$  be endowed with the discrete topology, and suppose  $\mathcal{B}$  is the Borel  $\sigma$ -field on this space. For rectangles of the form  $\mathcal{T} \times H$ , where  $\mathcal{T} \subset \Theta$ , and  $H$  is a measurable subset of  $\Omega$ , let  $P_i(\mathcal{T} \times H)$  be given by

$$P_i(\mathcal{T} \times H) = \sum_{\theta \in \mathcal{T}} \mu_{i,1}(\theta) P^\theta(H). \quad (13.35)$$

for each individual  $i \in N$ . Each  $P_i$  extends uniquely to all  $\mathcal{B} \times \mathcal{F}$ . We will assume that every individual's prior belief lies in the interior of  $\mathcal{P}(\Theta)$ , i.e., individuals assume every state is possible. The stochastic processes are defined on the measurable space  $(\Theta \times \Omega, \mathcal{B} \times \mathcal{F})$ .

A typical sample path is of the form  $\omega = (\theta, \omega')$ , where  $\theta$  is the state of nature and  $\omega'$  is an infinite sequence of sample outcomes:

$$\omega' = ((y_{i,1}^a)_{a \in A, i \in N}, (y_{i,2}^a)_{a \in A, i \in N}, \dots), \quad (13.36)$$

with  $y_{i,t}^a \in Y_{i,t}^a \equiv \mathcal{Y}$ . Let  $C_{i,t} = b_i(\mu_{i,t})$  denote the action of individual  $i$  in period  $t$ ,  $Z_{i,t}$  the outcome of this action, and let  $U_{i,t} = u(C_{i,t}, \mu_{i,t})$  be the expected utility of  $i$  with respect to his own action at time  $t$ . Given this notation the posterior beliefs of individual  $i$  in period  $t+1$  are:

$$\mu_{i,t+1}(\theta|g) = \frac{\prod_{j \in N_i^d(g) \cup \{i\}} \phi(Z_{j,t}; C_{j,t}; \theta) \mu_{i,t}(\theta)}{\sum_{\theta' \in \Theta} \prod_{j \in N_i^d(g) \cup \{i\}} \phi(Z_{j,t}; C_{j,t}; \theta') \mu_{i,t}(\theta')}. \quad (13.37)$$

In what follows, we will take  $\theta_1$  to be the true state of nature. Note that

$$Q^{\theta_1} = \{\omega = (\theta, \omega') | \theta = \theta_1\} \quad (13.38)$$

has  $P^{\theta_1}$  probability 1. It will be assumed that the strong law of large numbers holds on  $Q^{\theta_1}$ . All statements of the form 'with probability 1' are with respect to the measure  $P^{\theta_1}$ . Show that the following statement is true:

- The utilities of individuals converge:  $\lim_{t \rightarrow \infty} U_{i,t}(\omega) = U_{i,\infty}(\omega)$ , for every  $i \in N$ , with probability 1. If the society is strongly connected then every individual gets the same long run utility:  $U_{i,\infty}(\omega) = U_{j,\infty}(\omega)$  for every pair of individuals  $i, j \in N$ , with probability one.
2. Turning to the result on long run optimal actions, recall that if  $\mu_{i,0} \geq 1/2$  then the optimal action is  $a_1$ . Show that the following property holds:

- Let  $B(\delta_{\theta_1})$  is the set of beliefs on which optimal action corresponds to optimal action in state  $\theta_1$ . Fix some individual  $i \in N$  with  $|N_i(g)| + 1 \leq K$ . For any  $\lambda \in (0, 1)$ , there exists a set of sample paths  $W_i$  satisfying  $P^{\theta_1}(W_i) \geq \lambda$  and  $d(\lambda) \in (0, 1)$ , such that if  $\mu_{i,1}(\theta_1) \geq d(\lambda)$  then

$$\omega \in W_i \Rightarrow A_i(\omega) \subset B(\delta_{\theta_1}). \quad (13.39)$$

i.e., if the path of outcomes lies in  $W_i$ , then the path of actions taken must converge to  $a_1$ .

- Thus for an individual whose prior  $\mu_{i,1}(\theta_1) \geq d(\lambda)$ , there is a set of sample paths  $W_i$  with probability  $\lambda$  such that  $i$  will choose an optimal action for ever on sample paths  $\omega \in W_i$ . Recall that two individuals  $i$  and  $j$  are said to be *locally independent* if they share no neighbours, i.e.,  $N_i(g) \cup \{i\} \cap N_j(g) \cup \{j\} = \emptyset$ . A pairwise locally independent group of individuals is a subset of  $N$  such that any two persons  $i, j$  in the set are mutually locally independent. Fix two numbers  $K > 0$  (that sets an upper bound to the size of the neighbourhood) and a  $\bar{\lambda} > 0$  (that relates to the likelihood of positive information on action  $a_1$ ). Let  $\bar{d} = d(\bar{\lambda})$  be the corresponding value whose existence is guaranteed by previous step. Consider the collection of individuals  $i \in N$  such that  $|N_i| \leq K$  and that satisfy  $\mu_{i,1}(\theta_1) \geq \bar{d}$ . Let  $N_{K,\bar{d}}$  be a maximal group of pairwise locally independent individuals chosen from this collection. Show that the following statement is true:

- Assume a strongly connected society. Then

$$P^{\theta_1}(\cup_{i \in N} \{A_i(\omega) \not\subset B(\delta_{\theta_1})\}) \leq (1 - \bar{\lambda})^{N_{K,\bar{d}}}. \quad (13.40)$$

In particular, if for some  $\bar{\lambda} > 0$  and  $\bar{d} = d(\lambda)$ ,  $|N_{K,\bar{d}}| \rightarrow \infty$  then the probability of everyone choosing the optimal action goes to 1.

- Consider the model of learning with Bayesian learning in a network. The network is as follows: individuals observe their neighbors and a set of common individuals: i.e.,  $N_i = \{i - 1, i + 1\} \cup \{7, 8, 9, 10, 11\}$ , for all  $i \in N$ . Suppose that everyone is optimistic and that beliefs satisfy the following condition.

$$\inf_{i \in N} \mu_{i,1} > \frac{1}{2}; \quad \sup_{i \in N} \mu_{i,1} < \frac{1}{1+x^2} \quad (13.41)$$

where  $x = (1 - \pi)/\pi \in (0, 1)$ . Provide the reasoning to establish that there is a

strictly positive probability for everyone to choose action  $a_0$  from period 2 onward.

5. Show the one or more agents having positive self-weight and strong connectedness of the network are sufficient for the corresponding weighted matrix to be primitive.
6. (Jackson [2008]) Consider the model with DeGroot updating. This question presents a slightly more general version of the convergence result, Proposition 13.3. In a network  $g$ , define a closed set of agents as  $C \subset N$  such that there is no directed link from an agent in  $C$  to an agent  $j \notin C$ ; that is there is no pair  $i \in C$  and  $j \notin C$  such that  $W_{ij} > 0$ . Show that every network contains at least one closed and strongly connected set of agents. Next show that every network can be partitioned into a collection of strongly connected and closed groups and remaining agents who each have at least one directed path to an agent in a strongly connected and closed group.
7. A matrix  $W$  is periodic if all cycles in the matrix  $W$  are of equal length. A matrix is aperiodic if it is not periodic:  $W$  is aperiodic if the greatest common divisor of all directed cycle lengths is 1, where the directed cycles are defined relative to a directed network in which a directed link exists from  $i$  to  $j$  only if  $W_{ij} > 0$ . Show that opinions converge for a  $W$  if and only if every set of nodes that is strongly connected and closed is aperiodic. Show that opinions converge to consensus in a strongly connected network that has a aperiodic  $W$ .
8. (Jackson [2008]). Consider the network given in Figure 13.15; the link pointing from  $i$  to  $j$  indicates the place  $i$  places on  $j$ . Observe that this network is not strongly connected that agent 1 will retain his original opinion through time. However, the other individuals in this society are influenced by each other. Compute the social influence vector and the limit beliefs in this society.
9. (Jackson [2008]) Suppose the network is strongly connected and aperiodic. Show that if  $W_{ij} = W_{ji}$ , for every pair  $i, j$  of individuals then  $s_i = 1/n$  for every  $i \in N$ . (Hint: use proposition 13.3).

# Chapter 14: Epidemics and Diffusion

## 14.1 Introduction

Large scale diseases have had a profound impact on human history and influenza, measles, tuberculosis, and sexually transmitted diseases infect millions of people every year. In extreme instances – such as the spread of small pox, measles and tuberculosis in Central and South America – epidemics can lead to the collapse of entire civilizations. The spread of a disease is determined by the properties of the pathogen (its contagiousness, the length of its infectious period, and its severity) and on how infected individuals interact with others. This chapter studies the relation between the networks of interaction and the dynamics of epidemics.

We start in the next section with a brief overview of the empirical evidence on major disease epidemics. The discussion covers important episodes of epidemics in history and then turns to contemporary epidemic diseases. We note that some diseases can only be had once while others can be borne multiple times; some need only casual contact while others need close or intimate contact. We also note that some diseases exhibit explosive growth while others persist at low levels. How can we explain the extinction of some diseases and the persistence of others? What is the role of contacts networks in shaping the persistence of epidemics? What sort of policies can help in alleviating these epidemics? The chapter will develop theoretical models in order to understand these questions.

The pathogen and the network are closely intertwined: even within the same population, the contact networks for two different diseases can have very different structures, depending on the diseases' respective modes of transmission. For a highly contagious disease, involving airborne transmission based on coughs and sneezes, the contact network will include a huge number of links, including any pair of people who sat together on a bus or an airplane. For a disease requiring close contact, such as a sexually transmitted disease, the contact network will be much sparser, with fewer pairs of people being connected.

At an intuitive level, the spread of a disease from one person to others should depend on its infectiousness and on how many contacts this person has. Our first step is to formalize

this idea in the context of a model where starting with a single infected person everyone person meets  $k$  distinct and new individuals. We study the conditions under which the disease will spread and when it will die out. The analysis clarifies the key role of the *reproductive number* – the product of the infectiousness and the number of contacts. We show that in this simple network, a disease will spread if and only if the reproductive number is larger than 1. We then turn to the spread of diseases in more general networks.

We introduce the Susceptible-Infected-Recovered (SIR) model of disease dynamics: a node is either susceptible to a disease (S), infected by the disease (I) or has recovered from the disease (R). The aim is to understand how infectiousness and network structure determine the size of the epidemic. A key observation is that we can study the dynamics of the disease in terms of an equivalent static model – we refer to this static formulation as a *percolation*. With this perspective, we show how methods from random graph theory can be employed to understand how far a disease spreads in Erdos-Renyi random graphs. We then study disease spread in general random graphs (building on our discussion of configuration model in chapter 2). We show that the disease is more likely to spread the greater is the dispersion in degrees relative to the mean degree in the network. The ratio may be interpreted as giving us a measure of the relative influence of a node: greater variance indicates the presence of individuals whose degree is much higher than the average. As this ratio grows without a bound in a scale free network, diseases with arbitrarily small infectiousness can spread to a large population in such networks.

We then turn to diseases that an individual can suffer from multiple times. This calls for a modification of the basic SIR model. Individuals can be one of two states: they are susceptible (S) or infected (I); once they recover from a disease they become susceptible again. A prominent example of such a disease is the flu. We locate the SIS process on a network and study the size of infection. The analysis yields an insight that is similar to what we found for the SIR model: diseases with arbitrarily small infectiousness can be sustained by scale free networks.

Our theoretical results on the permeability of networks are empirically relevant. In chapter 1 we presented a study of romantic and sexual relationships in an American High School and we showed that there exists a giant component in that network: this suggests that once a sexually transmitted disease takes hold, it can potentially infect a very large number of people. Our results on scale free networks draw attention to the role of superspreader events: an event that brings large number of people from different parts of a country can facilitate the explosion of a disease. We present a case study of major religious festivals in India in this context. Similarly, in chapter 1 we showed that real world computer and information networks (like Twitter and the World Wide Web) have a very

unequal degree distribution. Our theoretical results suggest that these networks may be vulnerable to the diffusion of worms and viruses.

We then turn to the diffusion of behaviour and optimal targeting of interventions. We show that random vaccinations may be helpful to contain diseases in homogenous random graphs like the Erdos-Renyi network, but that they are very ineffective in scale free networks. However, targeting highest degree nodes for vaccination can be very effective in scale free networks.

Finally, we study applications of epidemiology models to the diffusion of human behaviour. We present a case study of the adoption of micro-finance in South Indian villages. This study draws attention to the advantages of seeding more central nodes in facilitating diffusion of new products. Identifying more central individuals requires investments in network information that may be very large and motivates an enquiry into the value added of optimal versus random seeding. We conclude with a discussion of the circumstances in which random seeding may be attractive.

The chapter contains an appendix that provides an exposition of the Bass model of diffusion.

## 14.2 Empirical Background

In this section, we provide a very brief description of a few diseases – plague, small pox, tuberculosis, influenza, and AIDS – that have had large scale impact on society.

### PLAQUE

Plague is caused by a bacterium, *Yersinia pestis*. Plague has been the cause of some of the most-devastating epidemics in history – the Black Death in the 14th century and a pandemic in Asia in the late 19th and early 20th centuries. *Yersinia* causes three types of plague in humans: bubonic, pneumonic, and septicemic. Plague is transmitted between animals and humans by the bite of infected fleas, direct contact with infected tissues, and the inhalation of infected respiratory droplets. Plague can be a very severe disease with a case-fatality ratio of 30% to 60% for the bubonic type; pneumonic plague is almost always fatal when left untreated. We focus on the time-line and impact of the Black Death here. Our discussion draws on documents provided by the Center for Disease Control (CDC) (<https://www.cdc.gov/plague>) and the Encyclopedia Britannica (<https://www.britannica.com/everything/black-death>).

The plague that caused the Black Death probably originated in China in the early to mid-1300s. In 1347 the plague decimated the army of the Kipchak Khan Janibeg while he was besieging the Genoese trading port of Kaffa (now Feodosiya) in Crimea. Janibeg cat-

apulted plague-infested corpses into the town in an effort to infect his enemies. From Kaffa, Genoese ships carried the epidemic westward to Mediterranean ports, affecting Sicily (1347), North Africa, mainland Italy, Spain, and France (1348) and Austria, Hungary, Switzerland, Germany, and the Low Countries (1349). A ship from Calais carried the plague to Dorset, England in 1348. The plague reached the extreme north of England, Scotland, Scandinavia, and the Baltic countries in 1350.

Roughly one third of the European population – around 25 million people – is estimated to have died from the plague between 1347 and 1351. The population of western Europe did not again reach its pre-1348 level until the beginning of the 16th century (one hundred and fifty years later).

The Black Death had profound and wide ranging effects on society. Trade suffered and wars were temporarily abandoned. There were more long lasting effects: as a large number of workers died, the balance of power between landlords and workers altered. This led to landowners to pay wages and money rents. Wages for artisans and other workers increased. Commentators view the Black Plague as a turning point in large scale changes in the feudal structures of society that ultimately gave rise to the Renaissance in Europe.

Plagues are no longer a major source of concern today – the total number of cases at a global level rarely exceeds a few thousand. This is because we understand how plague spreads and because there are drugs that can effectively treat those infected.

#### SPANISH FLU

The 1918 influenza pandemic was perhaps the biggest pandemic of the 20th century. A virus called influenza type A subtype H1N1 was the cause of this pandemic. name Influenza is transmitted from person to person through airborne respiratory secretions. Our discussion draws on the Encyclopedia Britannica (<https://www.britannica.com/event/influenza-pandemic-of-1918-1919>) and the web page of the Center for Disease Control (CDC) (<https://www.cdc.gov/resources/>)

The origins of the flu are unclear but it was first widely discussed by the press in Spain and this gave the pandemic its name. As the World War was drawing to an end, the movement of troops was probably a key mechanism for the spread of this virus. By the summer of 1918, the virus had reached parts of Russia, Africa, Asia, and New Zealand. This first wave was comparatively mild. But a second more lethal wave began in August/September 1918. During this wave, pneumonia often developed quickly, with patients often dying only two days after experiencing the first symptoms of the flu. As social distancing measures were enforced, the second wave began to die down toward the end of November. However, once those measures were relaxed, a third wave began in the winter and early spring of 1919. Though not as deadly as the second wave, the third wave still claimed a

large number of lives. By summer the virus had run its course in many parts of the world. Some historians suggest that there was a fourth wave in winter 1920 (though it was far less virulent).

It is estimated that about 500 million people – roughly one third of the world's population were infected with this virus. The number of deaths is estimated to be at least 25 million though some scholars claim that it was in excess of 50 million.

As no vaccine was available and there are no antibiotics to treat secondary bacterial infections that can be associated with influenza infections, health policy measures were limited to non-pharmaceutical interventions. These included limits on contact and interaction (isolation quarantine and restrictions on public meetings good) and improvements in personal hygiene (e.g., use of disinfectants). While the Spanish Flu has become part of history, influenza remains a health problem of major concern even today: there are three to five million cases of acute influenza and between 250,000- 500,000 deaths annually.

### AIDS

Acquired immunodeficiency syndrome (AIDS) is a transmissible disease of the immune system caused by the human immunodeficiency virus (HIV). HIV is a lentivirus (literally meaning “slow virus”; a member of the retrovirus family) that slowly attacks and destroys the immune system, the body's defense against infection, leaving an individual vulnerable to a variety of other infections (and malignancies) that eventually cause death. HIV is transmitted by the direct transfer of bodily fluids—such as blood and blood products, semen and other genital secretions, or breast milk—from an infected person to an uninfected person. AIDS is the final stage of HIV infection, during which time fatal infections and cancers frequently arise. Our discussion draws on documents from the Centre for Disease Control (CDC) web site (<https://www.cdc.gov/hiv/>).

The origins of HIV remain unclear. A virus that is genetically similar to HIV has been found in chimpanzees and gorillas in western equatorial Africa. That virus is known as *simian immunodeficiency virus* (SIV). It was originally thought to be harmless in chimpanzees, but in 2009 a team of researchers investigating chimpanzee populations in Africa found that SIV causes AIDS-like illness in the animals. SIV may have migrated to humans through the consumption of infected chimpanzee flesh.

The first cases of AIDS may be traced to a CDC reports published in 1981. These reports drew attention to pneumonia in five homosexual men in Los Angeles that was likely acquired through sexual contact. The reports described an outbreak of a rare cancer called Kaposi sarcoma in homosexual men in New York City and San Francisco. Researchers subsequently established that the infections and cancers were manifestations of an acquired immunodeficiency syndrome.

According to the World Health Organization about 36.7 million people were living with HIV, approximately 1.8 million people were newly infected with HIV, and about 1 million people died of HIV-related causes in 2016. In the period 1981-2016 about 35 million people have died from HIV infection. From wreaking havoc on certain populations (such as the gay community in San Francisco in the 1980s) to infecting more than one-third of adults in sub-Saharan African countries such as Botswana, Swaziland, and Zimbabwe at the turn of the 21st century, AIDS continues to have a devastating social impact.

### TUBERCULOSIS

Tuberculosis (TB) is an infectious disease that is caused by the tubercle bacillus, *Mycobacterium tuberculosis*. The tubercle bacillus is a small, rod-shaped bacterium that is extremely hardy; it can survive for months in a state of dryness and can also resist the action of mild disinfectants. Infection spreads primarily through the respiratory route directly from an infected person who discharges live bacilli into the air. Minute droplets ejected by sneezing, coughing, and even talking can contain hundreds of tubercle bacilli that may be inhaled by a healthy person. Our discussion draws on the Encyclopedia Britannica (<https://www.britannica.com/science/tuberculosis>).

During the 18th and 19th centuries, tuberculosis reached near-epidemic proportions in the rapidly urbanizing and industrializing societies of Europe and North America. Indeed, "consumption," as it was then known, was the leading cause of death for all age groups in the Western world from that period until the early 20th century. Since the 1940s, antibiotic drugs have reduced the span of treatment to months instead of years, and drug therapy has done away with the old TB sanatoriums where patients were nursed for years.

Due to a combination of more hygienic living conditions and antibiotic drugs the rate of deaths from tuberculosis in developed countries declined sharply over the first half of the 20th century. In England and Wales the death dropped from 190 per 100,000 population in 1900 to 7 per 100,000 in the early 1960s. In the United States during the same time period, it dropped from 194 per 100,000 to approximately 6 per 100,000. In the early 21st century, tuberculosis is mainly a disease of the developing world, especially in regions of Africa, South and Southeast Asia, and the eastern Mediterranean. There are 8-10 million new cases and between 1.6 million and 2 million die due to tuberculosis every year.

### SMALL POX

Smallpox is caused by the *variola* virus. Small pox begins with a high fever, headache, and back pain and then proceeds to an eruption on the skin that leaves the face and limbs covered with pockmarks (or pox). Small pox spreads from one person to another through close contact, usually by inhalation of virus that had been expelled in the breath

or saliva droplets of an infected person. Despite the hardiness of the variola virus, smallpox is not a highly infectious disease; infected persons usually did not infect more than two to five of their closest contacts. Our discussion draws on the Encyclopedia Britannica (<https://www.britannica.com/science/smallpox>) and Center for Disease Control (CDC) (<https://www.cdc.gov/smallpox/>)

There is evidence on the prevalence of small pox going back three thousand years to the time of the Pharaohs in Egypt. For centuries, smallpox was one of the world's most-dreaded plagues, killing as many as 30 percent of its victims, most of them children. Those who survived were permanently immune to a second infection, but they faced a lifetime of disfigurement and, in some cases, blindness.

There are systematic records of small pox epidemics starting in the 17<sup>th</sup> century: a huge pandemic spread from Europe to the Middle East in 1614, and epidemics occurred regularly in Europe throughout the 17<sup>th</sup> and 18<sup>th</sup> centuries. In the 18<sup>th</sup> century an estimated 400,000 people died annually of smallpox. Introduced to the Americas by European conquerors and settlers, smallpox decimated indigenous groups in North America, the Aztecs of Mexico, the Incas of South America, and the Araucanians of Chile. The Australian Aboriginal populations also suffered large losses from the disease in the 19th century. It is estimated that over 300 million people have died due to small pox in the 20<sup>th</sup> century. But smallpox was also one of the first diseases to be controlled by a vaccine, following the experiments of the English physician Edward Jenner in 1796. The World Health Organization (WHO) began an intensive global eradication program against smallpox in 1967 and in 1980 the disease was officially declared eradicated.

### COVID-19

Covid-19 is an acute disease that is caused by a *coronavirus*. The main symptoms are a high temperature, a continuous cough and a loss of sense of and taste. Over time, a variety of complications may arise such as acute pneumonia. The first cases of Covid-19 were identified in the Chinese city of Wuhan in December 2019. Covid spreads through contact with infected individuals. As of August 2021, it is estimated that over 200 million people have been infected and that over 4 million people have died due to Covid. It is the most devastating epidemic of the 21<sup>st</sup> century. Our discussion draws attention to the role of contact networks in the explosive spread of Covid in India in 2021. The data is taken from [coronavirus.jhu.edu/region/india](http://coronavirus.jhu.edu/region/india).

The first cases in India were detected in January 2020 but throughout the year 2020 rates of infection remained below 50,000 per day. Similarly, death rates remained below 500 per day through most of the 2020. In the first quarter of 2021 (January until mid-March) rates of infection and mortality were very low. However, by the end of March rates of infection

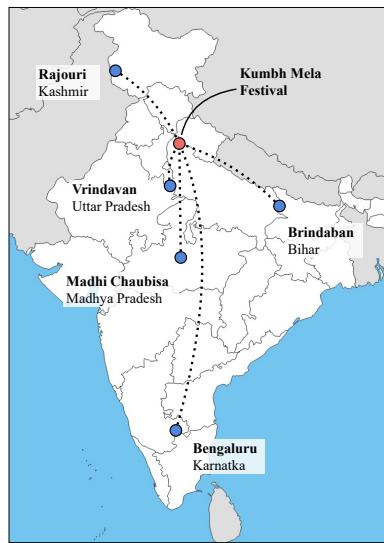

Figure 14.1: Superspread Event: The Kumbh Mela (Source: May 30, 2021 The Guardian Newspaper)

started climbing. Over the period Mid-April to Mid-May, over 250,000 new cases were recorded daily. As a result, from end of April to mid-June, over 3000 deaths were recorded daily. We elaborate below on one of the events that are believed to have led to a massive increase in infections in April-May 2021.

As Covid spreads through human to human contact, an event that brings very large number of individuals together can dramatically increase the rate of infection. We illustrate this point through a discussion of the Kumbh Mela in India in April 2021. Our discussion draws on an article in the Guardian newspaper from 30 May 2021: <https://www.theguardian.com/>

On 12 April, India registered 169,000 new Covid-19 cases. However, in the same week, millions of people were gathering on the banks to the Ganges in the holy city of Hardwar to celebrate the Kumbh Mela, one the holiest festivals in the Hindu calendar. By the time the festival ended, on 28 April, more than 9 million people had attended. By 15 April, more than 2,000 festival goers had already tested positive for Covid-19. We now briefly describe how the Mela acted as a key spreader of Covid-19 infection by tracing the routes taken by two pilgrims from different parts of the country. Figure 14.1 presents a snapshot of the spread across space.

We start with the case of Thakur Puran Singh, 79, from Rajouri in Kashmir. Singh and his extended family drove to Hardwar on April 9. For the next five days, the family took multiple dips in the Ganges. On 16 April, the day after returning, Singh began to experience symptoms and by April 21 his condition had deteriorated and he died shortly afterward. Eight days later, his elder brother Balwant Singh also died. A test-and-trace

official said more than two dozen people contracted the virus after contact with Singh's family members. We turn next to the case of 67-year-old woman from Nandini Layout, a suburb of Bengaluru, who tested positive for Covid days after returning from the Kumbh Mela. She lived with her daughter-in-law who worked in a hospital: tests soon confirmed she too had Covid. Testing teams at the hospital found that 12 patients and 3 staffers had contacted Covid-19 positive. Eighteen other close contacts of the woman were eventually diagnosed with Covid, but the true spread of the virus was probably even higher.

*Computer viruses* The discussion above has focused on biological diseases that infect human beings. Over the past three decades with the growth of the internet, the spread of computer viruses and worms has become important. In 2009, roughly 10 million computers were infected with malware designed to steal online credentials. It is estimated that in Europe, annual damages caused by malware is around 9.3 billion Euros in Europe. while in the US, the annual costs of identity theft are estimated at 2.8 billion USD. For a general overview of computer security issues see Anderson [2020].

We present a short discussion of one computer epidemic, 'ILoveYou'. The worm originated in Philippines on May 5, 2000. It spread westward across the world: Hong Kong, Europe, then United States. Within ten days, over fifty million infections had been recorded. Once the worm infected a computer it would overwrite files, spread through email messages to contacts of the captured computer. It is estimated that the cost of this worm was 5.5–8.7 USD billion in damages and that it cost around USD over 15 billion to remove the worm (<https://en.wikipedia.org/wiki/ILOVEYOU>).

Let us summarize a few points arising from these case studies. Large scale disease epidemics are a major presence in human history and diseases account for several million deaths every year even now. The scale and persistence of COVID reaffirms the seriousness of the threat posed by such diseases. Many of these diseases originated in animals while some of them have a human origin. The mode of contagion of these diseases varies greatly: in some case, it requires frequent and intimate contact among humans (such as AIDS), while in others infection can spread via casual contact (such as in the case of flu), and in still others infection occurs via third agents (such as plague) who carry disease from an infected person to an uninfected one. Some diseases (like small pox) can infect a person only once while others (like flu) can infect the same person multiple times. Finally, human responses to diseases range from the development of vaccines, to limitations on contact, to changes in standards of hygiene. In all these cases, patterns of human interaction plays a central role in the spread of diseases.

## 14.3 A simple threshold for epidemics

We consider a model in which there is an initial infected individual, who remains infected for some time; during this time, he can infect those he comes in contact with. Each of his contacts in turn also have a set of (distinct) contacts, who have their contacts, and so forth. The infectiousness of the disease is captured in a number  $p \in (0, 1)$  that may be interpreted as the probability that a contact is infected. Suppose for simplicity that everyone has  $k$  contacts. Our goal is to understand how  $p$  and  $k$  determines the size of the epidemic. The exposition draws heavily on Easley and Kleinberg [2010].

The contact network is illustrated in Figure 14.2: in this network the number of contacts,  $k = 4$ , and we present the first three layers of the network. This network is a tree with a single root – the initially infected individual. Every ‘node’ is connected to  $k$  nodes in the level below it; and every node (other than the root) is connected to a single node in the level above it. As we wish to understand whether a disease will persist indefinitely, we will find it convenient to work with a tree that is infinite.

To appreciate the basic forces at work, it is helpful to plot a few examples of disease spread through the network. Figure 14.2 describes the evolution of an epidemic that infects one person in the first level, two in the second level and one again in the third level (and possibly none in the subsequent layers). Figure 14.2 shows a more virulent epidemic with three people infected in the first level, nine infected in the second level and twenty eight at level three (and possibly even more in the subsequent levels). As a result, the disease grows explosively. We may interpret the difference between figures 1 and 2 as arising from differences in the infectiousness of the disease: the value of  $p$  is much higher in the latter case.

Figure 14.3 brings out the role of connectivity of the network: there is relatively little infection in the network in the top panel while there is persistent and continuing infection in lower panel.

These figures suggest that if the disease ever fails to infect at a level, then it will die out. In other words, there are two possibilities – either the disease dies out after a finite number of steps or it continues to infect people in every wave, proceeding infinitely through the contact network. Figures 14.2 and 14.3 suggest that higher  $p$  and  $k$  make a long lasting epidemic more likely. To make this idea more precise we will develop the notion of a fundamental notion in epidemics: the *reproductive number*.

The reproductive number, denoted  $R_0$ , is the expected number of new cases of the disease caused by a single individual. In our model, everyone meets  $k$  new people and infects each of them with probability  $p$ . The reproductive number here is given by  $R_0 = pk$ . We

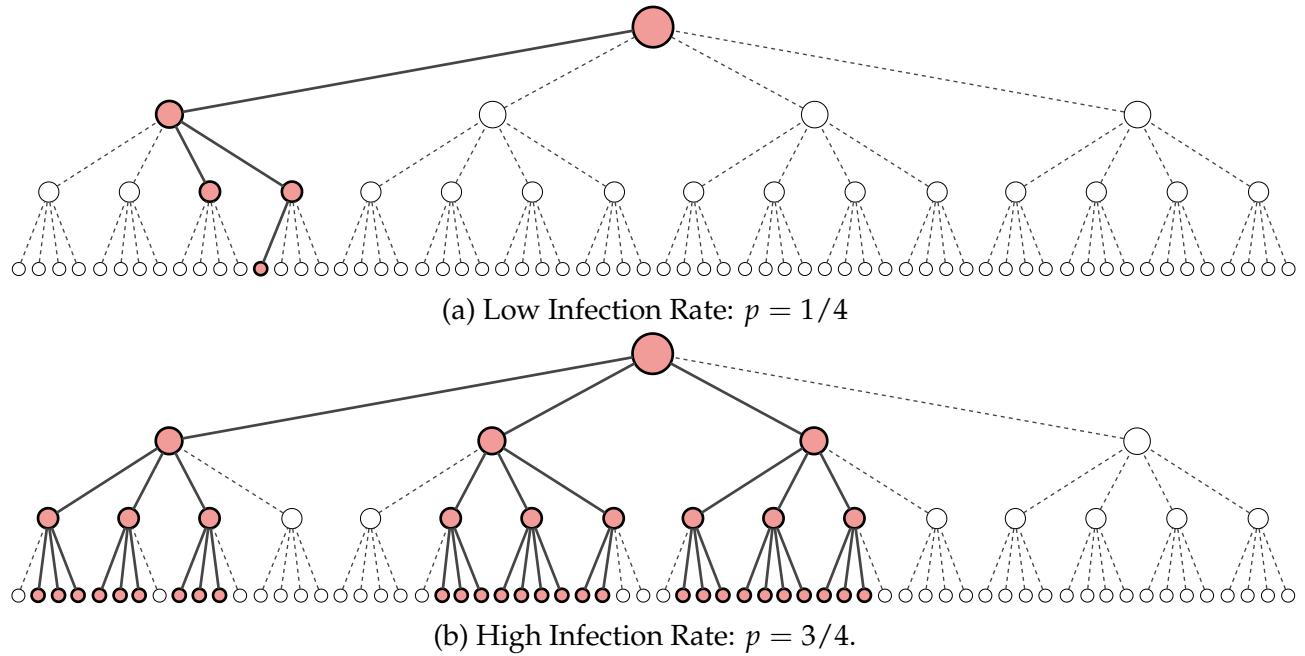

Figure 14.2: Spread of disease: varying infectiousness.

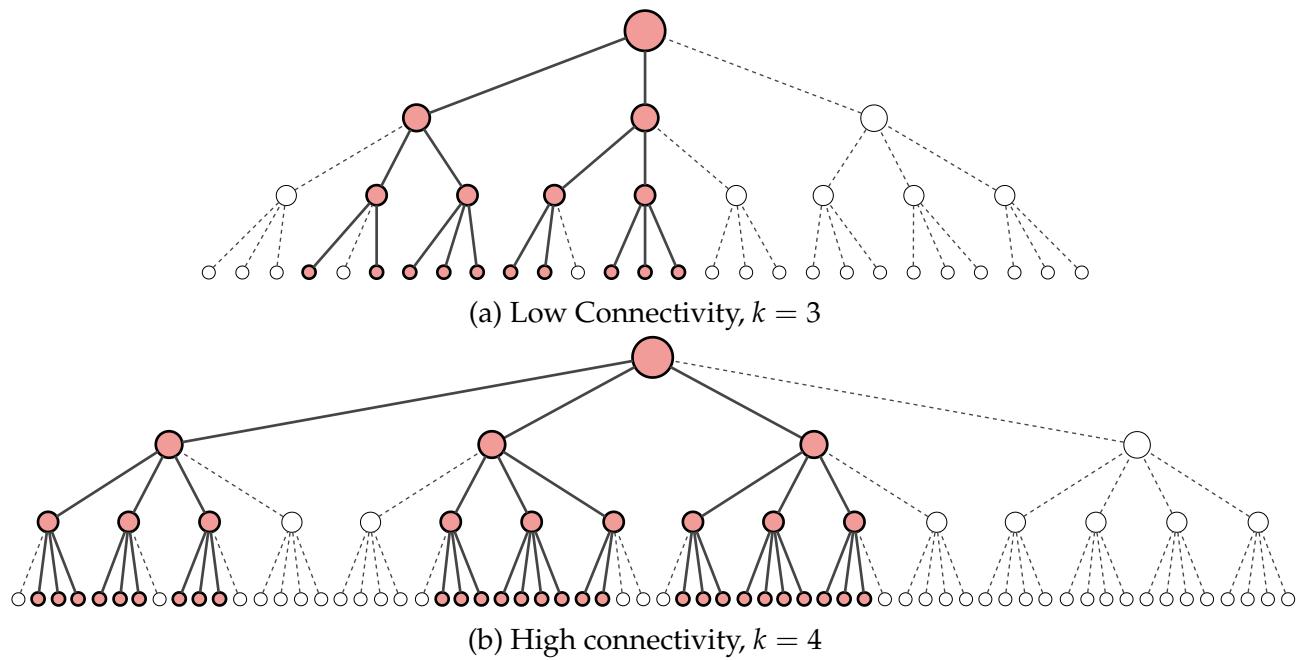

Figure 14.3: Spread of disease: varying  $k$

will show that outcome of the disease is determined by whether  $R_0$  is smaller or larger than 1.

Let  $q_n$  denote the probability that the epidemic survives for at least  $n$  levels — in other words, that some individual in the  $n^{\text{th}}$  level of the tree becomes infected. Let  $q^*$  be the limit of  $q_n$  as  $n$  goes to infinity; we can think of  $q^*$  as the probability that the disease persists indefinitely. We will establish the following result.

**Proposition 14.1.** *Consider the tree network with a single root and suppose that infection spreads from the root downwards. If  $R_0 < 1$  then  $q^* = 0$ , and if  $R_0 > 1$  then  $q^* > 0$ .*

It is instructive to work through the argument step by step. Note that the number of individuals at any given level exceeds the number at the previous level by a factor of  $k$ , so the number who are at level  $n$  is  $k^n$ . Let us examine the expected number of infected individuals at different levels. For level  $n$ , this will be a (random) number ranging from 0 to  $k^n$ .

Define  $X_d$  to be a random variable equal to the number of infected individuals at level  $d$ . For every person  $j$  at level  $n$ , let  $Y_{nj}$  be a random variable equal to 1 if  $j$  is infected, and equal to 0 otherwise. Then

$$X_n = Y_{n1} + Y_{n2} + \cdots + Y_{nm}, \quad (14.1)$$

where  $m = k^n$ . Using the result that the expectation of the sum of a random variables is equal to the sum of their expectations, we may rewrite the above equation as

$$E[X_n] = E[Y_{n1} + Y_{n2} + \cdots + Y_{nm}] = E[Y_{n1}] + E[Y_{n2}] + \cdots + E[Y_{nm}] \quad (14.2)$$

Note that  $E[Y_{nj}] = 1 \times \Pr[Y_{nj} = 1] + 0 \times \Pr[Y_{nj} = 0] = \Pr[Y_{nj} = 1]$ , and so the expectation of any  $Y_{nj}$  is just the probability that  $j$  gets infected. But what is the probability that  $j$  at level  $n$  gets infected? This happens when each of the  $n$  contacts leading from the root to  $j$  successfully transmit the disease. The probability of this event is  $p^n$ :  $E[Y_{nj}] = p^n$ .

$$E[X_n] = p^n k^n = (pk)^n = R_0^n \quad (14.3)$$

Equipped with this formula let us return to the original object of interest,  $q^*$ . We note that

$$E[X_n] = 1\Pr[X_n = 1] + 2\Pr[X_n = 2] + 3\Pr[X_n = 3] + \cdots \quad (14.4)$$

An equivalent way to write the expected value is

$$E[X_n] = \Pr[X_n \geq 1] + \Pr[X_n \geq 2] + \Pr[X_n \geq 3] + \dots \quad (14.5)$$

It follows then that the expected value  $E[X_n] \geq \Pr[X_n \geq 1]$ . However,  $\Pr[X_n \geq 1]$  is the definition of  $q_n$ ; thus  $E[X_n] \geq q_n$ . But if  $R_0 < 1$  then  $R_0^n \rightarrow 0$  as  $n$  grows, hence  $q_n$  too must also converge to 0. This shows that  $q^* = 0$  when  $R_0 < 1$ .

Let us take up the case of  $R_0 > 1$  next. It is easy to see that  $E[X_n]$  grows and is unbounded in  $n$ . However this is not in general sufficient to ensure that the disease persists. A question at the end of the chapter examines this issue. So we need to dig a little deeper into the structure of the model. Our method is to compute  $q_n$  in terms of  $q_{n-1}$  and we will use the formula to work out the value of  $q^*$ .

Consider the event: *The disease spreads through the root node's first contact  $j$  and then continues to persist down to  $n$  levels in the part of the tree reachable through  $j$ .* For this event to obtain, we need  $j$  catches the disease directly from the root, which happens with probability  $p$ . At this point,  $j$  becomes completely analogous to the root node of its own branching process, consisting of all nodes reachable from it downward in the tree. So, for the event to obtain, after  $j$  is infected, the disease must persist for the remaining  $n - 1$  levels: by definition this occurs with probability  $q_{n-1}$ . As  $j$  is infected by the root with probability  $p$ , it follows that the probability of the event is  $pq_{n-1}$ . This event fails to hold with probability  $1 - pq_{n-1}$ . There is an identical copy of the event for each of the direct contacts of the root node, and each fails to hold with probability  $1 - pq_{n-1}$ . As each of them starts with a different 'root' and we are considering a tree network, the events are independent, and so the probability that they all fail to hold is  $(1 - pq_{n-1})^k$ .

But by definition of  $q_n$ , we know that the probability that the event fails to obtain is  $1 - q_n$ . Hence,

$$1 - q_n = (1 - pq_{n-1})^k \quad (14.6)$$

Simplifying, we get

$$q_n = 1 - (1 - pq_{n-1})^k. \quad (14.7)$$

We are interested in values of  $q_n$  as  $n$  gets large. Let us define the function  $f(x) = 1 - (1 - px)^k$ , then we can write Equation (14.7) as  $q_n = f(q_{n-1})$ . Now our goal is to study the limit of the sequence  $1, f(1), f(f(1)), f(f(f(1))), \dots$ , obtained by applying  $f$  repeatedly. The function  $f$  satisfies the following properties:

1.  $f(0) = 0$  and  $f(1) = 1 - (1 - p)^k < 1$ .
2.  $f'(x) = pk(1 - px)^{k-1}$  is positive but monotonically decreasing.
3.  $f'(x)$  at  $x = 0$  is equal to  $f'(0) = pk = R_0$ .

In the case  $R_0 > 1$ ,  $f(x)$  therefore lies above  $x$  for small values of  $x$ . Putting together these observations and noting that  $f$  is a continuous function on the range  $x \in [0, 1]$  we conclude that there exists a unique value  $x^* > 0$  such that  $x^* = f(x^*)$ . This concludes the proof. ■

The threshold property develop in Proposition 14.1 highlights a sharp transition at the threshold point. Suppose  $R_0$  is just slightly below 1 and we increase the probability  $p$  by a little that  $R_0$  above 1. This could result in a positive probability of a large outbreak. Similarly, if  $R_0$  is just slightly above 1, then slightly reducing  $p$  to push  $R_0$  below 1 would eliminate the risk of a large epidemic. For example, if  $k = 3$  and  $p = 0.4$  then  $q^* = .44$ . Reducing  $p$  to 0.35 reduces  $q^*$  to .14; reducing  $p$  further to below 1/3 reduces  $q^*$  to 0. As  $R_0$  is the product of  $p$  and  $k$ , we can think of two basic types of public-health policies to lower  $R_0$ : quarantining people (this lowers  $k$ ), and encouraging changes in behaviour (such as wearing masks or being more hygienic) that lowers  $p$ .

In the model of this section, the disease can only move from high to lower levels and there is only one route to the spread of the disease from an upstream to a downstream node (as the network is a tree). As we turn to more general networks, we will need to think about both these assumptions. We first take up the case of a disease that a person can only get once (such as small pox) and then we study diseases (such as flu) that a person can get multiple times.

## 14.4 The Susceptible-Infected-Recovered (SIR) model

We consider a model of a disease that an individual can suffer from only once. There are therefore three states for an individual: she may be susceptible, infected or recovered, leading to the acronym the Susceptible-Infectious-Recovered (SIR) model. Our discussion will focus on the relation between network structure and the spread of a disease; we will draw on the exposition of the basic theory in Easley and Kleinberg [2010] and Jackson [2008].

The dynamics of infection are determined by the contact network, the probability of contagion  $p$ , and the length of infection time  $t_I$ . At the start of the process, some nodes are in the state  $I$  and all other nodes are in state  $S$ . A node  $v$  that enters state  $I$  remains

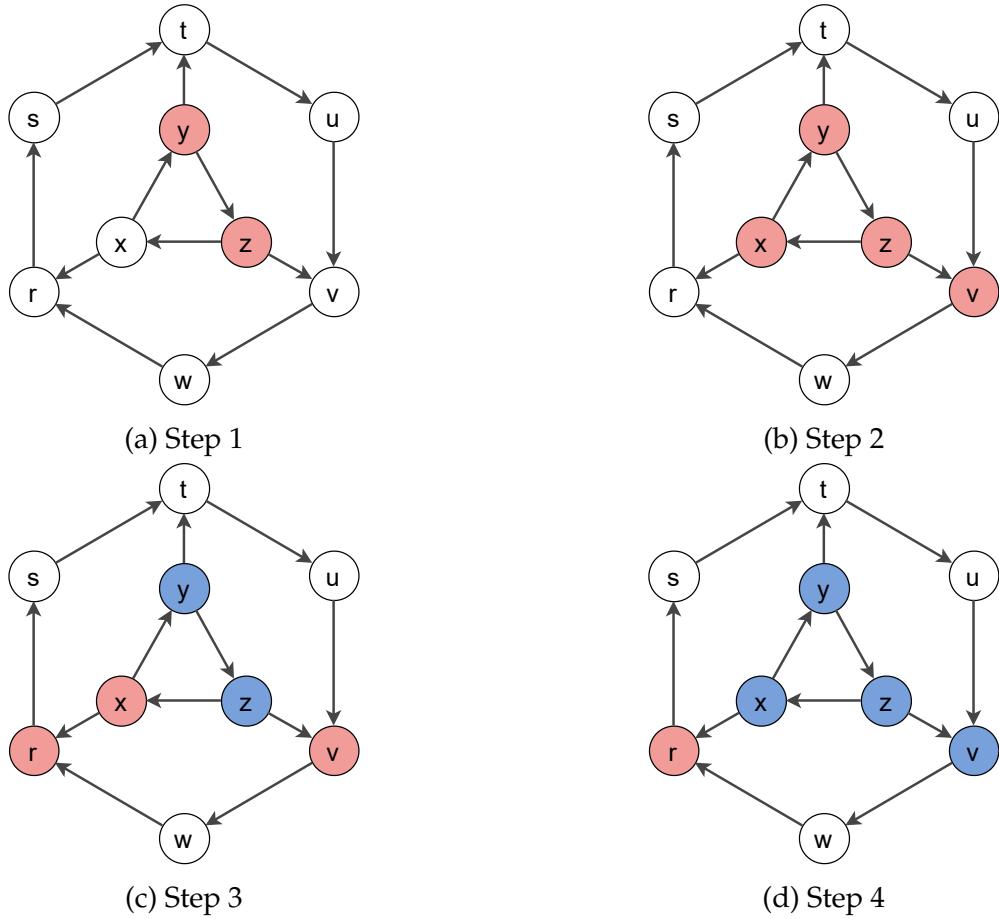

Figure 14.4: The SIR Process

infectious for  $t_I$  steps. During each of these  $t_I$  steps,  $v$  has a probability  $p$  of passing the disease to each of its susceptible neighbors. After  $t_I$  steps, node  $v$  is no longer infectious or susceptible to further bouts of the disease and is referred to as recovered/removed.

Figure 14.4 presents an example of the SIR model unfolding on a contact network. At each step, blank nodes are in susceptible state, shaded nodes in red are in the  $I$  state, and shaded nodes in blue are in the  $R$  state. Notice that the basic model in the previous section is a special case of the SIR model: it corresponds to the case  $t_I = 1$  and a contact network that is an infinite tree, with each node connected to a fixed number of neighbors in the level below.

We now explain how a network structure can alter the dynamics as compared to the basic tree structure in the previous section. The simplest way to see this is to reconsider the threshold result Proposition 14.1. Recall that in the tree network, the disease dies out if and only if the reproductive number  $R_0 < 1$ . We will show that this result is no longer true when we consider more general networks.

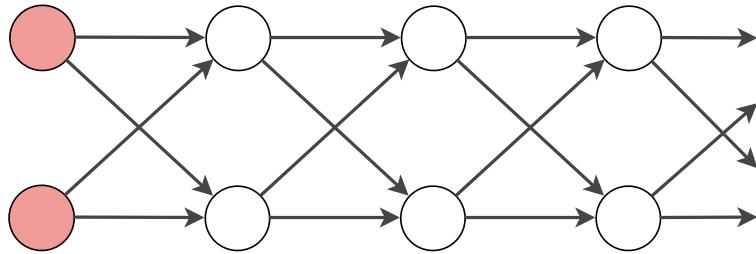

Figure 14.5: Tunneling in Networks

Consider the network illustrated in Figure 14.5 and suppose that these levels of two nodes continue indefinitely to the right. To fix ideas, let us consider an SIR epidemic in which  $t_I = 1$ , the infection probability  $p$  is  $2/3$ , and the two nodes at the far left are the only nodes that are infected at the start.

In this simple network each infected node has edges to two nodes in the next layer: as every link comes alive with probability  $2/3$ , the expected number of new cases is  $2 \times 2/3 = 4/3 > 1$ . Hence in this example,  $R_0 > 1$ . In the original model with the tree network, from the previous section we know that this means that there is a strictly positive probability that the disease will persist indefinitely.

However, in the network in Figure 14.5, the disease will die out almost surely after reaching only a finite number of steps. To see this note that in each layer, there are four edges leading to the next layer. As each can fail with probability  $1/3$ , there is a probability  $(1/3)^4 = 1/81$  that all four edges will fail to transmit the disease. It follows that there is a probability of at least  $1/81$  that each layer will be its last. Therefore, from standard reasoning the disease will cease to spread after a finite number of layers, with probability one.

This is a very simple example but it helps us understand that network structure can be more or less conducive to the spread of a disease. This happens because the network forces the disease to pass through a narrow “tunnel” in which a small breakdown in contagion can wipe it out.

#### 14.4.1 Percolation

We have presented the SIR model as a dynamic processes, in which the state of the nodes evolves over time, one step at a time. This is illuminating because it captures the temporal patterns of the disease as it spreads through a network. In this section, we will explore an alternative perspective on the spread of the disease that is static and at the same time equivalent in a suitable sense. The static formulation is very helpful as we can use models

of random graphs to understand disease progression.

Let us consider the basic SIR model in which  $t_I = 1$ . Consider a point in an SIR epidemic when a node  $v$  has just become infectious, and it has a susceptible neighbor  $w$ . Node  $v$  has one period – and therefore one chance – to infect  $w$ , and it succeeds with probability  $p$ . The outcome of this random event can be thought of as the outcome of a coin flip that has a probability  $p$  of coming up ‘heads’. To understand how far a disease travels, it is important to examine whether the disease will proceed from  $v$  to  $w$  but it is not important when the coin was flipped. Keeping in mind this atemporal interpretation, we can now take one link in a network at a time and ask whether it comes up ‘heads’ or not and we can assume that the coin toss is independent across links. Once we have stored the results of all the coin tosses we can then proceed to examine the extent of spread of the disease as follows.

The links in the contact network for which the coin flip was heads – i.e., successful – are declared open; the remaining edges are interpreted as blocked. This thought process is represented in Figure 14.6. The picture shows a sample result of coin flips that is consistent with the pattern of infections in the example from Figure 14.4. And we can now see how to make use of the open and blocked edges to understand the course of the disease in this network: let us start with some initially infected nodes, then a node  $v$  will become infected if and only if there is a path consisting only of open edges from one of these infected nodes to  $v$ . Figure 14.6 is a concise way to summarize the course of the disease. This static view of the progression of a disease is referred to as *percolation*. Percolation has been extensively studied by physicists and mathematicians. We now use the percolation perspective to understand the SIR process on a network.

Let us note that starting from an initially infected node a disease will spread to another node as long as there is a path from the initially infected node to this node in the subgraph of open edges in the original network. In other words, to understand the extent of spread of the disease, we need to know the distribution of the component sizes of the open subgraph. This leads us to an exposition of one of the most celebrated results in graph theory: the distribution of component sizes in the Erdos-Renyi model of random graphs. Our exposition here draws on Jackson [2008] and is carried out at a heuristic level. For more formal proofs the interested reader is urged to consult Bollobás [1998a] and Bollobás [2004].

Consider the Erdos-Renyi model (as in chapter 2) on  $n - 1$  nodes with a probability of any given link being  $p > 1/n$  (in principle  $p$  is a (decreasing) function of  $n$  (as we increase  $n$ ), but we are suppressing this dependence for simplicity). Add a new node, numbered  $n$ . Connect this last node with the existing  $n - 1$  nodes where the probability of each link is

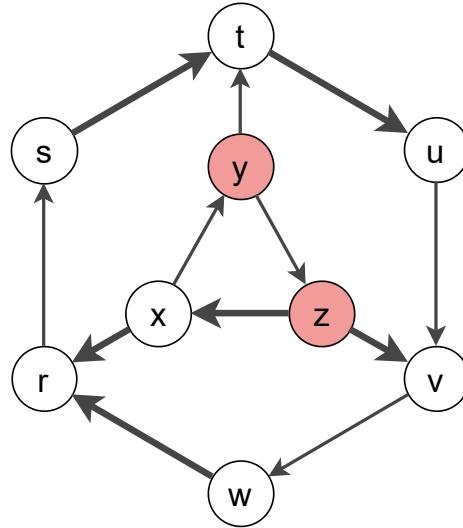

Figure 14.6: From SIR to percolation: open edges in bold dark.

independent and given by  $p$ . Let  $q$  be the fraction of nodes in the largest component of the original network. For large  $n$ , the number  $q$  will also be a fairly good approximation for the share of nodes in the largest component in the network with  $n$  nodes. The only case where this may not be true is that the new node successfully connected two hitherto unconnected large components. However, the likelihood of this happening becomes negligible under the assumption  $p(n - 1) > 1$  (the details are provided in the proof of connectedness of Erdos-Renyi graphs in Chapter 2). The new node is not in the largest component if none of its neighbours are in the giant component, if the new node has degree  $d$ , then for large  $n$  this probability is roughly equal to  $(1 - q)^d$ .

Generalizing this reasoning, the probability that a node with degree  $d$  is not a member of the largest component is  $(1 - q)^d$ . This leads us to the identity: the fraction of nodes outside the largest component,  $1 - q$ , is equal to the expected probability of a node lying outside the largest component, i.e.,

$$1 - q = \sum_d (1 - q)^d P(d). \quad (14.8)$$

Recall the Poisson degree distribution

$$P(d) = \frac{e^{-(n-1)p} ((n-1)p)^d}{d!}. \quad (14.9)$$

Substituting for  $P(d)$  in (14.8), we get

$$1 - q = \sum_d \frac{e^{-(n-1)p}((n-1)p)^d}{d!}(1-q)^d. \quad (14.10)$$

Recalling the definition

$$\sum_d \frac{((n-1)p)^d(1-q)^d}{d!} = e^{(n-1)p(1-q)}, \quad (14.11)$$

we arrive at the following approximation for  $q$ :

$$q = 1 - e^{-q(n-1)p} \quad (14.12)$$

A first point to note is that  $q = 0$  is always a solution to this equation. Whether there exists a positive solution depends on the value of  $p$ . Intuitively, if  $p$  is very small then the network will be fragmented. To derive the threshold probability define  $f(q) = 1 - e^{-q(n-1)p}$ . Observe that  $f(0) = 0$ . Consider the first derivative

$$f'(q) = (n-1)p e^{-q(n-1)p}. \quad (14.13)$$

and the second derivative

$$f''(q) = -((n-1)p)^2 e^{-q(n-1)p}. \quad (14.14)$$

The function  $f(\cdot)$  is concave as the second derivative is negative. Next observe that  $f(1) = 1 - e^{-(n-1)p} < 1$ , so long as  $p(n-1)$  is bounded. So  $f(q) = q$  at some  $q > 0$  if and only if  $f'(0) = (n-1)p > 1$ . This yields us a threshold: *the size of the giant component become negligible and the network is fragmented in case  $p(n-1) < 1$  and the giant component is non-vanishing in a large network only if  $p(n-1) > 1$* . We note in passing that the threshold for Erdos-Renyi graphs is very much in the spirit of the reproductive number result obtained for trees in the previous section (see Proposition 14.1).

What can we say for general random graphs? Recall that in chapter 3 we introduced the configuration model as a way to think of general degree distributions. We now study giant components in networks that have been generated using the configuration model.

Let  $P^n(d)$  describe the degree distribution for a network with  $n$  nodes. As we are interested in properties of networks as  $n$  gets large, for reasons of tractability, we place some restrictions on  $P^n(d)$  as  $n$  grows.

1.  $P^n(d)$  converges uniformly to a degree distribution  $P$  with a finite mean.
2. there exists  $\epsilon$  such that  $P^n(d) = 0$  for  $d > n^{\frac{1}{4}-\epsilon}$

3.  $(d^2 - 2d)P^n(d)$  converges uniformly to  $(d^2 - 2d)P(d)$ .
4.  $E_{P^n}[d^2 - 2d]$  converges uniformly to its limit (which may be infinite)

The high level idea is the following: starting at a random node, we should be able to trace out larger and larger neighbourhoods as distance increases. The first step in the argument is to note that below the threshold as we move outward from a node, we do not encounter an already visited node, in other words, the network is a tree. Consider a link in a network generated using a configuration model that satisfies the four conditions above. The probability that a link connects two nodes that already have a path between them in a component with  $s$  nodes is the probability that both the nodes (of the link) lie in the component: this is proportional to  $(s/n)^2$ . Thus the fraction of links that end up in cycles is of the order

$$\sum_i \left[ \frac{s_i}{n} \right]^2 \quad (14.15)$$

where  $s_i$  is the size of a component  $i$  in the network. Let  $S$  be the size of the largest component. Then it follows that, since  $\sum_i s_i = n$ , this sum is smaller than  $S/n$ . If we are below the threshold at which the giant component emerges then, by definition,  $S/n$  is converging to 0 for large  $n$ . This completes a sketch of the argument that the network is a collection of trees below the threshold. For a more precise statement and the details of the proof the interested reader is referred to Molloy and Reed [1995].

Let us now turn to the size of the giant component above the threshold. Define  $\phi$  as the number of nodes that can be found on average by tracing the paths outward from an end node taken from a link picked at random in the network (as it gets large). As, there are no cycles, the number of nodes reached starting from a link is 1 plus the number of nodes reached starting from each of the neighbours of the node. Define  $\langle d \rangle = E(d) = \sum dP(d)d$  and  $\tilde{P}(d) = \frac{P(d)d}{\langle d \rangle}$ . Then

$$\phi = 1 + \sum_{d=1}^{\infty} \frac{P(d)d}{\langle d \rangle} (d-1)\phi \quad (14.16)$$

Simplifying, we obtain:

$$\phi = 1 + \frac{(\langle d^2 \rangle) - \langle d \rangle}{\langle d \rangle} \phi \quad (14.17)$$

This yields us:

$$\phi = \frac{1}{2 - \frac{\langle d^2 \rangle}{\langle d \rangle}} \quad (14.18)$$

Equipped with this expression we can now compute the threshold for the emergence of the giant component. Observe that  $\phi$  is finite if  $2\langle d \rangle - \langle d^2 \rangle > 0$ . Thus there exists a giant component if

$$2\langle d \rangle - \langle d^2 \rangle > 0. \quad (14.19)$$

This in turn yields us the threshold  $2\langle d \rangle = \langle d^2 \rangle$ . To appreciate the implications of this result, let us apply it to some well known degree distributions.

First consider the Erdos-Renyi random graph: recall that when  $n$  is large this graph has a Poisson degree distribution so that  $\langle d^2 \rangle = \langle d \rangle + \langle d \rangle^2$ . Our threshold result then tells us that the giant component emerges if  $\langle d \rangle > 1$ . Turning next to a regular network with degree  $k$ ,  $\langle d \rangle^2 = 2\langle d \rangle$ , implies that  $k = 2$ . Finally, for a scale free degree distribution  $P^n(d) = cd^{-\gamma}$ , the term  $\langle d^2 \rangle$  diverges when  $\gamma < 3$ . This means that there exists a giant component for all degree distributions that satisfy the finite mean condition mentioned above.

We next turn to the size of the giant component. Recall that expression (14.8) does not assume a specific degree distribution, so the same formula applies for the configuration model:

$$1 - q = \sum_d (1 - q)^d P(d). \quad (14.20)$$

A first order stochastic shift in degree distribution will mean that the right hand side is smaller for every finite  $q$ , and this in turn means that the  $1 - q$  that solves the equation must be smaller, i.e., the giant component must be larger. This is intuitive as we are implicitly raising the probability of linking. A question at the end of the chapter explores the implications of varying degrees distributions for size of giant component.

We now apply the result to the study of vaccination policies.

**Random Vaccination:** Suppose that some fraction  $\pi$  of nodes have been vaccinated and are therefore immune. How does that affect the size of the epidemic? The initially infected person interacts with her neighbours, of whom  $\pi$  are immune.

To address this question, it is helpful to lay out the sequence of events: first, a network is formed. Second, a fraction of nodes  $n\pi$  is deleted at random, leaving a residual network in place. Three, we identify the component of a randomly chosen initial infection in the residual network.

We first take up the Erdos-Renyi random graph. As node vaccination is random, we may study the extent of spread of the disease by considering an alternative network with  $n(1 - \pi)$  individuals in which all links are created with probability  $p$ . Recall from our

earlier computations that the threshold for the emergence of a giant component is given by  $pn(1 - \pi) = 1$ : thus the disease is contained within a small/finite component if  $pn(1 - \pi) < 1$  and it spreads over a unbounded component if  $pn(1 - \pi) > 1$ . Moreover, the fraction of nodes that will be infected is given by the number  $q$  where  $q$  solves

$$q = 1 - e^{-q(1-\pi)np} \quad (14.21)$$

Taking logs, we can use this equation to write  $q$  in a more useful form:

$$-(1 - \pi)np = \frac{\log(1 - q)}{q}. \quad (14.22)$$

We can infer that an increase in  $p(1 - \pi)n$  leads to a corresponding increase in the size of the giant component and hence in the size of the infected fraction of the population.

Let us now turn to disease spread in network with a general degree distribution. We start with a study of configuration model. For the network obtained after deletion of  $\pi$  nodes we get the following threshold property for the emergence of a giant component:

$$2\langle d \rangle_\pi = \langle d^2 \rangle_\pi. \quad (14.23)$$

To apply this formula we need to have an expression for the degree distribution of the network,  $P_\pi$ , after the immune nodes have been deleted. Let us start with a node in the original network  $P$ . The probability that a node starting with degree  $d'$  has a degree  $d \leq d'$  is given by

$$\binom{d'}{d} (1 - \pi)^d \pi^{d' - d}. \quad (14.24)$$

The degree distribution in the modified network after eliminating immune nodes

$$P_\pi(d) = \sum_{d' \geq d} P(d') \binom{d'}{d} (1 - \pi)^d \pi^{d' - d}. \quad (14.25)$$

Next note that

$$E_\pi[d] = \sum_d \sum_{d' \geq d} d P(d') \binom{d'}{d} (1 - \pi)^d \pi^{d' - d}. \quad (14.26)$$

This expectation may be rewritten as

$$E_\pi[d] = \sum_{d'} P(d') \sum_{d' \geq d} d \binom{d'}{d} (1 - \pi)^d \pi^{d' - d}. \quad (14.27)$$

The expectation can be expressed more compactly as  $\sum_{d'} P(d') M_\pi(\hat{d}; d')$ , where  $M_\pi(\hat{d}; d')$  is the expectation of  $\hat{d}$  from a binomial distribution with parameter  $(1 - \pi)$  and a maximum of  $d'$  draws. It then follows that  $M_\pi(d; d') = d'((1 - \pi))$  and that  $M_\pi(d^2; d') = \langle d \rangle^2 + d' \pi(1 - \pi)$ . Using these facts, we may write

$$\langle d \rangle_\pi = \langle d \rangle(1 - \pi). \quad (14.28)$$

$$\langle d^2 \rangle_\pi = \langle d^2 \rangle(1 - \pi)^2 + \langle d \rangle \pi(1 - \pi). \quad (14.29)$$

Using equation (14.23), the threshold for a giant component of susceptible nodes is given by a  $\pi$  that solves

$$\langle d^2 \rangle(1 - \pi) = \langle d \rangle(2 - \pi) \quad (14.30)$$

Solving for  $\pi$ , we get

$$\pi = \frac{\langle d^2 \rangle - 2\langle d \rangle}{\langle d^2 \rangle - \langle d \rangle} \quad (14.31)$$

Let us consider a few examples of networks to develop an appreciation for the threshold in equation 14.31. In the regular network, every node has degree  $k$ . The threshold is then given by  $\pi = (k - 2)/(k - 1)$ . So if  $k = 2$  then the threshold is  $\pi = 0$ : in other words, immunization of any positive fraction of nodes will eliminate the spread of the disease. On the other hand if  $k = 3$  then  $\pi = 0.5$ , meaning that we would need to vaccinate at least one half of the nodes to prevent a serious epidemic. We recall from above that in the Erdos-Renyi network (with a Poisson degree distribution),  $\langle d^2 \rangle = \langle d \rangle^2 + \langle d \rangle$  and  $\langle d \rangle = (n - 1)p$ . This implies that the threshold is given by  $\pi = 1 - \frac{1}{(n-1)p}$ , or equivalently by  $p n(1 - \pi) = 1$ . A threshold that is reminiscent of the basic threshold with regard to the reproductive number we obtained in Proposition 14.1.

Finally, consider the scale free network with degree distribution  $P(d)$  proportional to  $d^{-\gamma}$ . Recall that  $\langle d^2 \rangle$  is diverging for  $\gamma < 3$ . This immediately implies that the threshold value for  $\pi$  is 1! In other words, the disease spreads to a giant component even when virtually all nodes are immune. This means that the nodes with very high degrees play a central role in the spread of disease.

Thus whether a network successfully diffuses a disease or not turns on the relationship between the variance and mean: when the variance is sufficiently large relative to the mean the network will diffuse the disease even when large parts of the population are immune. This motivates the study of targeted vaccination policies.

**Targeted Vaccination:** Suppose that the policy maker knows the degrees of everyone and can target individuals based on their degrees. Let us consider the policy of immunizing a

fraction  $\pi$  of the highest degree individuals. To assess the impact of this policy, we start with a network formed with the original degree distribution  $P$ . Suppose that a share  $H$  of the highest degree individuals are deleted. For simplicity suppose all nodes with degrees higher than  $\bar{d}$  are immunized/deleted. This in turn means that all links emanating from these immunized nodes are also deleted and this lowers the degree of the remaining nodes. In other words, if we are immunizing a fraction  $\pi$  then

$$\sum_{d=1}^{\bar{d}(\pi)} P(d) = 1 - \pi. \quad (14.32)$$

Observe that we have removed a share  $\pi$  of nodes, but as these are highest degree nodes, we have removed a higher fraction of links that is given by

$$f(\pi) = \frac{\sum_{d=\bar{d}+1}^{\infty} P(d)d}{\langle d \rangle} \quad (14.33)$$

Thus a node in the residual network loses each of its links with probability  $f(\pi)$ . The new degree distribution is given by

$$P_{\pi,H}(d) = \sum_{d=1}^{\bar{d}(\pi)} \frac{P(d')}{1 - \pi} \binom{d'}{d} (1 - f(\pi))^d f(\pi)^{d' - d} \quad (14.34)$$

Building on the thresholds obtained in equation 14.30, and using 14.34, we arrive at

$$\langle d^2 | d \leq \bar{d}(\pi) \rangle (1 - f(\pi)) = \langle d | \bar{d}(\pi) \rangle (2 - f(\pi)) \quad (14.35)$$

where  $\langle . | \bar{d}(\pi) \rangle$  is the expectation with respect to the original distribution (that is truncated at  $\bar{d}(\pi)$ ).

We use this threshold to clarify the effects of immunizing the high degree nodes in scale-free networks. It is convenient to work with a continuous approximation of the degree distribution. Let the density be given by  $(\gamma - 1)d^{-\gamma}$ . Observe that

$$\int_1^x (\gamma - 1)d^{-\gamma} dd = 1 - x^{-\gamma+1}. \quad (14.36)$$

Next we note that

$$\int_1^{\bar{d}(\pi)} P(d) dd = 1 - \pi. \quad (14.37)$$

Substituting for the density,

$$\int_1^{\bar{d}(\pi)} (\gamma - 1)d^{-\gamma} dd = 1 - \pi. \quad (14.38)$$

Hence  $1 - \bar{d}(\pi)^{\gamma-1} = 1 - \pi$ , implying  $\pi = \bar{d}(\pi)^{\gamma-1}$  and so  $\bar{d}(\pi) = \pi^{1/(1-\gamma)}$ .

We can obtain an explicit formula for  $f(\pi)$  using the density  $P(d)$ :

$$f(\pi) = \frac{\sum_{d=\bar{d}+1}^{\infty} P(d)d}{\langle d \rangle} \quad (14.39)$$

$$= \frac{\lim_{t \rightarrow \infty} \int_{\bar{d}(\pi)}^t (\gamma-1)d^{-\gamma+1}dd}{\lim_{t \rightarrow \infty} \int_1^t (\gamma-1)d^{-\gamma+1}dd} \quad (14.40)$$

$$= \frac{\frac{1}{-\gamma+2} \lim_{t \rightarrow \infty} [d^{-\gamma+2}]_t \bar{d}\pi}{\frac{1}{-\gamma+2} \lim_{t \rightarrow \infty} [d^{-\gamma+2}]_1^t} \quad (14.41)$$

Taking limits with respect to  $t$ , and substituting for  $\bar{d}(\pi)$ , we obtain  $f(\pi) = \pi^{(\gamma-2)/(\gamma-1)}$ . Let us next obtain an explicit expression for  $\langle d^x | d \leq \bar{d}(\pi) \rangle$

$$\langle d^x | d \leq \bar{d}(\pi) \rangle = \int_1^{\bar{d}(\pi)} d^x (\gamma-1)d^{-\gamma} dd \frac{1}{1-\pi} \quad (14.42)$$

$$= (\gamma-1) [d^{x-\gamma+1}]_1^{\bar{d}(\pi)} \frac{1}{x-\gamma+1} \frac{1}{1-\pi} \quad (14.43)$$

$$= \frac{\gamma-1}{\gamma-1-x} \frac{1}{1-\pi} [1 - \bar{d}(\pi)^{-\gamma+1+x}] \quad (14.44)$$

Note that the final term  $1/(1-\pi)$  is a rescaling due to truncated distribution. Substituting for  $x = 1$  and  $x = 2$  in above expression, we obtain:

$$\langle d | d \leq \bar{d}(\pi) \rangle = \frac{(\gamma-1)(1-\bar{d}(\pi))^{-\gamma+2}}{(\gamma-2)(1-\pi)} \quad (14.45)$$

$$\langle d^2 | d \leq \bar{d}(\pi) \rangle = \frac{(\gamma-1)(1-\bar{d}(\pi))^{-\gamma+3}}{(\gamma-3)(1-\pi)} \quad (14.46)$$

Substituting for  $f(\pi)$  and for  $\langle d | d \leq \bar{d}(\pi) \rangle$  and  $\langle d^2 | d \leq \bar{d}(\pi) \rangle$  in equation 14.35, the threshold maybe expressed as

$$(\gamma-2) \left[ 1 - \pi^{(\gamma-3)(\gamma-1)} \right] = (\gamma-3) \left[ 2 - \pi^{(\gamma-2)(\gamma-1)} \right] \quad (14.47)$$

To get a sense of the large effects of targeted immunization let us consider a few examples: If we set  $\gamma = 2.5$  then the threshold equation above is simplified and yields  $\pi^{1/3} + \pi^{-1/3} = 3$ , which means that  $\pi = 0.06$ . Thus immunizing only 6% of the (highest

degree) nodes is sufficient to eliminate the large scale spread of the disease. By contrast, the immunization of a positive fraction of nodes at random cannot eliminate the risk of large scale spread. If we raise the coefficient and set  $\gamma = 2.9$ , then the corresponding threshold is 0.030, thus suggesting that as the coefficient  $\gamma$  grows the required fraction of high connected nodes needed shrinks.

This section has presented the Susceptible-Infected-Recovered (SIR) model. We first showed through an example how the threshold level of the reproduction number depends on the network structure. This set the stage for a more systematic study of threshold levels and how they depend on networks. We showed that this issue can be usefully reformulated as a question on the circumstances under which a giant component emerges in a large graph. We first established a threshold result for infection rate in the Erdos-Renyi graph. As empirical networks exhibit very unequal degrees, we then examined general degree distributions and obtained the key result that a giant component emerges for arbitrarily low rates of infectiousness if the variance in degrees is sufficiently large relative to the mean degree. Finally, we applied the threshold results to understand the attractiveness of different types of vaccination policies.

## 14.5 The Susceptible-Infected-Susceptible (SIS) Model

We now take up diseases that people can suffer from multiple times. The mechanics of the disease spread are as follows: initially, some nodes are in infectious state,  $I$ , state, while all others are in susceptible state,  $S$ . A node that enters state  $I$  remains in it for a fixed number of steps  $t_I$ . During each of these  $t_I$  steps,  $v$  has a probability  $p$  of passing the disease to each of its susceptible neighbors. After  $t_I$  steps, the node is longer infectious, it returns to state  $S$ . This gives rise to the susceptible-infected-susceptible (SIS) model. This model has been studied in a number of research papers, see e.g., Pastor-Satorras and Vespignani [2001a], Pastor-Satorras and Vespignani [2001b], and López-Pintado [2008]. Our discussion draws on Jackson [2008] and López-Pintado [2008]. As in the previous section, the interest here will be on the relation between disease spread and the structure of networks.

We will study the dynamics of disease using an SIS model in a network. The networks will be described by a degree distribution,  $P$ . An individual of degree  $d_i$  will have  $d_i$  interactions with other individuals in a period. The probability that individual  $i$  meets with an individual who has degree  $d$  is

$$\frac{P(d)d}{\langle d \rangle} \tag{14.48}$$

where  $\langle d \rangle = E(d)$  is the expected degree in distribution  $P$ . Thus individuals are more likely to meet individuals who have higher degree. Define  $\rho(d)$  as the fraction of  $d$  degree nodes who are infected. The average proportion of infected individuals is given by  $\sum \rho(d)P(d)$ . Using this notation and the degree distribution of contacts, we may write the expected probability of meeting an infected person as

$$\theta = \sum_d \frac{P(d)d\rho(d)}{\langle d \rangle} \quad (14.49)$$

Observe that  $\theta$  is different from the average rate of infection in the population:

$$\rho = \sum_d P(d)\rho(d). \quad (14.50)$$

We next turn to the important question of how an infection arises out of interaction. In principle, this can take different forms. It may be that  $i$  gets infected if she meets a single infected individual. An alternative is that she gets infected only if the fraction of infected individuals in her neighbourhood is above a certain threshold. We will suppose that there is a ‘linear’ rate  $v$  at which an infected person passes on infection. For simplicity, suppose that probability that a degree  $d$  individual becomes infected is given by  $v\theta d$ , where  $v \in (0, 1)$ . If we assume that  $vd \leq 1$  for the highest degree in the network allows us to interpret this terms as a probability. This expression is a good approximation of the probability of infection when  $v$  is small.

In the SIS model, an infected individual recovers and becomes susceptible again. Let the recovery rate – from infection to susceptible – in any period be given by  $\delta > 0$ . We note that while this formulation makes the model tractable, it implicitly assumes that the duration of infection has no bearing on the probability of recovery.

We start with a comment on the finite model: as in our earlier discussions above, if the network is finite, and the recovery rate  $\delta$  is independent across persons, then everyone will eventually be in a susceptible state: the long run outcome is an infection rate of zero. In what follows, we will take limits on the size of the network and assume an infinite population.

We will study the steady state of the process of disease spread. Our interest will be in the conditions on probability of infection  $v$ , rates of recovery  $\delta$ , and the network  $P$  under which infection rates are positive.

In a steady state the rate of new infections must equal the rate at which infected move to susceptible state. In other words, for every degree,  $d$

$$(1 - \rho(d))vd\theta = \rho(d)\delta. \quad (14.51)$$

Defining  $\lambda = v/\delta$ , we can write the steady state infection rate for degree  $d$  as:

$$\rho(d) = \frac{\lambda\theta d}{\lambda\theta d + 1}. \quad (14.52)$$

Recall that

$$\theta = \sum_d \frac{P(d)\rho(d)d}{\langle d \rangle} \quad (14.53)$$

Substituting for steady state  $\rho(d)$  we obtain

$$\theta = \sum_d \frac{P(d)\lambda\theta d^2}{(\lambda\theta d + 1)\langle d \rangle} \quad (14.54)$$

A first point to note is that  $\theta = 0$  is always a steady state of this process. Let us examine the conditions under which there also exists a non-zero steady state.

It is helpful to begin with the simple case in which all individuals have the same degree, i.e., the network is regular. We can rewrite the formula for steady state infection rates as

$$\theta = \frac{\lambda\theta d}{(\lambda\theta d + 1)}. \quad (14.55)$$

In the positive solution for this equation

$$\theta = 1 - \frac{1}{\lambda d}. \quad (14.56)$$

Positive infection obtains if  $d\lambda > 1$  (this threshold is reminiscent of our results in the SIR model and also the threshold obtained in Proposition 14.1). Given a net rate of infection  $\lambda$ , we require degree to be large. On the other hand, for a given degree, we require the net rate of infection to be large.

To see the role of networks, let us next consider a scale free distribution:  $P(d) = 2d^{-3}$ . Substitute this distribution in the expression for the steady state infection rate and we get

$$\theta = \sum_d \frac{2d^{-3}\lambda\theta d^2}{(\lambda\theta d + 1)\langle d \rangle}. \quad (14.57)$$

Let us solve for a nonzero  $\theta$ . First note that we can rewrite the right hand side as

$$\frac{2\lambda\theta}{\langle d \rangle} \sum_d \frac{\frac{1}{\lambda\theta}}{d(d + \frac{1}{\lambda\theta})}. \quad (14.58)$$

Set  $x = 1/\lambda\theta$ . Taking a continuous approximation we get

$$\frac{2\lambda\theta}{\langle d \rangle} \int_1^\infty \frac{x}{d(d+x)}. \quad (14.59)$$

Rearranging, we get

$$\frac{2\lambda\theta}{\langle d \rangle} \int_1^\infty \left[ \frac{1}{d} - \frac{1}{d+x} \right]. \quad (14.60)$$

Integrating and simplifying, we get

$$\frac{2\lambda\theta}{\langle d \rangle} \log\left(1 - \frac{1}{\lambda\theta}\right) \quad (14.61)$$

Simplifying and rearranging, we obtain

$$\theta = \frac{1}{\lambda(e^{\frac{1}{\lambda}} - 1)}. \quad (14.62)$$

Observe that this expression is always positive, regardless of the value of  $\lambda$ : in other words, infection rate is positive in the steady state no matter how low is the infectiousness of the disease. A comparison of this result with the positive threshold in the regular graph give us a first intuition for how degree inequality may facilitate the spread of a disease.

To develop a more general understanding for the prospects of infection in networks, we examine the following question. Suppose a small fraction of the population is infected. Would the dynamics take us toward a zero infection steady state or toward a significant positive infection rate? We follow López-Pintado [2008] in addressing this question.

We start by defining the function

$$H(\theta) = \sum_d \frac{P(d)d}{\langle d \rangle} \left( \frac{\lambda d\theta}{\lambda d\theta + 1} \right) \quad (14.63)$$

The function  $H(\cdot)$  keeps track of the number of people who become infected starting from  $\theta$ . if  $H(\theta) > \theta$ , then the new infection rate will be larger than the initial rate, while if  $H(\theta) < \theta$ , then the new rate will be smaller than the initial rate. Therefore fixed points of the function  $H(\theta) - \theta$  correspond to the steady states of the dynamic process. First note

that  $H(0) = 0$ : so zero infection is always a steady state.

It is easily verified that  $H(\theta)$  is increasing and (strictly) concave in  $\theta$ . Also observe that  $H(1) < 1$ . So there exists a positive infection steady state if and only if  $H'(0) > 1$ . Moreover, if it exists, such a positive steady state will be unique (this is due to the strict concavity of  $H$ ).

When  $H'(0) > 1$ , at low values of  $\theta$ , the function  $H$  pushes the infection rate away from 0, and so the zero infection rate steady state is unstable. On the other hand, if  $H'(0) < 0$ , then there is only one steady state and at low values of  $\theta$ , the function  $H$  pushes back toward this unique zero rate steady state. Let us now examine the conditions under which  $H'(0) > 1$ .

Differentiating  $H(\cdot)$  with respect to  $\theta$  yields:

$$H'(\theta) = \sum_d \frac{P(d)d}{\langle d \rangle} \frac{\lambda d}{(\lambda d\theta + 1)^2}. \quad (14.64)$$

We can rewrite this to obtain:

$$H'(0) = \lambda \langle d^2 \rangle / \langle d \rangle \quad (14.65)$$

This RHS of the equation is greater than 1, if and only if,

$$\lambda > \frac{\langle d \rangle}{\langle d^2 \rangle}. \quad (14.66)$$

In a regular graph  $\langle d \rangle = d$  and  $\langle d^2 \rangle = [\langle d \rangle]^2$ . Condition (14.66) is equivalent to  $\lambda > 1/d$  (this is the condition we obtained above in equation (14.56)). If on the other hand,  $P(d)$  is scale free, then we know that  $\langle d^2 \rangle$  grows without bound as  $n$  grows, so that the inequality is satisfied for all  $\lambda > 0$ .

Finally, consider the Poisson degree distribution; in this distribution,  $\langle d^2 \rangle = (\langle d \rangle)^2 + \langle d \rangle$ . So we can rewrite the inequality (14.66) as

$$\lambda > \frac{1}{\langle d \rangle + 1}. \quad (14.67)$$

The threshold for Poisson degree distribution lies between the threshold for the regular and the scale-free degree distribution cases.

The intuition for this result is as follows: high degree individuals serve as conduits for the disease to spread. This means that even very low rates of net infection, i.e., low  $\lambda$ , leave open the possibility for the hubs to be infected: this is because they have a very large number of contacts. Moreover, once hub is infected, it can in turn infect many others, due to its high degree. The contrast with regular networks is clear: everyone has the same degree.

If it is high enough infection persists, otherwise not. In a Poisson distribution with the same average degree, there are individuals with higher as well as some with lower degrees. The existence of the higher degrees helps lower the threshold needed for positive infection steady state. Moving from Poisson to scale-free networks further increases the variance in degrees, giving rise to even higher degree nodes. This further lowers the threshold needed for a positive infection rate steady state.

This section introduces the Susceptible-Infected-Susceptible (SIS) model. The principal insight was that the level of spread of a disease depends on the relative magnitude of the variance in degrees versus the mean degree. This yields a positive threshold for infectiousness in Erdos-Renyi graphs. However, in scale-free graphs, the variance in degrees grows without bound and so diseases with arbitrarily small levels of infectiousness can persist in the population.

## 14.6 Diffusion of behaviours

Information on new products or behaviours spreads through personal contact in a population. So, we would like to understand how best to implant the information at a few select points so that it benefits the largest number of individuals. In this section we will present a case study of the diffusion of micro-finance in Indian villages that will draw attention to the role of central seeded nodes. We will examine circumstances when random seeding can perform close to optimal seeding.

We discuss the diffusion of micro-finance in south Indian villages of Karnataka. This study is taken from Banerjee, Chandrasekhar, Duflo, and Jackson [2013]. For a general introduction to micro-finance the reader is referred to the chapter on economic growth. There is a sample of 75 villages where the micro-finance institution, Bharatha Swamukti Samsthe (BSS) was planning to start operating. These villages are spread across five districts in Karnataka, India (we discussed these villages in the introductory chapter and will also take them up in chapter on economic growth). In 2006, 6 months before BSS's entry into any village, a baseline survey was conducted in all 75 villages. These villages had very limited access to any type of formal credit, prior to this move of BSS.

In 2007, after this data collection was completed, BSS began operations in some of these villages. The study covers a period from 2006 until 2011. Over this period, BSS had entered 43 of the villages. There were large differences in adoption rate of micro-finance across the villages. We examine the role of the seeding points in explaining these differences.

We start by noting that, with a view to maximizing adoption, BSS sought out a number of village 'leaders' – they included teachers, leaders of self-help groups, and shopkeepers

– individuals BSS expected to be well connected and credible. BSS held a private meeting with the leaders (the subset that was amenable). In this meeting, credit officers explained the program and asked the leaders to help organize a meeting to present information about micro-finance to other villagers. These leaders were therefore the seeding points into a village.

A first thought is that villages in which the seeds had greater degree would perform better. Figure 14.7 provides a first impression of the correlation between network location of leaders and eventual adoption of micro-finance. Panel (A) shows that degree centrality is not strongly correlated with diffusion of micro-finance. This leads us to dig deeper into the location of seeds in the local village network.

We will explore the idea that diffusion of micro-finance is a dynamic process and that the direct as well as indirect connections of seeds will play a role. Let us consider the following process: First, the initial households have one opportunity to choose whether to take up micro-finance or not. Second, the seeds have one opportunity to talk with their network neighbours: this happens with a probability  $q_p$  if they adopt, and a probability  $q_n$  if they do not. In subsequent periods, households that have been informed choose to adopt or not to adopt and they also pass on information to their neighbours, and so forth. Let us say that the process stops after  $T$  periods (observe that if  $q_n = 0$  and  $T$  grows without bound then the process is a variant of the SIR model (susceptible before exposure to micro-finance, infected if adopting, and removed after period of communication is over)). The finite number of periods is reasonable as we will be studying relatively small networks. There are therefore three parameters in this diffusion process:  $q_p$  and  $q_n$ .

In the data from these 75 villages, the value of the parameters were estimated as follows:  $q_p = 0.35$ ,  $q_n = 0.07$ . Thus non-adopters are much less likely to share information but they matter for diffusion as a large share of villagers are non-adopters.

With these parameters in hand, we can compute the centrality measures for different nodes in a network. Let us define communication centrality of a leader as the estimated number of adopters under the assumption there is only one seed and the diffusion is as in the model with the parameters. Panel (B) shows that there is a positive correlation between communication centrality and adoption rates. This supports the idea that good injection points can make a large difference in diffusion.

Indeed, we can simplify the model further and compute a measure of diffusion centrality as follows: set  $q_n = q_p = q$ . Define the diffusion centrality of a node  $i$  as the  $i^{th}$  entry of the vector

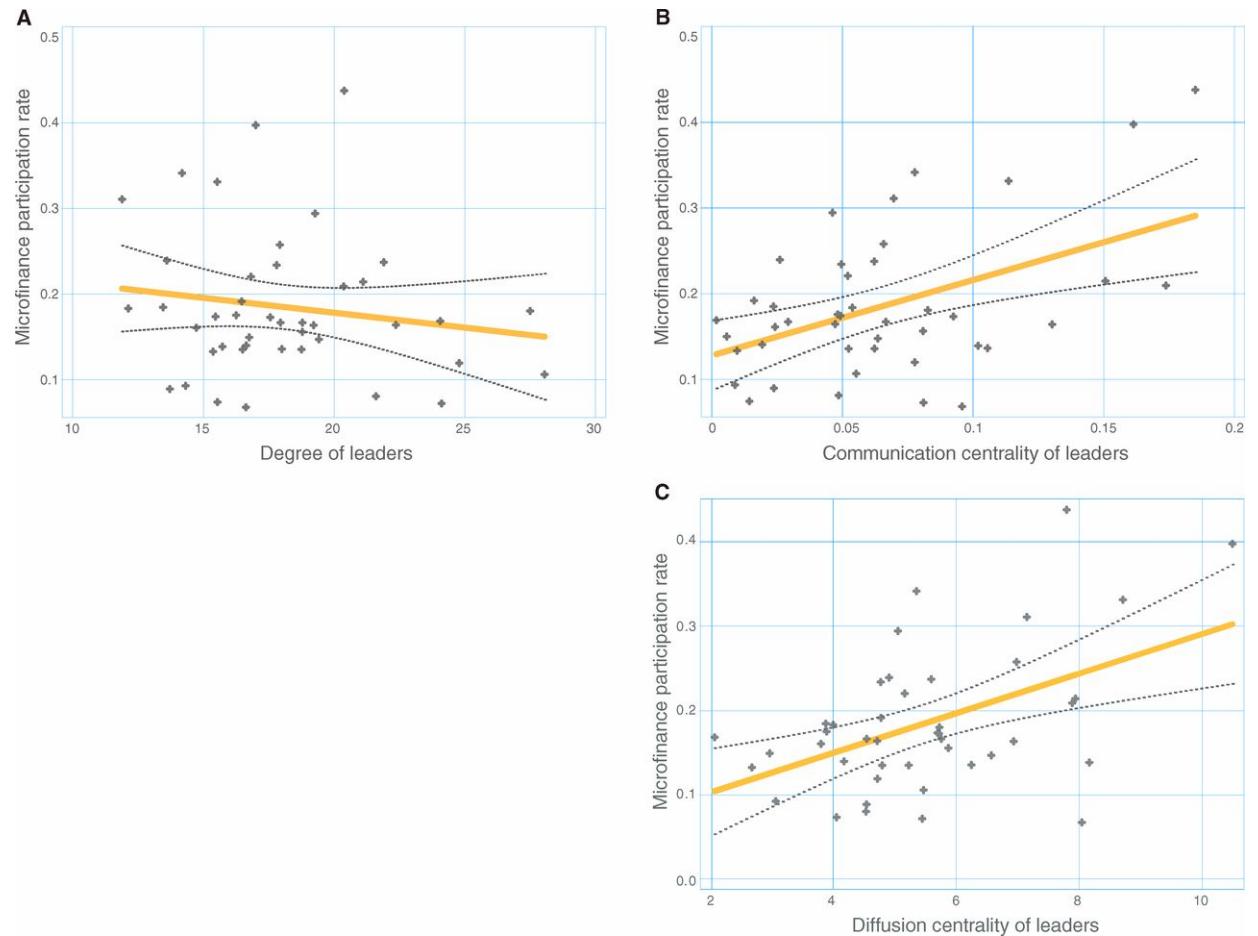

Figure 14.7: Injection Points. Taken from Figure 2 in Banerjee, Chandrasekhar, Duflo, and Jackson [2013]

$$C_D(g, q, T) = \left[ \sum_{t=1}^T (qg)^t \right] \cdot 1. \quad (14.68)$$

This is a measure of the expected number of times that all individuals taken together hear from individual  $i$ . When  $T = 1$  diffusion centrality is proportional to degree centrality. If  $T \rightarrow \infty$ , diffusion centrality is proportional to Katz-Bonacich centrality or eigenvector centrality, depending on whether  $q$  is smaller than or larger than the inverse of the first eigenvalue of the adjacency matrix (for a discussion on the measures of centrality, see chapter 1). In the intermediate region of  $T$ , diffusion centrality differs from these standard centrality measures. Figure 14.7 shows that (average0 diffusion centrality of leaders is positively correlated with adoption rates for micro-finance (in this figure, the  $q$  value is set equal to inverse of the first eigenvalue of the adjacency matrix of the village social network. The value of  $T$  is taken from the number of trimesters that a village was exposed to the micro-finance and was set equal to 6.6).

### 14.6.1 On the value of targeting in diffusion problems

The micro-finance case study draws attention to the role of identifying seed nodes. However, collecting detailed information on networks is costly and even if we did collect all information there are computational limitations on working out the optimal seeds. It is therefore important to understand how much benefit there is from optimal seeding strategies and when does it justify the expense. Our discussion in this section draws on Akbarpour, Malladi, and Saberi [2020].

Consider a population of  $n$  individuals who are connected to each other through a social network. At time  $t = 0$ , a small collection of individuals – the seeds – are informed and everyone else is uninformed. An individual has *one* chance to speak to each of its uninformed neighbors. This information sharing is successful with some probability  $c \in (0, 1)$  independently for each neighbor. If the information sharing is successful then the neighbor becomes informed at the next period. This informed neighbour now speaks to each of her neighbours at time  $t + 1$  and so forth. The process continues until there is no individuals left with an opportunity to be informed. This is therefore a variant of the SIR model we considered in section 14.4.

To quantify the value of network information we contemplate two scenarios. In scenario one, suppose there is access to full network data and in addition also know the communication links that come ‘alive’ (as in the percolation model studies earlier in this chapter). Moreover, suppose we can compute the optimal  $s$  seeds. Under scenario two, we

ignore the network and simply pick  $s + x$  initial seeds uniformly at random. We are interested in understanding the value of  $x$  for which diffusion in the second scenario will exceed that in the first scenario. Observe that comparing this ‘omniscient’ seeding with random seeding provides a generous upper bound for the value of network information: this is because for all ‘realizations’ of the random communication graph, the omniscient strategy will perform at least as well as the optimum.

The main insight is as follows: the difference in expected fraction of informed individuals between the random seeding strategy with  $s + x$  seeds and the omniscient strategy with  $s$  seeds disappears as we increase  $x$ . The intuition underlying this result can be appreciated through a consideration of some well known networks.

First consider networks that are homogenous (where nodes are similar): in such networks, it would not matter how we seed the network. Thus optimal seeding should be similar to random seeding in Erdos-Renyi networks. Next consider unequal networks, such as network with a hub. Observe that targeting seeds at random will involve nodes that are connected to the hubs. Thus random seeds are very likely to get information across to the hubs, who will in turn spread it to everyone else. Optimal seeding will directly target the hubs. Thus random seeding is likely to reach hubs with a one-period lag, as compared to optimal seeding. This suggests that as long as timing is not critical, random seeding will do almost as well as optimal seeding.

To develop a better feeling for the relative reach of random versus optimal seeding, let us consider the reach of different targeting strategies in the Indian villages considered in Banerjee, Chandrasekhar, Duflo, and Jackson [2013]. Figure 14.8 compare the average performance of random, degree-central, diffusion-central, eigenvector-central, and omniscient seeding strategies (for a definition of centrality measures see chapter 1).

The figures presents diffusion for different values of communication probability  $p$ . We see that under both cases, random seeding with a few extra seeds compares well with network-guided seeding heuristics. For instance, when  $c = 0.1$ , random with 5 seeds performs as well as degree- and diffusion-central seeding with two seeds, and better than omniscient with one seed. When  $c = 0.2$ , random with 5 seeds performs better than all heuristics with an equal number of seeds, and better than omniscient with one seed.

Turning finally to a comparison to optimal seeding (OPT) and omniscient seeding (OMN); this is the case where the external observer knows the links that actually get ‘activated’). Let us denote average degree in the underlying social network by  $d$ . Simulations show that when the average number of activated links  $cd = 1.5$ , random with 3 extra seeds beats both OPT and OMN. Similarly, when  $cd = 2$ , random with 2 and 3 extra seeds beat both OPT and OMN.

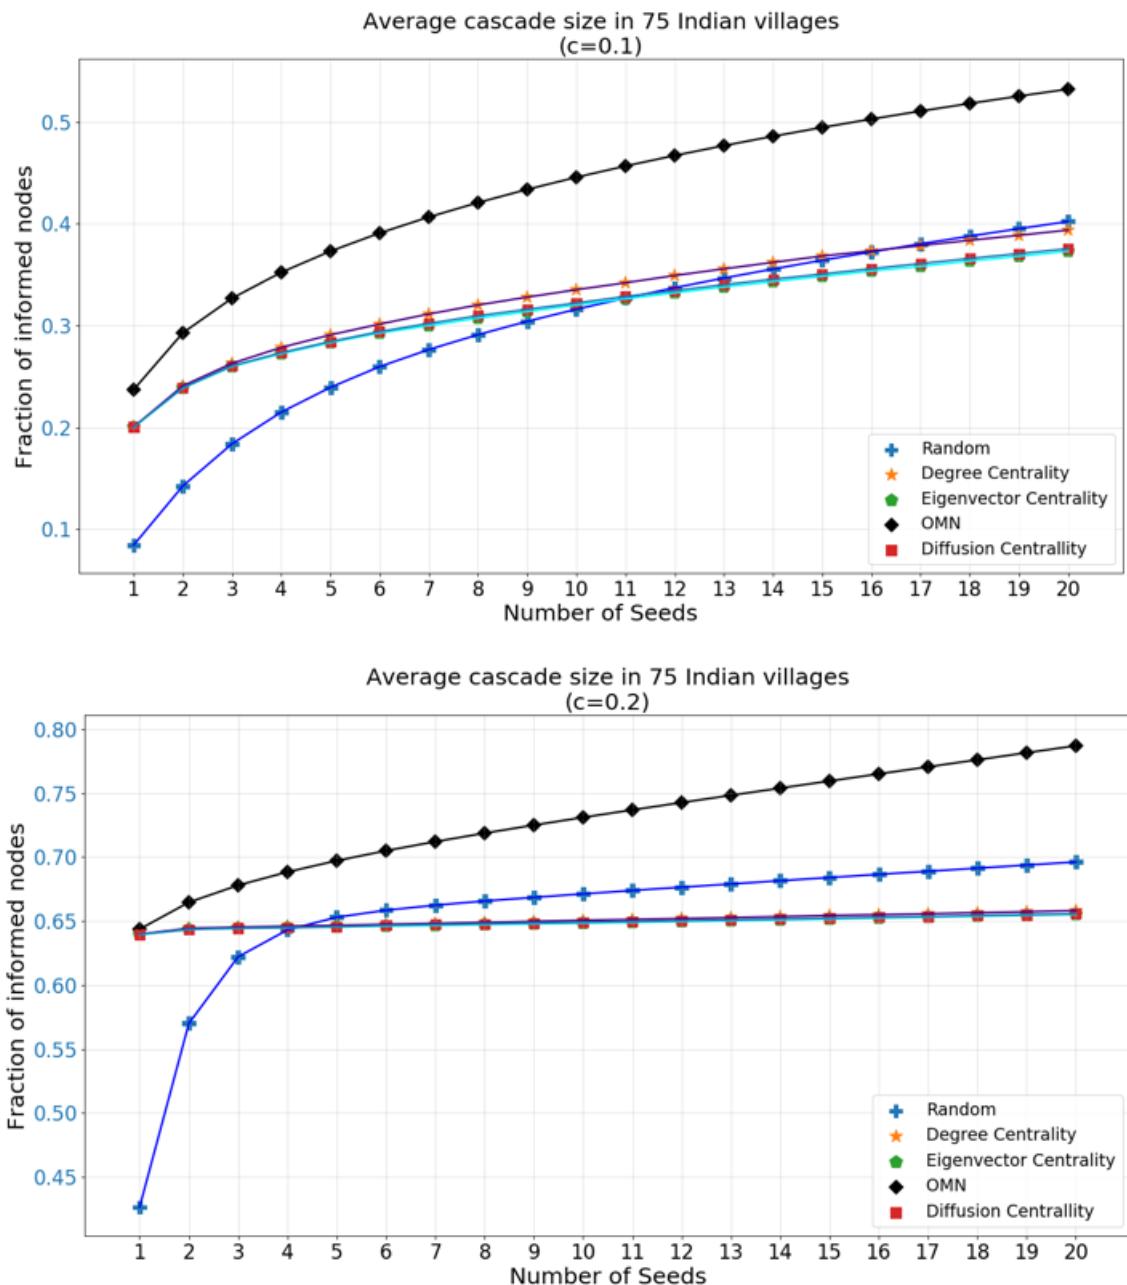

Figure 14.8: A comparison of average diffusion for various seeding strategies (omniscient, random, degree-, diffusion-, and eigenvector-central seeding) across Indian village network data. Two different levels of communication probabilities. Taken from Akbarpour, Malladi, and Saberi [2020].

We conclude with two comments on the scope of this reasoning. The first point pertains to timing and we have already alluded to it. It is clear that in hub-spoke or scale free networks, optimal seeding will be faster than random seeding, because random seeding will get to hubs only indirectly, while optimal seeding will directly target the hubs. A second point pertains to the mechanics of the diffusion process: if information and behaviour is related to thresholds of neighbours affected than random seeding may yield poorer outcomes as compared to optimal seeding. To see this let us consider the example of the hub-spoke network again. Suppose a person believes a piece of information or adopts an action only if a high enough fraction of her neighbours adopt it. Random seeding will then fail to persuade the hub – with many connections – and that would lead to a failure of diffusion. Optimal seeding will take this into account and target a collection of hub-nodes that will ensure wide-spread diffusion.

## 14.7 Appendix

By way of background to the study of diffusion we present the Bass model (Bass [1969]). In this model there are two motivations for adopting an opinion or product: one, a spontaneous desire, and two, social influence or peer effect. The social influence is assumed to operate at the global level and depends on the aggregate measure of adopters in a society. By contrast, the focus in the chapter was on models in which the details of the social interaction were spelled out.

Suppose time is discrete  $t = 1, 2, \dots$ . let  $F(t)$  be the fraction of population that has adopted a product at time  $t$ . This fraction is expressed as follows:

$$F(t) = F(t-1) + p(1 - F(t-1)) + q(1 - F(t-1))F(t-1), \quad (14.69)$$

where  $p$  captures the rate of spontaneous adoption and  $q$  reflects the magnitude of social influence. Observe that  $(1 - F(t-1))$  is the share of population that has not adopted. The last term in the formula says that the social influence acts on the fraction of population that has not adopted  $(1 - F(t-1))$  and the size of the effect is  $F(t-1)$ . We may express the rate of adoption in continuous time as follows:

$$\frac{dF(t)}{dt} = (p + qF(t))(1 - F(t)). \quad (14.70)$$

If we set the initial condition  $F(0) = 0$  and assume that  $p > 0$ , then we get the following solution to the differential equation:

$$F(t) = \frac{1 - e^{-(p+q)t}}{1 + \frac{q}{p}e^{-(p+q)t}} \quad (14.71)$$

As we vary the two parameters  $p$  and  $q$  we trace out a range of adoption curves. The Bass curve can be enriched by introducing pricing and advertising effects, among others.

An important feature of the Bass diffusion curve that has been widely studied is that it gives rise to an *S*-shaped adoption curve, the rate of adoption is small initially, it speeds up and then it tapers off over time. The intuition for this is that when adoption is close to zero there is little social influence and so the rate is given by  $p$ . As adoption progresses the social influence kicks in and adoption enters a reinforcement phase, with rapid adoption. However, as the fraction of adopters expands, while the scope of social influence expands, there is less and less fraction of non-adopters left and this leads to an eventual fall in the rate of adoption. The *S*-shaped adoption curve has been widely studied in empirical research (see e.g., Ryan and Gross [1943], Griliches [1957a] and Coleman et al. [1966]).

## 14.8 Reading Notes

Infectious diseases have had profound effects on human history. A number of diseases continue to be widely spread causing large scale mortality. The experience of COVID-19 in 2020-2021 shows that diseases can still cause global upheaval. The spread of disease depends on its inherent infectiousness and on ways in which it spreads. Diseases differ greatly on these two dimensions. There is a vast literature spanning many disciplines on the nature of infectious diseases. It is impossible to cover the different strands of work. The focus in this chapter is on theoretical models that bring out the role of networks in shaping the spread of diseases and in the design of policies to limit their spread. Two well-known book length overviews of the infectious diseases research are Anderson and May [1992] and Bailey et al. [1975].

We have concentrated on infectious biological diseases in the chapter, but it is clear that diffusion of information and computer viruses may be amenable to similar methods of analysis. Indeed, some of the mathematical results we discussed were first developed in the context of non-biological infections. For expositional simplicity, we have limited ourselves to biological diseases. The final section on diffusion of micro-finance serves to illustrate the general applicability of these methods.

The SIR and SIS models were originally studied in the context of large compartmentalized populations – with individuals belonging to different groups and interacting with uniform probability. Early work goes back to Ross [1916], and Ross and Hudson [1917a]

and Ross and Hudson [1917b]. An early SIR model was presented in Kermack and McKendrick [1927]. These models were gradually elaborated to include richer interaction structures, see e.g, Anderson and May [1992]. Explicit models of networks were introduced in Kretzschmar and Morris [1996] and Pastor-Satorras and Vespignani [2001a]. The literature on diseases and epidemic dynamics on networks has grown greatly over the past two decades. For a panoramic overview of the theoretical research on epidemics in complex networks the interested reader should refer to Pastor-Satorras, Castellano, Van Mieghem, and Vespignani [2015].

Some of the key results on the role of network structure in shaping spread of disease have been inspired by the spread of computer viruses, see in particular Pastor-Satorras and Vespignani [2001a] and Cohen, Erez, Ben-Avraham, and Havlin [2001] and Cohen, Erez, and Havlinl [2000].

Finally, we draw on research on dynamic processes and percolation on random graphs. Special mention must be made of Molloy and Reed [1995] and Chung and Lu [2002a] in this connection. For an overview of this line of work the reader is referred to the excellent collection of articles in Newman, Barabasi, and Watts [2006].

There is a vast literature spanning different disciplines on diffusion of information and behaviours; Rogers [1995b] presents an important overview of the early literature. As we discuss in chapter on communication and social learning, an early study of diffusion in social networks is Coleman, Katz, and Menzel [1966]; other early studies on diffusion include Ryan and Gross [1943] and Griliches [1957b]. More recently, easily availability of data on large scale networks, has led to a revival of interest in the problem of optimal targeting. Domingos and Richardson [2001] provide a formal statement of the problem of optimal seeding and Kempe, Kleinberg, and Tardos [2003] develop a model of optimal seeding. They explore the computational challenges involved in optimal seeding and propose appropriate algorithms that are computationally efficient. The problem of optimal influence strategies remains an active field of research; for recent theoretical contributions see for example Galeotti and Goyal [2009] and Goyal, Heidari, and Kearns [2019]. Our case study of micro-finance is based on Banerjee, Chandrasekhar, Duflo, and Jackson [2013]; for closely related other recent empirical studies on diffusion in social networks see Beaman, BenYishay, Magruder, and Mobarak [2021], Kim, Hwong, Stafford, Hughes, O'Malley, Fowler, and Christakis [2015], and Cai, De Janvry, and Sadoulet [2015].

## 14.9 Questions

1. In the basic tree network example with a single original infected node, show that  $E[X_n] = R_n$  going to infinity is consistent with  $P(q_n \geq 0) \rightarrow 0$  as  $n$  grows.
2. This question explores an aspect of the proof of Proposition 14.1. In the basic tree network with a single original infected node, use the construction of  $f$  to demonstrate that  $q^* = 0$  when  $R_0 < 1$ .
3. Easley and Kleinberg [2010]) Imagine that you're advising a group of agricultural officials who are investigating measures to control the outbreak of an epidemic in its early stages within a livestock population. On short notice, they are able to try controlling the extent to which the animals come in contact with each other, and they are also able to introduce higher levels of sanitization to reduce the probability that one animal passes the disease to another. Both of these measures cost money, and the estimates of the costs are as follows. If the officials spend  $x$  dollars controlling the extent to which animals come into contact with each other, then they expect each animal to come into contact with

$$40 - \frac{x}{200,000} \tag{14.72}$$

others. If the officials spend  $y$  dollars introducing sanitization measures to reduce the probability of transmission, then they expect the probability an infected animal passes it to another animal contact to be

$$0.04 - \frac{y}{100,000,000} \tag{14.73}$$

The officials have two million dollars budgeted for this activity. Their current plan is to spend one million on each of the two kinds of measures. Using what you know about epidemics, would you advise them that this is a good use of the available money? If so, why? If not, can you suggest a better way to allocate the money?

4. Consider diffusion with immune nodes as discussed in section 14.4. Fix a degree distribution  $P(d)$  and suppose that the threshold  $\pi$  for the emergence of a giant component of susceptible nodes lies between 0 and 1. Consider a first order stochastic shift in the degree distribution to  $P'(d)$ : how does the threshold change? Similarly consider a mean-preserving spread of the degree distribution  $P''(d)$  and study how the threshold changes (for definitions of first order stochastic dominance and mean

preserving spread refer to chapter 1).

5. (Jackson [2008]) This question provides us with a foundation for the linear infection model studied in section 14.5. Suppose that the probability of becoming infected in any given meeting with an infected individual is  $v$ . Then the probability of becoming infected in  $d$  random meetings with individuals who are independently infected with probability  $\theta$  is

$$\sum_{x=1}^d (1 - (1 - v)^x) \binom{d}{x} \theta^x (1 - \theta)^{d-x}. \quad (14.74)$$

We are summing over the number of infected neighbours,  $x$ , that an individual with  $d$  neighbours is likely to have, where  $\binom{d}{x} \theta^x (1 - \theta)^{d-x}$  is the probability of having  $x$  infected meetings. The term  $(1 - (1 - v)^x)$  is then the probability of not becoming infected in any of the meetings with infected individuals. Show that if  $v$  is small relative to  $d$  (so that  $(1 - v)^x$  is approximately equal to  $1 - vx$ , for any  $x \leq d$ ) then expression (14.74) reduces to  $v^d \theta$ .

6. (López-Pintado [2008]) Consider the SIS model. Suppose that probability of infection depends not on absolute number of neighbours but on the average rate of infection in the neighbourhood. This suggests that the probability of getting infected with degree  $d$  is  $v\theta$ , where  $\theta$  is the neighbour infection rate. Show that  $\rho(d)$  is independent of  $d$ :  $\rho = \theta = \frac{\lambda-1}{\lambda}$  if  $\lambda > 1$  and 0 otherwise.

# **Chapter 15: Social Ties and Markets**

## **15.1 Introduction**

Our life takes place at the intersection of the global and the local. Networks offer us a natural language to think about overlapping social connections. Traditional models in economics assume that individuals are anonymous and act in isolation. Over the past two decades, economists have developed a framework that includes networks alongside the familiar notions of strategy, information, prices and competition. The goal of this chapter is to provide an introduction to this framework.

In our discussion on product markets, we will study how firms can use knowledge of social networks to better design advertising, product placement and pricing strategies. We will point to ways in which a firm can use different types of network information and how that can significantly improve firm performance. Our analysis draws attention to the important role of both the level and the content of interaction. In some situations, an increase in network connectivity calls for an increased engagement from the firm, while in other instances, the converse may hold. In a similar vein, we show that in some settings, it is optimal for a firm to target the most connected individuals, while in others it is better to target poorly connected ones.

We then turn to the study of pricing in networks: we study optimal pricing discrimination under incomplete as well as with complete network information. The general finding is that firms will find it attractive to tailor prices to network location of consumers, offering discounts to consumers who are highly influential and charging mark-ups to consumers who are more susceptible to influence.

We next take up the role of social ties in labour markets. We start with an overview of the wide ranging empirical evidence on this subject. This discussion brings out the extensive use of social ties in job search and recruitment both by workers and by firms. We then present theoretical models to understand how the use of social ties affects wages, employment, and inequality in labour markets.

## 15.2 Product Markets

Traditionally, in the theory of industrial organization a firm chooses prices, advertising strategy and quality against a background assumption that individuals are anonymous and act in isolation of each other (see e.g., Tirole [1988]). However, a number of studies have brought out the important role of friends, neighbors, and colleagues in shaping consumer choice; for studies on these influences. This social influence arises out of information sharing and also due to compatibility pressures. In the past, the practical use of such social influences for advertising or pricing was limited due to the absence of good data on social networks. The availability of large amounts of data on social networks along with the advances in information technology make it possible for firms to harness the power of social networks to promote their goals.

In particular, the massive quantities of data available on social networks, such as chat rooms, social networking web-sites, newsgroups, has given rise to measures of the *network value of a customer*: the expected increase in sales to others that results from marketing to that customer. For instance, social networking sites like Facebook and Twitter help firms target consumers by sharing their demographic characteristics and information on their social interactions and new firms have emerged that use these data to create a profile of consumers' online behaviour and their influence score. Take for instance the company, Klout: it creates a 'Klout' influence score and firms pay Klout for the use of these influence scores.

At the outset, it is useful to distinguish between the level and the content of social interaction. At a high level the level of interaction is described by the social network. There are a number of different aspects to social networks. A natural statistic is the number of people someone talks to or the number of friends she has: this is the degree. In many of the models in this chapter, we will use the degree as a measure of the social network. Empirical work suggests that degree distributions vary across product categories and that they are correlated with individual demographic characteristics. In some cases, further details on the social network may be available. This will lead us to also study models in which the firm has complete information on the network.

The content of interaction refers to how an individual's action affects the returns to others. For instance, interaction may involve word of mouth communication about product quality and prices. In this case, the presence of a single informed neighbor leads to product awareness and possibly purchase. Alternatively, interaction may involve working together on a project: in this an individual may choose a computer word processing language. A sufficient proportion of neighbors need to choose an action before an individual will switch to this action.

### 15.2.1 Advertising and Seeding

We study the problem of a firm that chooses advertising intensity to maximize profits. The behaviour of these individuals is influenced by their interactions. Our discussion will draw attention to the content and the level of interaction. Content covers the uses of the social interaction: examples include the sharing of information about new products and the sharing of computer files in collaborative work. The level of interaction refers to the number of contacts. The discussion is based on Galeotti and Goyal [2009].

There is a unit measure of individuals  $N = [0, 1]$  who are located in a social network. For an individual  $i \in N$ , the level of social interaction is parameterized by her degree  $k$ . Suppose that every individual draws  $k$  others with probability  $P(k) \geq 0$ ,  $k \in \mathcal{K}$ , where  $\mathcal{K} = \{0, 1, \dots, \bar{k}\}$ ;  $\sum_{k \in \mathcal{K}} P(k) = 1$ . Conditional on degree  $k$ , she makes  $k$  draws from the population, using a uniform distribution on the unit interval. As there is a continuum of individuals, the probability of drawing the same person two or more times is zero. We say that there is fraction  $P(k)$  of individuals who choose a  $k$  sized sample. In what follows, we will refer to  $P$  as the out-degree distribution. It will be convenient to define  $\hat{k} = \sum_{k \in \mathcal{K}} P(k)k$  as the mean out-degree. As we wish to focus on out-degrees here, we assume that everyone has the same in-degree (and it is equal to the mean out-degree,  $\hat{k}$ ).

The firm seeks to maximize its profits by selling its product to the population  $N$ . The firm knows the degree distribution  $P(\cdot)$  and chooses an action  $x \in [0, 1]$ . We will say that the profits from an individual influenced by  $k$  others are given by  $\phi_k(x)$ , where  $\phi_k(\cdot) : [0, 1] \rightarrow \mathbb{R}$ . For ease of exposition, we will assume that  $\phi_k(\cdot)$  is twice continuously differentiable. The expected profits of the firm from strategy  $x$  are:

$$\Pi(x|P) = \sum_{k \in O} P(k)\phi_k(x) - C(\alpha, x), \quad (15.1)$$

where  $C(\alpha, \cdot) : [0, 1] \rightarrow \mathbb{R}$  is the cost of effort and the parameter  $\alpha \geq 0$  indicates the efficiency in generating efforts.

We develop two examples to clarify how the ‘content’ of interaction among consumers shapes the returns function  $\phi_k(\cdot)$ .

#### **Example 15.1.** Word-of-Mouth Communication

Consider a firm advertising to a group of consumers who share product information among themselves. The price of the product is 1, while the cost of producing the good is zero. Every buyer has inelastic demand and the reservation value 1. These buyers are unaware of the product. The firm uses advertising to inform them of the product.

The firm chooses the fraction of individuals that will receive advertisements  $x \in [0, 1]$ . Let the cost of effort  $x$  be  $\alpha x^2/2$ , where  $\alpha > 0$ . A consumer buys either if she receives the advertisement from the firm or if she receives information via word-of-mouth communication from her neighbours. Thus the expected profits from a degree  $k$  buyer are

$$\phi_k(x) = 1 - (1 - x)^{k+1}. \quad (15.2)$$

Note that  $\phi_k(x)$  is increasing and concave in  $x$  and in  $k$ . Given the degree distribution,  $P$ , the expected profits are

$$\Pi(x|P) = \sum_{k \in O} P(k)[1 - (1 - x)^{k+1}] - \frac{\alpha}{2}x^2.$$

Note that we have assumed that information travels only one link; a question at the end of the chapter explore the case of indirect information transmission.  $\square$

### **Example 15.2. Adoption Externalities**

Suppose that a firm is introducing a new product into the market. This product exhibits positive externalities: individual returns from a product depend on how many neighbours buy it. Examples of such products include fax machines, telephones, video-conference technologies, online games, online social network, and file-sharing tools. There are two periods, 1 and 2. In period 1, the firm ‘seeds’ the network by distributing free samples of the product. Let  $x \in [0, 1]$  be the fraction of individuals who are sent free samples and let the price of the product be set equal to 1. A consumer with degree  $k$  of whom  $s$  are using the product, buys the product with probability  $\psi(k, s)$ . Suppose a consumer earns  $v = 1$  if all neighbors adopt and 0 otherwise. Then returns from a  $k$  degree individual are:

$$\phi_k(x) = (1 - x)x^k \quad (15.3)$$

The first term is the probability of not receiving a free sample and the second term is the probability that all neighbours receive a seed. This function is increasing and convex for low  $x$ , and decreasing and concave for large  $x$ , and it is decreasing and convex in  $k$ . The expected profits under  $x$  are:

$$\Pi(x|P) = \sum_{k \in O} P(k)(1 - x)x^k \quad (15.4)$$

Expected profits are zero at  $x = 0$  and  $x = 1$  and positive for all  $x \in (0, 1)$ . The cost of production and dissemination of samples is zero but a free sample has an implicit cost for the firm since a consumer who gets a free product does not buy at a positive price later.  $\square$

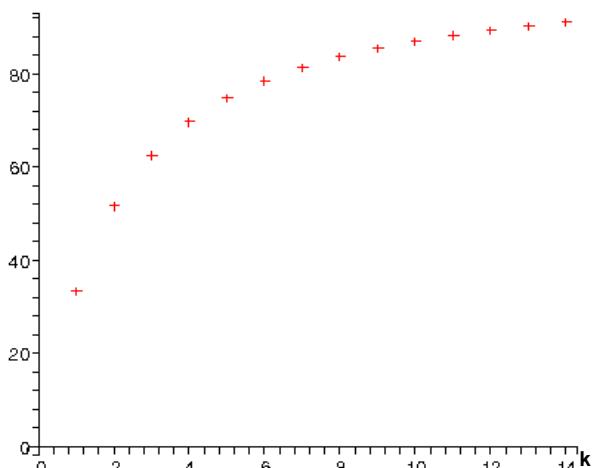

Figure 15.1: Value of Incorporating WOM. Percentage difference in profits,  $P(k) = 1/k$ ,  $k = 1, 2, \dots$  and  $\alpha = 1$ .

In this section, we will explore the effects of networks in the word-of-mouth example. Questions at the end of the chapter further explore the role of networks in the adoption externalities example. First consider the effects of networks on profits. Suppose for simplicity that in equation (15.2.1),  $\alpha = 1$ . Then the optimal strategy of a firm which ignores word-of-mouth advertising is to set  $x = 1$  and earn profits  $\Pi(1) = 1/2$ . Suppose next that everyone has degree  $k$ . The optimal strategy of a firm which incorporates the word-of-mouth communication is given by  $x_k^*$ , where  $x_k^*$  solves:

$$(k+1)(1-x_k^*)^k - x_k^* = 0.$$

Let  $\Pi(x_k^*)$  be the profits from the optimal advertising. Let us define the advantages of using social networks using the difference in profit as  $[\Pi(x_k^*) - \Pi(1)]/\Pi(1)$ . These advantages are plotted in Figure 15.1: we note that if  $k \geq 10$  then the optimal use of word-of-mouth can raise profits by more than 80%.

Denote the optimal strategy under a degree distribution  $P$  by  $x_P^*$ . The interior optimal strategy  $x_P^*$  solves:

$$\sum_{k=1}^{\bar{k}} P(k)(k+1)(1-x_P^*)^k - \alpha x_P^* = 0. \quad (15.5)$$

Observe that optimal  $x_P^*$  is falling in  $\alpha$ . Turning to the effects of networks, consider a first order stochastic shift from  $P$  to  $P'$  (refer to chapter 1 for definitions of changes in degree distribution). An informed individual will inform more of his cohort but an uninformed individual is more likely to hear from others. The first pressure increases incentives for advertisements, while the second pressure lowers them. The derivative of the marginal

returns with respect to degree  $k$  at  $x_P^*$  is:

$$\frac{\partial^2 \phi_k(x_P^*)}{\partial x \partial k} = (1 - x_P^*)^k [1 + (k + 1) \ln(1 - x_P^*)]. \quad (15.6)$$

For low  $x_P^*$  the marginal returns are increasing, while for high  $x_P^*$  the marginal returns are falling. This suggests that if the costs of advertising are large (small) then optimal advertising increases (decreases) with word-of-mouth. The intuition is as follows: If  $\alpha$  is large,  $x_P^*$  is small; at this stage, word-of mouth and advertising are complements. If on the other hand  $\alpha$  is low, then  $x_P^*$  is high and the relation is one of substitutes.

Turning to profits, observe that the term  $[1 - (1 - x)^{k+1}]$  is increasing in  $k$ ; so profits under  $P'$  are larger, keeping strategy fixed at  $x_P^*$ . It follows then that profits increase with an increasing in word-of-mouth.

Let us next examine the effects of greater dispersion in social connections. Consider a mean preserving spread change from  $P$  to  $P'$ . The effects depend on the curvature of marginal returns with respect to  $k$ .

$$\frac{\partial^3 \phi_k(x_P^*)}{\partial x \partial k^2} = (1 - x_P^*)^k \ln(1 - x_P^*) [2 + (k + 1) \ln(1 - x_P^*)] \quad (15.7)$$

For small  $x_P^*$  this effect is negative while for large  $x_P^*$  it is positive. Hence marginal returns are concave in  $k$  for large costs of adverts and convex in  $k$  for small costs of adverts. This suggests that if costs of advertising are large (small) then advertising falls (rises) under a mean preserving spread of word-of-mouth communication. Turning to profits, recall that  $[1 - (1 - x)^{k+1}]$  is concave in  $k$ . This means that profits fall under a mean preserving spread of word-of-mouth communication.

**Proposition 15.1.** *Suppose that firm expected payoffs are given by 15.2.1.*

- *If the costs of advertising are large (small) then optimal advertising increases (falls) with word-of-mouth; profits always increase in word-of-mouth.*
- *If the costs of advertising are large (small) then optimal advertising falls (rises) with greater dispersion in word-of-mouth; profits fall with greater dispersion in word-of-mouth.*

A recurring idea in marketing and public health is that organizations can target key individuals in networks to amplify the power of their messages or their strategies. To consider optimal targeting in our setting, suppose that the firm knows the distribution of degrees  $P$  and is able to partition the set  $N$  in  $\bar{k}$  groups.  $P(k)$  is the fraction of individuals in group  $k$  and individuals in group  $k$  have degree  $k$ . The strategy is a vector  $\mathbf{x} = (x_1, \dots, x_{\bar{k}})$ ,

where  $x_k \in [0, 1]$  indicates the effort that the firm targets to group  $k \in \mathcal{K}$ . It follows that  $\mathbf{x} \in [0, 1]^{\tilde{k}}$ . A strategy  $\mathbf{x}$  leads to total effort  $\theta(\mathbf{x}) = \sum_{k \in O} P(k)x_k$ . Let the expected profits from a degree  $k$  individual be given by  $\phi_k(x_k, \theta(\mathbf{x}))$ . The expected returns from a degree  $k$  consumer are:

$$\phi_k(x_k, \theta(\mathbf{x})) = 1 - (1 - x_k)(1 - \theta(\mathbf{x}))^k,$$

This is the probability that an individual with degree  $k$  will be informed either from direct advertisements or from word-of-mouth. Observe that  $\phi_k(x_k, \theta(\mathbf{x}))$  is concave in the first argument, i.e., the marginal returns are decreasing in degree. The expected profits of the monopolist:

$$\Pi(\mathbf{x}|P) = \sum_{k \in \mathcal{K}} P(k)[1 - (1 - x_k)(1 - \theta(\mathbf{x}))^k] - \frac{\alpha}{2}(\theta(\mathbf{x}))^2.$$

A threshold strategy  $\mathbf{x}$  has a  $\tilde{k} \in \mathcal{K}$  such that  $x_k = 1$  if  $k < \tilde{k}$ ,  $x_{\tilde{k}} \in [0, 1]$ , and  $x_k = 0$  if  $k > \tilde{k}$ . The marginal returns from a degree  $s$  individual are:

$$P(s) \left[ (1 - \theta(\mathbf{x}))^s + \sum_{k \in O} P(k)k(1 - x_k)(1 - \theta(\mathbf{x}))^{k-1} - \alpha\theta(\mathbf{x}) \right] \quad (15.8)$$

If  $x_s^* > 0$  for some  $s \in O$  then  $\frac{d\Pi(\mathbf{x}^*|P)}{dx_s^*} \geq 0$ . For all  $s \in O$ , the latter two terms are equal, the first term is strictly declining in  $s$  and so is the optimal strategy. Now suppose  $1 > x_{s'}^* \geq x_s^* > 0$ , for some  $s' < s$ . Since  $x_s^* > 0$ , it follows that  $\frac{d\Pi(\mathbf{x}^*|P)}{dx_s} \geq 0$ . However,  $(1 - \theta(\mathbf{x}^*))$  only depends on  $\theta(\mathbf{x}^*)$ , so  $\frac{d\Pi(\mathbf{x}^*|P)}{dx_{s'}^*} > 0$ . Thus the optimal strategy  $\mathbf{x}^*$  targets low degree individuals and ignores high degree consumers. The intuition for this is simple: consumers who are poorly connected are less likely to hear about product from word-of-mouth.

In the model so far, as links are drawn at random, on average everyone will receive the same number of incoming links, i.e., have the same ‘influence’. To explore the role of influencers, let us instead suppose that every individual draws a sample of the same size, but some individuals are drawn more than others. If an individual is sampled by  $l$  other individuals this means that there are  $l$  “links” pointing to individual  $i$ . We will refer to this as the in-degree. We can apply the methods of analysis above to study optimal advertising and targeting in this setting. In line with intuition, optimal advertising will target individuals with higher in-degrees. A question at the end of the chapter explores this model.

To summarize, we have studied the effects of networks on optimal advertising and

product placement in the word-of-mouth example; in this study we exploited properties of the content function – as reflected in  $\phi_k$ . We have seen that the example with adaption externalities leads to payoff function with different properties. Questions at the end of the chapter explore the role of social networks in that context.

### 15.2.2 Pricing Network Effects

We study price discrimination based on network information. Consider a product whose value is increasing in the consumption of other consumers. Suppose consumer A interacts with a large number of other individuals, who only interact with her. The firm would find it easier to get these consumers to buy its product if A buys it. There is therefore a priori a case for subsidizing consumer A and possibly selling the product with a mark up to these other consumers. This section explores the scope of this argument. Our discussion is based on Fainmesser and Galeotti [2016].

There are  $N = \{1, \dots, n\}$ ,  $n \geq 2$  individuals who are located in a network. A tie between two individuals  $i$  and  $j$ ,  $g_{ij} \in \{0, 1\}$ . The link  $g_{ij}$  reflects the influence of  $j$  on  $i$ . We will allow for influence to be asymmetric: so  $g_{ij}$  may be different from  $g_{ji}$ .

Suppose the firm faces constant marginal cost, normalised to zero and that a consumer  $i$ 's demand,  $x_i$ , is decreasing in the price offered received and is increasing in the consumption of her peers:

$$x_i = 1 - p_i + \gamma \sum_j g_{ij} x_j. \quad (15.9)$$

where  $\gamma \geq 0$ , captures social influence. This formulation allows for both divisible products and indivisible products. In the latter case, we interpret  $x_i$  as the probability that individual  $i$  will buy the product.

The outdegree of individual  $i$  is  $k_i = \sum_j g_{ij}$  and their indegree,  $l_i = \sum_j g_{ji}$ . Letting  $P(k)$  be the fraction of consumers with out-degree  $k$  and  $H(l)$  be the fraction of consumers with indegree  $l$ , it follows that average indegree is equal to average outdegree, i.e.,

$$\hat{l} = \sum_l l H(l) = \sum_k P(k) k = \hat{k} \quad (15.10)$$

Let  $\sigma_k^2$  denote the variance in outdegrees and  $\sigma_l^2$  be the variance in indegrees.

To begin, let us assume that the firm knows the distributions  $P(k)$  and  $H(k)$  as well as the indegree and the outdegree of every consumer. We will think of outdegree,  $k$ , as a measure of susceptibility and indegree,  $l$ , as a measure of influence. We will set  $x(k, l)$  as the demand of a consumer with susceptibility  $k$  and influence  $l$ . The firm sets prices  $(p(k, l))_{k,l}$

for different segments. Faced with these prices, consumers make purchase decisions  $x = (x_i)_{i \in N}$ .

As costs of production are equal to 0, the profit from consumers of type  $(k, l)$  is

$$\pi(k, l) = x(k, l)p(k, l). \quad (15.11)$$

The profit from a price strategy  $\mathbf{p}$  is

$$\Pi(\mathbf{p}) = \sum_k P(k) \sum_l H(l)x(k, l)p(k, l). \quad (15.12)$$

Facing a price profile  $\mathbf{p}$ , the utility of a consumer from different purchase choices will depend on the choices of her neighbours (due to the peer effects term in the demand). To ensure that the demands do not explode, we assume that  $\gamma \times k^{\max} < 1$ . Under this condition, for any  $\mathbf{p}$  there exists a unique demand equilibrium given by

$$x(k, l) = 1 - p(k, l) + \gamma \frac{1 - \bar{p}}{1 - \gamma \bar{k}} k \quad (15.13)$$

where  $\bar{p}$  is the average price paid by a neighbour of  $i$  and is given by

$$\bar{p} = \sum_l \frac{H(l)}{\hat{l}} \sum_k P(k)p(k, l) \quad (15.14)$$

In the demand equation (15.13), the first term reflects individual differences in (stand alone) valuation of the good, and so the demand is decreasing in the price offered  $p(k, l)$ . The second term captures the peer effects. In particular, we note that an additional out-degree shifts demand upward by:

$$\gamma \frac{1 - \bar{p}}{1 - \gamma \bar{k}}. \quad (15.15)$$

This term is a product of the peer effect parameter,  $\gamma$ , and the average consumption of a neighbouring node. The average consumption is increasing in the average connectivity of the network and it is decreasing in the average price paid by neighbouring nodes.

Let us compute the demands and profits when the firm sets a uniform price (that ignores peer effects). The optimal price is  $1/2$ . Faced with this price, the demand will depend only on susceptibility level and is given by

$$x(k) = \frac{1}{2} \left[ 1 + \frac{\gamma}{1 - \gamma \bar{k}} k \right] \quad (15.16)$$

The total profits are then given by

$$\frac{1}{4} \left[ \frac{1}{1 - \gamma \bar{k}} \right] \quad (15.17)$$

When we turn to optimal pricing with peer effects, we again need to be aware of the potential of peer effects leading to the possibility of multiple sets of optimal prices. To rule that out, we require that peer effects are sufficiently low.

Observe that when a firm increases the price,  $p(k; l)$ , there are two standard effects: a larger margin on sales and a lowering of demand. But there is also a third effect that is due to peer effects: the increase in price lowers demand of segment  $(k, l)$  and indirectly reduces the average consumption that all consumers expect from their neighbours.

**Proposition 15.2.** Suppose that peer effects  $\gamma k^{\max} < 1/2$ . The optimal pricing policy  $\mathbf{p}$  is

$$p(k, l) = \frac{1}{2} + \frac{\gamma \hat{k}}{2C\hat{k}^2} \left[ (\gamma \sigma_l^2 + 2\hat{k})k - (\gamma \sigma_k^2 + 2\hat{k})l \right]. \quad (15.18)$$

where  $C = 4 - 4\hat{k}\gamma - \gamma^2(\sigma_k^2 + \sigma_l^2) - \gamma^2\sigma_k^2\sigma_l^2$ . The consumption levels  $\mathbf{x}$  are given by

$$x(k, l) = \frac{1}{2} \left[ 1 + \frac{(\gamma \sigma_l^2 + 2\hat{l})k - (\gamma \sigma_k^2 + 2\hat{k})l}{\hat{k}^2 C} \hat{k}\gamma \right]. \quad (15.19)$$

The optimal pricing strategy thus has a simple structure: there is a baseline price,  $1/2$ , there is a markup that is increasing in the susceptibility,  $k$ , and falling in the influence  $l$ . It is instructive to work through the algebra step by step. Recall that firm profits are given by

$$\Pi(\mathbf{p}) = \sum_l \sum_k k H(l) P(k) p(k, l) x(k, l). \quad (15.20)$$

Taking the derivative with respect to the price we obtain

$$\frac{\partial \Pi(\cdot)}{\partial p(k, l)} = 0 \iff p^*(k, l) = \frac{1}{2} \left[ 1 + \frac{\gamma}{1 - \gamma \hat{k}} ((1 - \bar{p})k - \phi l) \right] \quad (15.21)$$

where  $\phi = \frac{1}{\hat{k}} \sum_l \sum_k H(l) P(k) k p^*(k, l)$ . Using  $p^*(k, l)$  and the definition of  $\bar{p}$  we obtain

$$\bar{p}^* = \frac{1}{2} \left[ 1 + \frac{\gamma}{1 - \gamma \hat{k}} ((1 - \bar{p}^*)\hat{k} - \phi \frac{\sigma_l^2 + \sigma_k^2}{\hat{k}}) \right] \quad (15.22)$$

Similarly, we substitute for  $p^*(k, l)$  in the definition of  $\phi$  to obtain

$$\phi = \frac{1}{2} \left[ 1 + \frac{\gamma}{1 - \gamma \hat{k}} ((1 - \bar{p}^*) \frac{\sigma_k^2 + \hat{k}^2}{\hat{k}} - \phi \hat{k}) \right] \quad (15.23)$$

We therefore have a system of two equations (15.22) and (15.23) in two unknowns,  $\bar{p}^*$  and  $\phi$ . We can solve the two equations to obtain:

$$\begin{aligned} \bar{p} &= \frac{\hat{k}(\gamma \hat{k} - 1)(2\hat{k} + \gamma \sigma_k^2)}{-4\hat{k}^2 + 4\hat{k}^3\gamma + \hat{k}^2\gamma^2\sigma_k^2 + \hat{k}^2\gamma^2\sigma_l^2 + \gamma^2\sigma_k^2\sigma_l^2} \\ \phi &= \frac{2\hat{k}^2 + 2\hat{k}^3\gamma + \hat{k}^2\gamma^2\sigma_k^2 + \hat{k}\gamma\sigma_l^2 - \gamma^2\sigma_k^2\sigma_l^2}{-4\hat{k}^2 + 4\hat{k}^3\gamma + \hat{k}^2\gamma^2\sigma_k^2 + \hat{k}^2\gamma^2\sigma_l^2 + \gamma^2\sigma_k^2\sigma_l^2} \end{aligned}$$

Substituting these values of  $\bar{p}$  and  $\phi$  in (15.21) we obtain optimal prices

$$p^*(k, l) = \frac{1}{2} + \frac{\gamma \hat{k}}{2} \left[ \frac{(\gamma \sigma_l^2 + 2\hat{k})k - (\gamma \sigma_k^2 + 2\hat{k})l}{\hat{k}^2(4 - 4\hat{k}\gamma - \gamma^2(\sigma_k^2 + \sigma_l^2) - \gamma^2\sigma_k^2\sigma_l^2)} \right]. \quad (15.24)$$

When we substitute these optimal prices in equation (15.13), we obtain the required equilibrium demand expression. ■

We compute optimal prices and profits as a function of the network to illustrate the effects of networks.

### Example 15.3. The effects of networks on pricing

Suppose that  $\gamma = 0.012$ . The distribution  $F(\cdot)$  is as follows: one third of the population has susceptibility 10, one third has susceptibility 25 and one third has susceptibility 40. The distribution of influence is identical. Optimal prices are presented in Figure 15.2. In this picture, under each bar, that reflects the level of the price, the first number is the outdegree and the second number is the indegree. We note that the prices are increasing in susceptibility and falling in influence. The consumption of different types is plotted in Figure 15.2: it is increasing in both influence (due to lower prices) and in susceptibility (due to larger peer effects). The profits of the firm are 0.362.

Proposition 15.2 tells us that optimal prices depends on the mean linking  $\hat{k}$  and the variance in links. Let us illustrate the effects of changes in mean and variance. Consider the network with the following susceptibility distribution,  $F''(\cdot)$ : 20% of the population has susceptibility 10, 30% has susceptibility 25 and 50% has susceptibility 40. The distribution of influence is  $H''(\cdot) = F''(\cdot)$ . It can be checked that  $F''$  first order stochastically dominates  $F$  (and hence has a higher mean). Optimal prices and equilibrium consumption are presented in Figure 15.3. An increase in susceptibility means that all consumers have

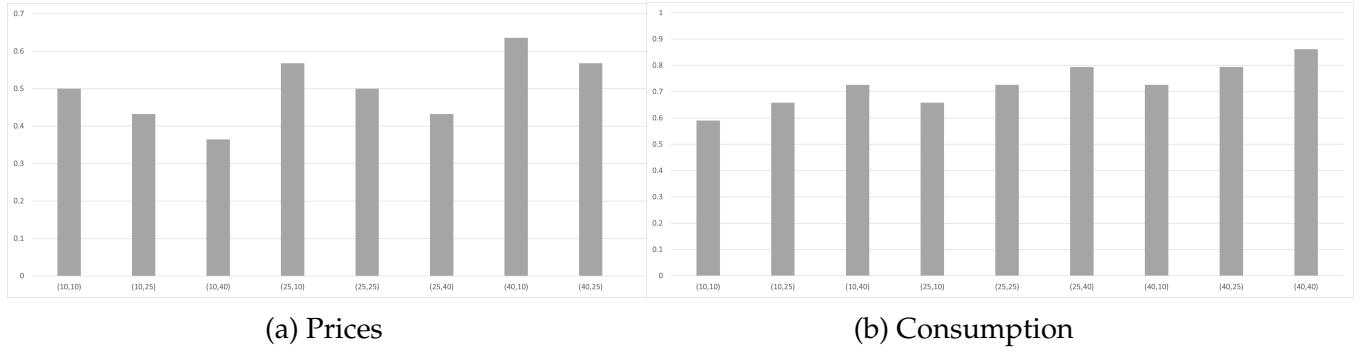

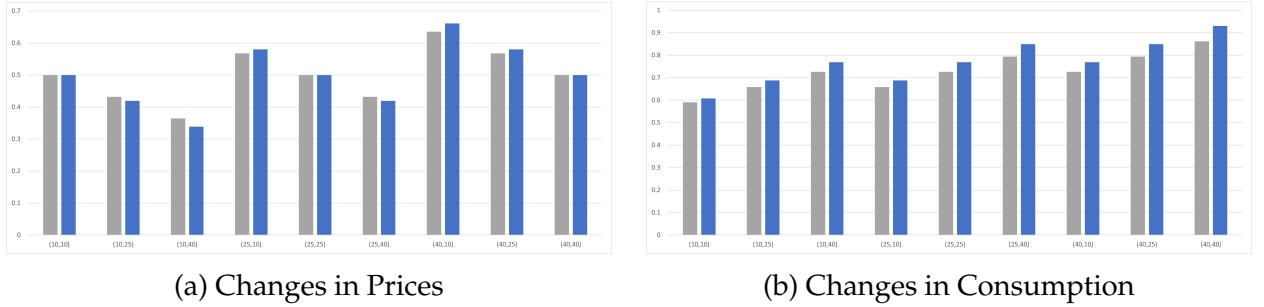

Figure 15.2: Equilibrium outcomes

Figure 15.3: Changes in mean:  $F$  in grey;  $F''$  in blue

access to higher positive peer effects and this pushes up the prices. The rise in prices is modest but the figure also shows that the effects on consumption are more significant. As a consequence, profits of the firm go up from 0.36 to 0.44.

### Pricing with complete network knowledge

So far we have studied the effects of networks in terms of degree distribution. In some cases, a firm may have more complete knowledge of the network. To see how additional information can be used by a firm we will consider the case where a firm has complete information on the network. We will see that the optimal pricing strategy has a similar structure to the one described above: consumers are offered a baseline price, a markup that depends on how much the consumer is susceptible to influence and a price discount which depends on the amount of influence that the consumer exercises on others. Our discussion is based on Bloch and Querou [2013] and Candogan, Bimpikis, and Ozdaglar [2012].

Suppose the firm sets prices targeted at specific individuals  $\mathbf{p} = (p_1, \dots, p_n)$ . Let  $\mathbf{q} = (q_1, \dots, q_n)$  denote the consumption profile. Given network  $g$  (with a corresponding adjacency matrix  $G$ ) prices  $\mathbf{p}$  and consumption  $\mathbf{q}$ , individual  $i$ 's utility is given by

$$u_i = \underbrace{\alpha x_i - \frac{\beta}{2} x_i^2}_{\text{A: Utility from own usage}} + \underbrace{x_i \sum_j g_{ij} x_j}_{\text{B: Utility from friends' usage}} - \underbrace{p_i x_i}_{\text{C: Cost of usage}} \quad (15.25)$$

Observe that marginal utility to own consumption is increasing in the consumption of neighbours, i.e., consumption choices of neighbours are strategic complements. We suppose that  $\alpha > 0$  and  $\beta > 0$ , and assume that  $\beta$  is large so that the negative quadratic term eventually dominates. Define average influence between  $i$  and  $j$  in a network  $g$  by

$$\bar{g}_{ij} = \frac{g_{ij} + g_{ji}}{2} \quad (15.26)$$

The profit of the firm is

$$\sum_{i=1}^n (p_i - c) x_i \quad (15.27)$$

where  $c > 0$  is the cost of production for the firm. As in the incomplete information setting, we will consider a two stage game. In the first stage the firm sets prices and in the second stage the consumers play an equilibrium in consumption choices.

$$\begin{aligned} \max_{\mathbf{p} \in \mathcal{P}} \quad & \sum_{i=1}^n (p_i - c) x_i \\ \text{s.t.} \quad & x_i \in \arg \max u_i(x_i, \mathbf{x}_{-i}), \quad \text{for all } i. \end{aligned}$$

Fix some prices  $\mathbf{p}$ . The first order condition for consumer  $i$ :

$$\alpha - \beta x_i + \sum_{j=1}^n x_j g_{ij} - p_i = 0. \quad (15.28)$$

Define  $S = \{i : x_i > 0\}$ . The first order condition for individual  $i \in S$ :

$$\alpha - \beta x_i + \sum_{j \in S} x_j g_{ij} - p_i = 0. \quad (15.29)$$

The best-response for consumer  $i$  may be written as:

$$x_i = \frac{1}{\beta} \max \left\{ \alpha - p_i + \sum_{j=1}^n g_{ij} x_i, 0 \right\}. \quad (15.30)$$

This can be written in matrix form as:

$$\beta x_S = \alpha \mathbf{1}_S - p_S + G_S x_S. \quad (15.31)$$

Rearranging, the equilibrium consumption for an active consumer is

$$x_S = \frac{1}{\beta} [I - \frac{1}{\beta} G_S]^{-1} (\alpha \mathbf{1}_S - p_S). \quad (15.32)$$

Equipped with this expression for equilibrium demand, we now solve for optimal prices. We will assume that  $\alpha > c$ . This ensures that marginal utility at  $x_i = 0$  is greater than the cost of production, thereby creating the space for profitable exchange between the firm and the consumers. It is possible to show that in a (sub-game perfect) equilibrium consumption is positive for every consumer (a question at the end of the chapter works through this property). Given the positive consumption property, the firm faces the following problem:

$$\begin{aligned} \max_p \quad & (p - c\mathbf{1})^T x \\ \text{s.t.} \quad & x = \frac{1}{\beta} (I - \frac{1}{\beta} G)^{-1} (\alpha \mathbf{1} - p). \end{aligned}$$

This may be rewritten as:

$$\max_p \quad (p - c\mathbf{1})^T (I - \frac{1}{\beta} G)^{-1} (\alpha \mathbf{1} - p). \quad (15.33)$$

The first order condition for the firm's problem is:

$$(I - \frac{1}{\beta} G)^{-1} (\alpha \mathbf{1} - p) - (I - \frac{1}{\beta} G^T)^{-1} (p - c\mathbf{1}) = 0.$$

Setting  $M = I - \frac{1}{\beta} G$ , we can rewrite the first order condition as:

$$M^{-1} (\alpha \mathbf{1} - p) - M^{-T} (p - c\mathbf{1}) = 0 \quad (15.34)$$

and after rearranging terms, we get

$$p = \left( \frac{\alpha + c}{2} \right) \mathbf{1} - \frac{M - M^T}{2} \left( \frac{M + M^T}{2} \right)^{-1} \left( \frac{\alpha - c}{2} \right) \mathbf{1} \quad (15.35)$$

Let us define Bonacich centrality in graph  $G$ :

$$C(G, \hat{\alpha}) = (I - \hat{\alpha}G)^{-1}\mathbf{1}$$

Since  $M = I - \frac{1}{\beta}G$ , it follows that:

$$\left(\frac{M + M^T}{2}\right)^{-1}\mathbf{1} = \left(I - \left(\frac{G + G^T}{2\beta}\right)\right)^{-1}\mathbf{1} = C\left(\frac{G + G^T}{2}, \frac{1}{\beta}\right). \quad (15.36)$$

We are now in a position to state the following result.

**Proposition 15.3.** Consider the monopoly firm choosing optimal prices with complete information on the network with adjacency matrix  $G$ . Optimal pricing is given by:

$$\mathbf{p} = \underbrace{\frac{\alpha + c}{2}\mathbf{1}}_{\text{nominal price}} + \underbrace{\frac{\alpha - c}{4\beta}GC\left(\frac{G + G^T}{2}, \frac{1}{\beta}\right)}_{\text{markup - influenced by others}} - \underbrace{\frac{\alpha - c}{4\beta}G^TC\left(\frac{G + G^T}{2}, \frac{1}{\beta}\right)}_{\text{discount - influence on others}}.$$

The intuition underlying this result is as follows: if an agent influences others then giving her a discount raises the consumption of her peers and this raises profits, while if she is influenced by others then her marginal utility is higher, and she can pay more for the product. In this respect the intuition is very much like in the earlier model of pricing conditional on the degrees of individuals. What is new here is that the influence is measured in terms of degree *and* the centrality of neighbours.

It is instructive to consider the case when influence and susceptibility are symmetric, i.e.,  $g_{ij} = g_{ji}$ . This means that  $G = G^T$ . Proposition 15.3 tells us that the optimal price is uniform. There are two forces at work: on the one hand, greater connectivity means greater utility and this pushes toward higher prices. On the other hand, greater connectivity also means greater externalities and this pushes towards lower prices (as that boosts direct demand and hence the demand of neighbors). In the linear model under study, these two effects cancel out exactly. Observe that with uniform prices, individual consumption will be proportional to Bonacich centrality.

To summarize: we studied price discrimination with incomplete as well as with complete network information. Our analysis shows that firms will tailor prices to network location of consumers: offering subsidies and discounts to consumers who are highly influential and charging mark-ups to consumers who are more susceptible to influence.

## 15.3 Labour Markets

Workers like jobs that fit their skills and location preferences and firms are looking to hire workers with the right skills. But both workers and firms face information constraints: workers do not know which firms have vacancies and firms have imperfect information on the ability of workers who apply for jobs. It is natural therefore for workers to tap into their social connections to find out more about jobs on offer, and for firms to ask their current employees for information on applicants. This section explores the implications of the use of social connections for the functioning of labour markets. Our exposition here draws heavily on Goyal [2007a], Goyal [2017] and Topa [2019].

In the context of labor markets, social interactions range widely from the simple transmission of information about job openings at a particular firm (letting a social contact know that a position is available at firm X) to the provision of a referral (recommending a social contact to a potential employer to be hired for a given position). Referrals can occur informally but can also be institutionalized as a recruiting tool by firms: firms set up formal referral systems for their employees, giving them the opportunity to refer potential candidates for a given position at the firm and rewarding them for a successful hire.

We start with a presentation of empirical evidence on the use of social ties. There is extensive evidence for the use of social ties in locating jobs. On the other side of the market, we present evidence for the use of referrals by firms. Finally, we present some evidence on the correlation between social networks and employment and wage levels.

This discussion sets the stage for a study of theoretical models on the use of social ties in labour markets. We first take up a model of referrals by firms to hire workers whose quality is unknown. This model highlights the role of social structure in shaping the functioning of the market and thereby determining the wage levels and inequality.

### 15.3.1 Empirical Background

Despite modernization, technology, and the dizzying pace of social change, one constant in the world is that where and how we spend our working hours, the largest slice of life for most adults, depends very much on how we are embedded in networks of social contacts – the relatives, friends, and acquaintances that are not banished by the never-ending proposals to pair people to jobs by some automatic technical procedures such as national computerized matching. *Granovetter [1995], page 141.*

Empirical work on the uses of social ties has looked at the use of contacts by

both employees as well as employers. With regard to the use of personal contacts by workers we take up three questions: one, to what extent do workers rely on personal sources of information in obtaining jobs, two, how does the use of personal contacts vary with the nature of the job and across countries and, three, how productive is this reliance upon contacts in terms of wages of the jobs obtained?

Early work by Rees [1966], Myers and Shultz [1951], and Granovetter [1973] demonstrated the extensive use of social connections in obtaining information about jobs. Myers and Shultz [1951] studied textile workers and found that almost 62% of those surveyed obtained their first job via personal contacts, in contrast to only 15% who obtained their job from agencies and advertisements. Similarly, in a widely cited study, Granovetter [1994] showed that almost one half of the people he surveyed received information about their current job from a personal acquaintance.

These findings have inspired an extensive body of empirical research. While most of the literature has focused on referrals usage by unemployed job seekers, recent work has highlighted that social networks and referrals are widely used also during on-the-job search by employed workers. Indeed, for employed workers, many job offers come about without the worker actively looking for a job but as the result of informal networking activities. For overview of the empirical research in this field see Ioannides and Datcher Loury [2004], Beaman [2016], Topa [2019].

Turning to variations in use of social ties across different types of jobs a broad finding is that there exists a negative correlation between age, education, and occupational status and the likelihood of finding one's job through personal contacts. This is observed in the 1978 Panel Study on Income Dynamics (Corcoran, Datcher, and Duncan [1980]), the study of Indianapolis labor market (Marsden and Campbell [1990]), and the 1970 Detroit area study (Marsden and Hurlbert [1988]). A similar negative correlation is also observed across European countries (Pellizzari [2010]).

A number of the studies find that personal contacts are an efficient way of finding jobs: a higher proportion of jobs found via contacts are likely to be accepted (Blau and Robins [1990], Holzer [1988]). Turning to the relation between wages of jobs found via personal contacts, the evidence is mixed. Early work by Ullman [1966] suggested that there is a positive relation between wages and hiring via contacts. In more recent work, Pellizzari [2010] finds that in some countries (Austria, Belgium, and Netherlands) there exists a wage premium for jobs found via personal contacts while in others countries (Greece, Italy, Portugal, and United Kingdom) there exists a wage penalty for jobs obtained via contacts. For a theoretical study of these empirical patterns see Granovetter [1994].

While most of the literature has focused on the use of social networks and referrals from

Black females	43.0	—	15.2	11.0	30.8	605

This table is based on information provided in Montgomery (1991). Rees and Shultz (1970) used data from the Chicago labor market; Granovetter (1974) used a sample of professional and managerial workers living in Newton, Massachusetts, while Corcoran et al (1980) used data from the Panel Study on Income Dynamics (11th wave) which followed 5000 families in the 1970's, in the United States. <sup>a</sup> Agencies and advertisements are collected together and are reported under employment agencies. <sup>b</sup> Gate applications are included under "other".

Table 15.1: Information on Jobs. Taken from Goyal [2007a].

the perspective of the job seeker, a growing body of research has looked at employer's use of formal or informal referrals. In an early study, Holzer [1987] found that over 35% of the firms interviewed filled their last vacancy via referral. Similarly, Marsden and Campbell [1990], in their study of 53 Indiana (United States) establishments, found that roughly 51% of the jobs had been filled through referrals.

More generally, looking at the process – from initial contact to job application to interview to hire – referrals seem to be associated with a higher probability of being hired relative to other job search or recruiting methods. Referred workers typically receive higher starting wages (relative to non-referred), but the wage gap tends to shrink with tenure at the firm. Referred workers are also less likely to separate from their employers – a possible sign of better match quality (see Dustmann, Glitz, and Schönberg [2009] and Brown, Setren, and Topa [2016]). Finally, the literature suggests that the joint distribution of referrer and referred characteristics matter for referral outcomes: for instance, referrals from employees who are older or at a higher staff level are associated with stronger salary advantages that persist longer.

We conclude our discussion of the use of social ties with some comments on strong and weak ties. Granovetter [1973] defined the strength of a tie over the past year as follows: the tie was strong if two people had interacted twice a week, medium for interactions less than twice a week but more than once a year, and weak if the pair had interacted less than once a year. In his study on workers in the state of Massachusetts, he found that of the 54 workers who had found their last job through a social contact, 16.7% found the job via a strong tie, 55.7% through a medium tie and 27.6% found it through a weak tie. This led him to coin the phrase *the strength of weak ties*.

We next present some evidence on correlations between social networks and employment rates.

Conley and Topa [2002] study the spatial patterns of unemployment in Chicago over two decades, 1980 and 1990. Their focus is on the investigation of unemployment clustering with respect to different distance metrics that reflect the structure of agents' social networks. With this in mind, the metrics are measures of physical distance, travel time, and the difference in ethnic and occupation distributions. Their empirical analysis reveals that there is a strong positive and statistically significant spatial dependence in the distribution of raw unemployment rates, at distances close to zero, for all these metrics. This correlation decays roughly monotonically with distance.

They also conduct a study of two-metric correlations. When the physical, travel time, or occupation metric is coupled with the ethnic metric, the latter drives most of the variation in spatial clustering: once we condition on ethnic distance, physical distance and other in-

dicators have relatively little impact on the correlations. On the other hand, when physical or travel time metrics are combined with distance in occupations, the correlations decline in both distances. Finally, they find that the variations in raw unemployment rates are well explained by tract level variables. This study suggests that social interaction effects at the tract level may be modest.

A large body of continuing research studies interaction effects. A difficulty is to find detailed data on social networks and at the same time also have data on employment status. One way to approximate the social interaction is to examine households at a finer level of granularity. This is the route taken in Bayer, Ross, and Topa [2008] who study block level outcomes for the city of Boston in the United States. They find evidence that households (with similar characteristics) located in the same block have more similar employment outcomes as compared to households located in different blocks. Their work also examines and rules out the reverse causation possibility – individuals are in the same block because they have similar employment outcomes.

Another route taken to study effects of social networks is to connect variations in group size to outcome variables of interest. This strand of work has found strong social interaction effects on employment and wage outcomes. For instance, Munshi [2003] studies Mexican migration to the United States. He uses variations in rainfall in Mexico as an exogenous shock: this rainfall affects incentives to move and hence rate of migration out of regions in Mexico for reasons that are unrelated to market conditions in the United States. He finds that having a higher number of migrants arrive more than 3 years ago has a positive effect on one's employment rate. In a similar vein, Beaman [2013] studies the employment rates and wages of refugees in the United States. She finds that the larger the number of political refugees from a foreign country allocated to a given area at least 2 years prior, the higher the current employment rate and wages of refugees.

### 15.3.2 Theoretical Models

On the one hand, referrals can potentially reduce the asymmetric information between firms and workers and lead to a better match between workers and firms. On the other hand, if workers of one type are better connected than other types this could also give them an advantage in the market and this could give rise to wage inequality. We present a theoretical model on the use of referrals to examine these issues. The model is taken from Montgomery [1991].

There are two periods, 1 and 2. There are a large number of firms and workers. In each period a firm hires one worker. The output of a firm is equal to the ability of the

worker who works for the firm. Workers know their ability while firms do not know their ability. In period 1, all firms therefore have an expectation on average quality of worker, and pay wages corresponding to this average. During period 1, a firm learns the ability of its worker. At the start of period 2, it has a choice between asking the period 1 worker for the name of a potential worker and offering a referral wage or simply posting a wage in the market, which can be taken up by any of the large number of workers. There are a large number of firms competing for workers, so wages are set to equate expected ability to wages and ex-ante (at the start of period 1) expected profits of firms are equal and zero.

We now describe the model more formally.

*Workers:* There are a large number of workers who all live for one period. The number of workers is equal in each period. There are two types of workers: High and Low and let us say that there is an equal number of each type. The productivity of a High type is 1, while the productivity of Low type is 0. Workers know their own ability but firms do not it.

*Firms:* There are a large number of firms; every firm employs one worker in each period. The profit of a firm is equal to the productivity of worker less the wage which is paid to the worker. Wages are set at the start of each period, and cannot be made contingent on the output. A simple way to model this is to suppose that wages are set prior to learning the productivity of workers.

*Social structure:* Each period 1 worker knows at most one period 2 worker and the probability of knowing someone is  $r \in [0, 1]$ . Conditional upon holding a tie, period 1 worker knows a period 2 worker of his own type with probability  $\alpha > 1/2$ . The assumption that  $\alpha > 1/2$  captures the idea that it is more likely that a worker knows someone with the same ability as himself. The social structure is thus defined by the two parameters,  $r$  reflecting the density of links, and  $\alpha$  reflecting the inbreeding bias in the links. Since links are randomly assigned it is possible that some period 2 workers have many connections while others have none.

*Timing of offers:* At the start of period 1, firms hire workers through the market: the market clears at wages given by  $w_{M1}$ . After this recruitment, production occurs in period 1. Every firm learns the ability of its worker. At the start of period 2, a firm decides on whether to hire through the market or via referral process. If a firm decides to offer a referral wage, then this is denoted by  $w_{R_i}$ . These wages are communicated via social contacts to workers in period 2. The workers in period 2 compare wage offers, and decide whether to accept one of them. If a worker rejects all offers, then he goes to the market. Similarly, if a firm's referral offer is rejected then it goes to the market. The market in period 2 clears at wage  $w_{M2}$ .

We first discuss the baseline case with no social ties. In the absence of social ties the two periods are completely independent. The probability that a firm hires a High type worker is equal to  $1/2$  in both periods; hence the market wage is  $1/2$  in both periods. Every worker earns  $1/2$ , and all firms make zero ex-ante profits.

Let us now take up the case with assortative social ties:  $r > 0$  and  $\alpha > 1/2$ . In this world, learning about period 1 worker gives the firm some information on the ability of a contact of its period 1 worker. If period 1 worker has ability High, then the firm expects that a worker contacted via a referral is more likely to be a High type. The converse is true if the period 1 worker has Low ability. A firm will want to hire via referral only if its period 1 worker is of High ability.

There cannot be a single referral wage for all firms: if there is such a single referral wage  $x$ , then a firm can deviate and set a slightly higher wage  $x + \epsilon$ , for some small  $\epsilon$ . All workers will prefer this slightly raised wage offer. Thus the deviating firm can strictly raise its probability of acceptance by paying a slightly higher wage. Firms will offer prices drawn from a distribution that has support on an interval  $[w_{M2}, \bar{w}_R]$ , where  $\bar{w}_R$  refers to the maximal referral wage offered by any firm. We next note that the probability density is positive for all wages in the interval. To see why this is the case, suppose that there is an interval of wage levels  $[\underline{w}, \bar{w}] \subset [w_{M2}, \bar{w}_R]$ , for which probability is zero. Observe that the firm offering a referral wage  $\bar{w}$  can lower the wage slightly. This will have no effect on the probability of acceptance but will strictly increase the surplus of the firm (upon acceptance of offer). In other words, a wage offer of  $\bar{w}$  cannot be optimal.

In period 2, a majority of the workers receiving (and accepting) the referral wages will be the High type workers. This implies that those who go on to the decentralized market will on average be lower quality than  $1/2$ : in other words, there is a *lemons effect* created by the use of social connections for referral wages.

With these observations in mind, let us comment on the profits of firms. A firm that has a High type worker in period 1 can hope to make positive profits in period 2. This is because it will use referral wages, and there is imperfect competition between firms who use referrals. Expected profits are positive (and constant) across the wages in the support of the distribution  $[w_{M1}, \bar{w}_R]$ . As there is free entry in the market for firms, expected profits in the two periods must be zero. In period 2, firms with High type workers will earn positive profits, but not the others. To compensate for this possibility of positive profits, firms have to set wages  $w_{M1}$  which are higher than the expected quality of workers in period 1,  $w_{M1} > 1/2$ . These points are summarized in the following result.

**Proposition 15.4.** *Consider the model of referrals. In an equilibrium the following properties hold.*

1. *A firm makes a referral offer in period 2 if, and only if, it employs a high-ability worker in*

*period 1.*

2. *Referral wage offers are dispersed over the interval  $[w_{M2}, \bar{w}_R]$  and the density of the referral wage is positive over the interval.*
3. *Period 2 wages are characterized by a lemons effect:  $w_{M2} < 1/2$ .*
4. *An increase in the density of links,  $r$ , or in the in-breeding bias,  $\alpha$ , leads to a fall in  $w_{M2}$  as well as an increase in the maximal referral wage  $\bar{w}_R$ .*

We now present the proof for this result. As is standard, we start from the last period, starting from period 2 market wages,  $w_{M2}$ , the profits of firms offering referral wages, then work backwards to period 1 market wages,  $w_{M1}$ , and finally the distribution of referral offers.

To compute the market wages, we need to understand the referral wages. Consider the decision problem of a high type worker  $H$ , faced with a referral wage  $w_{R_i}$ . The probability that he accepts a referral wage

$$\begin{aligned}\text{Prob}(H \text{ accepts } w_{R_i}) &= \text{Prob}(H \text{ receives no higher offer } w_{R_j} \forall j \neq i) \\ &= \prod_{j \neq i} \text{Prob}(H \text{ receives no higher offer } w_{R_j}) \\ &= \prod_{j \neq i} (1 - \text{Prob}(H \text{ receives } w_{R_j} > w_{R_i}))\end{aligned}$$

where

$$\text{Prob}(H \text{ receives } w_{R_j} > w_{R_i}) = \text{Prob}(\text{firm } j \text{ makes an offer}) \text{Prob}(\text{offer } w_{R_j} > w_{R_i})$$

Suppose  $F(\cdot)$  is the distribution of referral wages. Then this last expression is equal to

$$\left( \frac{\alpha r}{N} \right) (1 - F(w_{R_i})) \tag{15.37}$$

(Noting that there are  $N$  high workers and  $\alpha$  and  $r$  have the specified meaning).

Substituting in (15.37) yields

$$\text{Prob}(H \text{ accepts } w_{R_i}) = \left( 1 - \left( \frac{\alpha r}{N} \right) (1 - F(w_{R_i})) \right)^{N-1}$$

From standard considerations, it follows that

$$\lim_{N \rightarrow \infty} \text{Prob}(H \text{ accepts } w_{R_i}) = e^{-\alpha r(1-F(w_{R_i}))}$$

Similarly, for  $N$  large

$$\text{Prob}(L \text{ accepts } w_{R_i}) = e^{-(1-\alpha)r(1-F(w_{R_i}))}$$

Note that

$$\text{Prob}(H \text{ accepts } w_{R_i}) < \text{Prob}(L \text{ accepts } w_{R_i})$$

because a high type worker is more likely to receive more offers since  $\alpha > 1/2$ .

Note next that

$$\text{Prob}(\text{market}|H) = \text{Prob}(H \text{ accepts } w_{M_2}) = e^{-\alpha r}$$

$$\text{Prob}(\text{market}|L) = \text{Prob}(L \text{ accepts } w_{M_2}) = e^{-(1-\alpha)r}$$

Supposing that there is a continuum of workers, allows us to derive the expected productivity of workers in the period-2 market.

$$\begin{aligned} \text{Prob}(H|\text{market}) &= \frac{\text{Prob}(\text{market}|H)\text{Prob}(H)}{\text{Prob}(\text{market}|H)\text{Prob}(H)+\text{Prob}(\text{market}|L)\text{Prob}(L)} \\ &= \frac{e^{-\alpha r}}{e^{-\alpha r}+e^{-(1-\alpha)r}} \end{aligned}$$

In this derivation we have used the assumption that  $\text{Prob}(H) = \text{Prob}(L) = 1/2$ .

Note that we use underlying  $\alpha$  and  $r$ , not realized values. This is not a problem since we are assuming a continuum of workers. With finite  $N$ , the precise number of  $H$  types will vary depending on realizations. Next observe that the expected productivity is  $w_{M2}$ , given that the market is competitive. Hence

$$w_{M2} = \frac{e^{-\alpha r}}{e^{-\alpha r} + e^{-(1-\alpha)r}}$$

Notice that  $w_{M2} < 1/2$ , and that this means that market wage is less than the average period 2 productivity!

The profit earned by a firm, who has a period 1 high ability worker, and who chooses to offer a referral wage.

$$\begin{aligned} E(\Pi|w_R) &= \text{Prob}(H \text{ hired}|w_R)(1 - w_R) \\ &\quad + \text{Prob}(L \text{ hired}|w_R)(-w_R) \end{aligned}$$

We apply Bayes' Rule

$$\begin{aligned} \text{Prob}(H \text{ hired}|w_R) &= \text{Prob}(\text{offer made } H)\text{Prob}(H \text{ accepts } w_R) \\ &= \alpha r e^{-\alpha r(1-F(w_R))} \end{aligned}$$

Similarly,

$$\text{Prob}(L \text{ hired}|w_R) = (1 - \alpha)r e^{-(1-\alpha)r(1-F(w_R))}$$

Thus:

$$E(\Pi_H|w_R) = \alpha r e^{-\alpha r(1-F(w_R))}(1 - w_R) + (1 - \alpha)r e^{-(1-\alpha)r(1-F(w_R))}(-w_R)$$

For  $w_R \in [w_{M2}, \bar{w}_R]$  to be offered, firms must earn the same profits at all these wages:

$$\alpha r e^{-\alpha r(1-F(w_R))}(1 - w_R) + (1 - \alpha)r e^{-(1-\alpha)r(1-F(w_R))}(-w_R) = c \quad \forall w_R$$

Substitute for  $w_R = w_{M2} = \frac{e^{-\alpha r}}{e^{-\alpha r} + e^{-(1-\alpha)r}}$ , and we get

$$c(\alpha, r) = \frac{(2\alpha - 1)r}{e^{\alpha r} + e^{(1-\alpha)r}}$$

$c(\alpha, r) > 0$  since  $\alpha > 1/2$ . Thus such a firm will always offer referral wages. It may be checked that  $c(\cdot)$  is increasing in both  $\alpha$  and  $r$ .

We next derive  $\bar{w}_R$ . By definition,  $F(\bar{w}_R) = 1$ .

$$\begin{aligned} \alpha r(1 - \bar{w}_R) + (1 - \alpha)r(-\bar{w}_R) &= \frac{(2\alpha - 1)r}{e^{\alpha r} + e^{(1-\alpha)r}} \\ \implies \alpha r - r(\bar{w}_R) &= \frac{(2\alpha - 1)r}{e^{\alpha r} + e^{(1-\alpha)r}} \\ \implies r(\alpha - \bar{w}_R) &= \frac{(2\alpha - 1)r}{e^{\alpha r} + e^{(1-\alpha)r}} \\ &= c(\alpha, r) \end{aligned}$$

Hence

$$\bar{w}_R = \alpha - c/r$$

We now show that firms hiring a  $L$  type worker in period 1 will not make a referral offer in period 2.

$$E(\Pi_L|w_R) = (1 - \alpha)re^{-\alpha r(1-F(w_R))}(1 - w_R) + \alpha re^{-(1-\alpha)r(1-F(w_R))}(-w_R)$$

$$\begin{aligned}\frac{\partial E(\Pi_L|w_R)}{\partial w_R} &= (1 - \alpha)re^{-\alpha r(1-F(w_R))}(1 - w_R)\alpha r(F'(w_R)) \\ &\quad + (1 - \alpha)re^{-\alpha r(1-F(w_R))}(-1) \\ &\quad + \alpha re^{-(1-\alpha)r(1-F(w_R))}(-w_R)\alpha r(-F'(w_R)) \\ &\quad + \alpha re^{-(1-\alpha)r(1-F(w_R))}(-1)\end{aligned}$$

$$\begin{aligned}\frac{\partial E(\Pi_H|w_R)}{\partial w_R} &= \alpha re^{-\alpha r(1-F(w_R))}(1 - w_R)\alpha r(F'(w_R)) \\ &\quad + \alpha re^{-\alpha r(1-F(w_R))}(-1) \\ &\quad + (1 - \alpha)re^{-(1-\alpha)r(1-F(w_R))}(-w_R)\alpha r(-F'(w_R)) \\ &\quad + (1 - \alpha)re^{-(1-\alpha)r(1-F(w_R))}(-1)\end{aligned}$$

It is intuitive that

$$\frac{\partial E(\Pi_L|w_R)}{\partial w_R} < \frac{\partial E(\Pi_H|w_R)}{\partial w_R}$$

The latter is zero for all  $w \in (w_{M2}, \bar{w}_R)$ . Hence  $\Pi_L(w_R)$  is maximized at  $w_{M2}$ .

It can be checked that

$$E(\Pi_L|w_{M2}) = \frac{(1 - 2\alpha)e^{-r}}{e^{-\alpha r} + e^{-(1-\alpha)r}} < 0$$

since  $\alpha > 1/2$ . By going to the market it can ensure that  $E\Pi_L = 0$ . Hence a firm with a  $L$  type worker in period 1 will *not make a referral offer*.

Given free entry in period 1, firms set wages to equate expected profits

$$w_{M1}(\alpha, r) = \frac{1}{2} + \frac{1}{2}c(\alpha, r) = \frac{1}{2}(1 + c(\alpha, r))$$

■

The intuition for the effects of changes in density of connections  $r$  and inbreeding bias  $\alpha$  is as follows. An increase in  $r$  and  $\alpha$  both strengthen the lemons effect: a greater proportion of High type workers are employed via referrals. This lowers the average quality of workers who enter the market and this lowers  $w_{M2}$ . Turning next to the maximal referral wage, note that an increase in  $r$  increases the number of offers a period 2 workers receives, which increases competition, and pushes up wages. Similarly, an increase in  $\alpha$  increases the average type of a worker via referrals, which also pushes up the maximal referral wage. Thus an increase in either  $r$  or  $\alpha$  leads to a greater wage dispersion, in the sense of lowering

minimum wage and increasing the maximal wage.

As was noted above, the presence of social connections implies that market wages in period 1 exceed the average quality of workers, i.e.,  $w_{M1} > 1/2$ . An increase in  $r$  or in  $\alpha$  drives up profits of firms who make a hire through referrals. The zero profit market equilibrium condition implies that wages in period 1 must adjust to account for this. In other words, an increase in  $r$  or in  $\alpha$  pushes up the first period market wage  $w_{M1}$ . Since expected profits are zero in equilibrium, this implies a redistribution from period 2 referred workers to period 1 workers.

The social structure of contacts has powerful implications for wage inequality. A period 2 worker's wage is determined by the number and quality of ties that he holds. A Low quality period 2 worker is likely to have ties mostly with Low type period 1 workers; by contrast a High type period 2 worker is more likely to have ties with High type worker. This suggests that a High period 2 worker is more likely to receive referral wage offers, and will be at an advantage as compared to a situation in which the social structure was absent. Moreover, even among High type workers, those who have more links with period 1 High type workers will receive more offers and therefore will earn higher wages.

Let us summarize what we have learnt in this section. Labour economists have long recognized that many workers find jobs through friends and relatives. We have presented a stylized economic model that combined elements of market competition, asymmetric information, and social structure within a common framework. This allows us to study the relationship between social structure and wages. The analysis reveals that social connections can generate inequality and also how the use of referrals by firms can lead to higher profits for them. Moreover, an increase in the density of social ties or in homophily (by ability) will create greater wage dispersion.

## Information about Jobs

In the empirical background section, we discussed the role of strong and weak ties in shaping the flow of information on jobs. We also presented evidence on spatial correlation of the employment status. In this section, we begin with a model of network formation to understand when individuals will form weak and strong links and how that will shape overall employment outcomes. We then present a model of the dynamics of information flow in a social network to develop a deeper understanding of spatial and inter-temporal correlations in employment status.

Boorman [1975] is a seminal contribution on the uses of strong and weak ties in labour markets. There are many individuals, each of whom decides on how to allocate their time between strong and weak links. Strong links take more time to form as compared to weak

links. So an individual faces a trade off between having many ties that are weak or a few ties that are strong. If an individual has  $S$  strong ties and  $W$  weak ties, then she faces the following budget constraint with respect to time:

$$W + \lambda S = T \quad (15.38)$$

where  $\lambda > 1$  is a factor that indicating the extra time needed for a strong tie and  $T$  is the overall time available.

In the model, with probability  $\mu$  an individual needs for a job. Every person gets news about a job with some exogenous probability  $p$ . If he does not need the job then he can pass on the information of the vacancy to a neighbour/contact. The individual first picks someone with whom he has a strong tie. If there is no one in this set, he picks someone with whom he has a weak tie. He sends the information to one of the unemployed weak contacts. If there is no such person, then the job information is left unused. Suppose for simplicity that the network is a tree, so there are no cycles and common neighbours. Let  $q_w$  and  $q_s$  be the probability of not hearing about a job from a weak and strong tie, respectively. The probability of hearing about a job is

$$p + (1 - p)(1 - q_s^S q_w^W) \quad (15.39)$$

Starting with an allocation of strong and weak links, we can derive the values of  $q_s$  and  $q_w$ . Equipped with these probabilities, we can then ask what is the optimal allocation across strong and weak ties. This will define an equilibrium allocation between strong and weak ties. The model allows for multiple equilibria. The paper uses simulations to develop intuitions about the structure of networks and the implications for the functioning of labour market. An increase in  $\lambda$  raises the relative cost of strong ties: this will mean fewer strong ties. A decrease in  $\mu$  means that individuals are less likely to need a job, and this means that a weak link may suffice. This in turn pushes up the allocation toward a weak links. High  $\mu$  leads to more strong ties (and hence fewer ties in all).

The paper draws attention to an interesting externality in networking: as the number of strong ties goes up the total number of ties falls: as a result job information may be wasted. The model also brings out the difficulties of analytically solving models with networks and markets. To make progress we therefore turn to a simpler model of information sharing in a given network. The model is taken from Calvo-Armengol and Jackson [2004]; our exposition follows Goyal [2007a].

Consider a set of  $N = \{1, \dots, n\}$ ,  $n \geq 2$  individuals/workers who all have the same skills. Time evolves in discrete periods  $t = 1, 2, \dots$ . At the end of time  $t$  a worker is either

employed  $s_{i,t} = 1$  or unemployed  $s_{i,t} = 0$ . The vector  $s_t = \{s_{1t}, \dots, s_{nt}\}$  describes the employment status of everyone at end of time  $t$ . By convention, the employment status at the start of time  $t + 1$  is set equal to the employment status at the end of time  $t$ .

A period  $t$  starts with arrival of new information on jobs. Every worker hears about new jobs with probability  $a \in (0, 1)$ . Suppose that this probability is identical and independent across workers. If the worker is unemployed he takes the job, if he is employed then he passes on the information to one of his unemployed contacts. If a worker knows no one and is employed then the information is wasted. The pattern of contacts is captured by the (undirected) network  $g$ . The probability that a worker  $j$  gets a job that worker  $i$  originally heard about:

$$p_{i,j}(s) = \begin{cases} a & \text{if } s_i = 0 \text{ and } i = j \\ \frac{a}{\sum_{k:s_k=0} g_{i,k}} & \text{if } s_i = 1, s_j = 0, \text{ and } g_{i,j} = 1 \\ 0 & \text{otherwise.} \end{cases}$$

There is a competitive aspect to connections: if  $i$  knows other workers who are unemployed then this lowers the probability of worker  $j$  getting the information. There is a second more subtle effect that goes in the opposite direction. The existence of other workers linked to worker  $i$  also means that it is more likely that  $i$  will get information from them on jobs, which in turn means that it is more likely that he will pass on information about jobs which he receives on to worker  $j$ . To study the effect of indirect connections, it is helpful to recall that a pair of workers  $i$  and  $j$  are said to be path-connected in network  $g$  if there exists a path between them.

The final event within a period is the possibility that a worker losses his job; this happens with probability  $b \in (0, 1)$ , this probability being identical and independent across individual workers.

The model has been deliberately kept very simple to bring out the essential implications of the network transmission of information. It is possible to generalize the model to allow for heterogeneity in skills, indirect transmission of information, as well as make the transmission of information sensitive to the wages that different workers are earning. For the analysis of such a general model, see Calvo-Armengol and Jackson [2004].

To summarize, at the start of period  $t$ , the employment status of workers is given by a vector  $s_{t-1}$ . Workers receive information on new jobs, which is shared via the social network. Some workers may lose jobs and these factors together define a new employment status,  $s_t$  at the end of the period. We will examine how the network  $g$  shapes the employment status of workers.

We first take up the relationship between employment status of workers in the same network. Two workers  $i$  and  $k$  who are linked to the same worker  $j$ , compete for the information of worker  $j$ , and this may induce a negative correlation between the employment status of  $i$  and  $k$ . On the other hand, worker  $k$  receives information on jobs as well, and this information may be used by worker  $j$  to get a job. This in turn may allow worker  $j$  to pass on information on jobs to worker  $i$ , which may lead a positive correlation between the employment status of  $i$  and  $k$ . We will show that the second effect prevails: the employment status of path-connected workers is therefore positively correlated.

Let us define a few pieces of notation so as to spell this out more precisely. Observe that starting at some employment state,  $s_t$ , the arrival probability  $a \in (0, 1)$ , the job loss probability  $b \in (0, 1)$ , and a network of information communication together define the employment status at time  $t + 1$ . In other words, the probability of transition between employment status can be described by a finite state (reflecting the set of possible employment statuses of all individuals) Markov chain. Moreover, as  $a$  and  $b$  are both positive there is a positive probability of transiting from any state to any other state. From standard results in the theory of Markov Chains, we conclude that there exists a unique invariant distribution  $\mu$  on the set of employment states (Seneta [2006], Billingsley [2008]). The first observation about this invariant distribution is that *the employment status of path connected workers is positively correlated*. The intuition underlying this result is simple: if a group of workers are employed then it is more likely that they will share information on new jobs, which in turn makes it more likely that their friends and neighbors will be employed. We present an example to illustrate this positive correlation.

#### **Example 15.4.** Positive correlation of employment status

Suppose  $n = 4$ ,  $a = .100$ ,  $b = .015$ . Consider four networks – the empty network ( $g^e$ ), the network with 1 link ( $g^1$ ), the cycle network with 4 links ( $g^w$ ), and the complete network with 6 links ( $g^c$ ). These networks are presented in Figure 15.4. The following table taken from Calvo-Armengol and Jackson [2004] presents the probability of being employed and the correlations in employment status across workers in a network. Observe that workers 1 and 2 are directly connected in networks  $g^1, g^w, g^c$ , while workers 1 and 3 are indirectly connected in network  $g^w$  and directly connected in  $g^c$ .

In the empty network, there is no information sharing on jobs: every worker has the same probability of unemployment, given by 0.132. As links are added in the social network and more information is shared on jobs among the workers, less information on jobs is wasted. The result is that the probability of being unemployed falls: it is 0.083 in the single link network, 0.063 in the cycle network, and 0.050 in the complete network. This

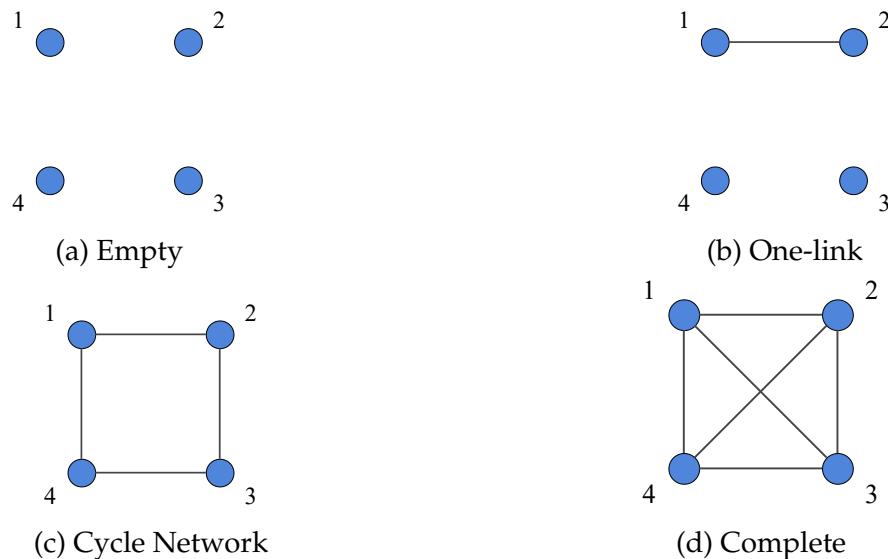

Figure 15.4: Examples of Networks,  $n = 4$

g	Prob( $s_1 = 0$ )	Corr( $s_1, s_2$ )	Corr( $s_1, s_3$ )
$g^e$	.132	—	—
$g^1$	.083	.041	—
$g^{\text{cycle}}$	.063	.025	.019
$g^c$	.050	.025	.025

Table 15.2: Employment in Networks. Taken from Calvo-Armengol and Jackson [2004].

suggests that a worker in a denser network faces better employment prospects. The next observation is about the correlation between the employment prospects of different workers. This correlation is positive across all workers and it is higher for directly linked workers 1 and 2 as compared to the indirectly linked workers 1 and 3 in the cycle network.

We now turn to the question of how the duration of unemployment affects future employment prospects. The model delivers a crisp result on this question: *the conditional probability that a worker will be employed in a given period is decreasing with the length of their observed unemployment spell.* In other words, there is positive duration dependence. The intuition goes as follows: the longer the duration of unemployment of an individual, the more likely it is that his neighbors, and the neighbors of his neighbors, are also unemployed. In other

g	1 period	2 periods	10 periods	limit
$g^e$	.099	.099	.099	.099
$g^1$	.176	.175	.170	.099
$g^c$	.305	.300	.278	.099

Table 15.3: Duration dependence in networks. Taken from Calvo-Armengol and Jackson [2004].

words, a longer duration of unemployment reveals that a worker's environment is poor, which in turn leads to low forecasts for future employment of the worker. To develop a better feel for this result, we present an example.

#### Example 15.5. Positive Duration Dependence

Let us again consider the four worker economy discussed in the previous example. The next table also taken from Calvo-Armengol and Jackson [2004] presents the probability of being employed, conditional on 1, 2 and 10 periods of unemployment.

In the empty network, the probability of getting employed depends solely on getting information on a new job and then on not losing the job. These events do not depend on the duration of unemployment duration and this explains the constant figure in the first row of the Table. However, as the network gets denser, a longer duration of unemployment tells us more about the status of the other workers: in particular, that the other workers are not employed. This negative information in turns means that the other workers are less likely to share any information they will get, and this implies that a longer duration of unemployment lowers the probability of getting a job in the near future.

△

In the model discussed the structure of links is kept very simple. It is plausible that the links will vary with the employment status because it may be easier for two employed people to maintain a tie as compared to an employed and an unemployed person keeping a tie. Similarly, it may be easier for two workers of the same ethnicity to maintain a link. These ideas broadly suggest a type of *in-breeding bias* in links. Bramoullé and Saint-Paul [2010] show that if linking is more likely between persons with the same employment status, then duration dependence arises in a strong form. A longer duration of unemployment leads to fewer employed contacts, and this lowers access to job information, which in turn prolongs unemployment.

## 15.4 Reading Notes

The industrial organization literature on consumption externalities starts with Rohlfs [1974]. In the two decades after this paper, most of the research focused on the role of group size. We presented an overview of this research in the chapter on platforms and intermediation. In the 1990's, as economists began to examine networks more systematically, interest progressed beyond the size of the group and onto a systematic exploration of the effects of network structure.

There is a long standing interest in using network knowledge in better targeting behavioural changes. The growth in our knowledge of empirical networks has further spurred the development of formal models. The literature on targeting in networks spans several disciplines. Domingos and Richardson [2001] is probably the first paper to study algorithms that maximize sales in a social network. They consider a model where consumers can be of two types, 0 and 1, reflecting whether they buy the product or not. Consumers' probability of buying a product depends on two factors: marketing expenditures and the probability that her direct neighbors have bought the product. The paper compares the performance of three algorithms: a single-pass algorithm which only looks at one iteration, a greedy algorithm which increases marketing expenditures wherever they increase payoffs and a hill-climbing algorithm which increases expenditures where it matters most. Using data on an experimental programme of movie recommendations, EachMovie (from the years 1996-1997), they compute the "multiplier effect" of marketing expenditures. A key finding is that the distribution of multipliers is very skewed, so that targeted marketing strategies can be very profitable.

In an influential contribution, Kempe, Kleinberg, and Tardos [2003] study the optimal targeting problem within the framework of standard diffusion processes. The objective of the firm is to select an initial set nodes in the social network in order to maximize the total number of informed nodes. They show that the optimal strategy is computationally hard and then establish bounds on the efficiency of the hill-climbing algorithm; these bounds draw attention the specifics of the dynamic processes. The role of the dynamics process (in other words, the content of interaction) is also illustrated in a model of competitive contagion in networks by Goyal et al. [2019]).

The chapter mostly restricts itself to the economics research on this subject. But it is worth noting there is a precursor to Klout like scores is the 1950's literature in sociology and communication on the "two-step flow of communication", which argues that the mass media does not directly influence consumption, but it was "opinion leaders" who were influenced by the mass media and that they in turn influenced members of their community,

Katz [1957]. Also see our discussion on the role of social networks in the chapter on the law of the few and the chapter on learning and communication.

Economists have focused on the structure of optimal or equilibrium outcomes and on the effects of different network statistics in shaping these optimal strategies. The material on optimal advertising and seeding is taken from Galeotti and Goyal [2009]. The model we used was taken from Galeotti and Goyal [2009]. It combines the formulation of advertising from Butters [1977] with the word of mouth communication model of Ellison and Fudenberg [1995]. In our exposition, we tried to bring out the richness of the processes and how the nature of the process determined the optimal targets.

A major issue in the design of peer-leader network intervention policies is to identify the influencers. A general practice is to submit questionnaires to members of the targeted group. Subjects are asked, among other things, to answer questions about their social network such as to nominate their best friends, to nominate other individuals with whom they talk about specific issues, etc. Individuals who receive more nominations from others are identified as network leaders. In turn, network leaders are asked to attend training section and then they are asked to spread what they have learnt to their acquaintances. For a detailed discussion on the implementation of these policies, see Valente, Hoffman, Ritt-Olson, Lichtman, and Johnson [2003].

Pricing in markets with network effects has been discussed at length in the chapter on platforms and intermediation. In that chapter, the focus was on size of the networks, while here we discussed richer statistics of the network such as degrees and centrality. The material on optimal pricing in networks draws on Fainmesser and Galeotti [2016]; the model with complete network knowledge was taken from Bloch and Quérou [2013] and Candogan, Bimpikis, and Ozdaglar [2012]. For a survey of this literature see Goyal [2017] and Bloch [2016]. The literature on pricing remains active, for a recent contribution to competitive pricing in networks see Fainmesser and Galeotti [2020].

It is clear that consumer search and their word of mouth communication interacts with firm advertising; for an early attempt at integrating social networks with search and pricing in product markets, see Galeotti [2004]. Let us briefly discuss an interesting model due to Campbell [2013]. This paper develops a model of demand, pricing and advertising in the presence of word-of-mouth communication taking place on a random graph. Consumers learn about a product via communication from their contacts. Information travels through paths in the network, unlike in some earlier work. The paper also advances by considering optimal prices for general networks.

The word-of-mouth creates a positive externality of consumption: a lower price increases direct demand and through word-of-mouth also enhances demand. This suggests

that optimal prices will be lower in the presence of word of mouth communication. While this intuition is true in some simple settings, Arthur shows that it is not true in general. In particular, in empirically interesting cases with correlations in valuations across connected consumers, this result no longer obtains. The paper then turns to the effects of networks on optimal pricing. He studies the effects of increasing connectivity, mean-preserving spread of friendships, and clustering of friends on prices. Finally, he studies the nature of optimal advertising: an interesting finding is that optimal targets for advertising may sometimes be less connected individuals (as they may not have heard about the product from contacts). Note that this is consistent with the result on targeting consumers with low degrees in the word-of-mouth model presented in section 15.2.1 of the chapter.

The role of social networks in labour markets has been a major field of study in economics in recent years but this work has a long history. The role of social connections in shaping employment relation is of course a major theme of research in economic sociology (see e.g., Granovetter [1973]). The aim of our brief presentation was to draw attention to one or two major themes in this line of work. Broadly, there is work that produces evidence for the use of social ties both by workers and by firms across industries and across countries. A large literature has documented the widespread use of referrals and social connections across both developed and developing countries. In addition to the information in the chapter we note here a few other studies. Burks, Cowgill, Hoffman, and Housman [2015] use personnel data from nine large firms in three industries to document the use of referrals and their impact on outcomes. Similarly, Gavazza, Mongey, and Violante [2018] use a novel survey of recruitment costs and practices for a sample of about 400 U.S. firms. It contains information on the amount of resources spent by employers on employee referrals (among many other recruiting channels). Ioannides and Datcher Loury [2004], Topa [2011], Topa [2019], Beaman [2016], Granovetter [1995] and Pellizzari [2010] provide excellent overviews of the literature. Then there is research on the effects of the use of social ties on the efficiency and the inequality in labour market; see Conley and Topa [2002] and Bayer, Ross, and Topa [2008].

The theoretical models help us develop a better understanding of how social networks interact with the familiar elements of asymmetric/inperfect information and market competition. The model of referral by firms was taken from Montgomery [1991]. For recent elaborations of this model that further develop the role of homophily in creating inequality, see Bolte, Immorlica, and Jackson [2020]. Turning to social sharing of job information, we started with the early model of Boorman [1975] and then turned to the more recent work of Calvo-Armengol and Jackson [2004]. For a more recent elaboration on the theme of correlations in employment status across connected workers see Bramoullé and Saint-

Paul [2010].

In the referral model a High type worker has no way of signalling his ability. In labor markets, workers often can use mechanisms such as certificates and educational degrees to communicate their ability. This leads naturally to the study of the role of social connections when workers also have access to such signalling mechanisms. Casella and Hanaki [2008] study this question using an extension of the Montgomery [1991]. The model contrasts signals and networks in the following plausible way: a signal can be bought at a cost and it offers a proof of ability which is valid across all potential employers, while a personal contact allows access to a single employer, and communicates ability via the assortative tie hypothesis (as in the referral model above). This model yields a simple insight: in a context where certificates are imperfect signals of ability, for signals to work well they must be costly to acquire. However, if they are costly to acquire then social ties (which are cheap) become attractive and signals are not used. These contradictory pressures on signals imply that social networks are quite resilient even in the presence of “anonymous” mechanisms – such as educational certificates.

Financial markets are one setting where the standard market model of anonymous traders and common prices that reveal information of traders has been especially dominant. A recent literature examines the role of social networks in shaping the functioning of financial markets. We have not covered this literature as it is mainly empirical and the focus in the chapter was on theoretical models. We conclude with a few pointers to interesting lines of enquiry. In a fascinating paper, Cohen, Frazzini, and Malloy [2008] study the role of school ties in facilitating flow of financially valuable information on firms. School ties typically been formed years in the past, and their formation is frequently independent of the information to be transferred. Social connection provides a useful tie because one side possesses private information and the other side has an incentive to access this private information. The value of the social tie can be computed relatively objectively in terms of returns to investments. Cohen, Frazzini, and Malloy [2008] find that portfolio managers place larger bets on a firm if they went to school that with its senior managers (or a board member) and that their investment on these firms outperforms better than other investments.

Turning to more general social interaction effects, Hong, Kubik, and Stein [2005] find that US fund managers located in the same city commit to correlated investment decisions. Such correlated choices may be due to peer-to-peer communication or because fund managers in a given area condition their decisions upon common sources of information. In a similar spirit, Kuchler et al. [2021] show that institutional investors are more likely to invest in firms located in regions to which they have stronger social tie. Interestingly, how-

ever, these investments do not earn a differential return. Firms located in regions that have stronger social ties with institutional investors have higher valuations and liquidity.

There is also a small strand of research on theoretical models of social networks in financial markets, see Ozsoylev, Walden, Yavuz, and Bildik [2014], Walden [2019], and Colla and Mele [2010]. These papers study asset pricing in markets where traders are located in information networks and obtain results on the relation between social network topology and equilibrium prices and trading. For a survey of social networks in finance see Allen and Babus [2009] and Hirshleifer [2020].

There is a small but interesting body of empirical research on how social ties – based on the flow of immigrants between two countries — can lead to positive effects on international trade. For an introduction and overview to this literature see Rauch [2001].

I thank Andrea Galeotti and Ozan Candogan for sharing materials on optimal pricing in networks. I am grateful to Mark Granovetter for helpful suggestions to related literature in sociology, and to Lin Peng for pointers to the literature on social networks in financial markets.

## 15.5 Questions

1. Consider the word-of-mouth example from the chapter. This question explores the value of network information. Show that value of network information is increasing with a mean preserving spread in the degree distribution. Hint: compare the profits of targeted versus untargeted firm strategies and show that this difference is increasing in a mean-preserving spread of the degree distribution.
2. Consider the model of optimal pricing based on complete network information. Show that in a sub-game perfect equilibrium every consumer must choose a positive quantity.
3. An important element in *viral marketing* is the idea that information can be passed on from person to person via social connections. Let us extend the model in the chapter to allow for this. Suppose that every buyer has the same degree, say  $k$ , and suppose that information flows  $r$  steps;  $r \geq 1$  is an integer and it indicates the radius of information diffusion. Assume that there is no overlap in neighborhoods.
  - (a) Given information radius  $r$  and strategy  $x$ , show that the probability that a consumer with  $k$  friends becomes aware of the product, is

$$\phi_k(x|r) = 1 - (1 - x)^{\sum_{s=0}^r k^s}$$

- (b) Next show that expected profits to firm  $\mathcal{M}$  are

$$\Pi(x|k, r) = 1 - (1-x)^{\sum_{s=0}^r k^s} - \frac{\alpha}{2}x^2.$$

- (c) Verify that (I.)  $\phi_k(x|r)$  is increasing and concave in  $x$ , in  $k$  and in  $r$ , (II.) the function  $\phi_k(\cdot)$  exhibits Increasing marginal returns from degree for low values of  $x$ , otherwise it exhibits decreasing marginal returns from degrees and (III.)  $\frac{\partial^2 \phi_k(x,r)}{\partial x \partial r}$  is positive for low values of  $x$  and negative otherwise.
- (d) Using properties I-III, show that the effects of an increase in the level of word of mouth communication on optimal advertising strategy and profits presented in the chapter extend to richer patterns of information diffusion, i.e.  $r \geq 1$ . Then show that an increase in the radius of information flow is analogous to an increase in the level of word of mouth communication.
4. This question asks you to apply the strategic diffusion model to the problem of product quality. There is asymmetric information between firms and consumers about quality and consumers share their experience about product quality via word of mouth communication. Suppose that there is one firm which is selling to a set of consumers. The set of buyers is  $\mathcal{N} = [0, 1]$ ; each buyer has inelastic demand and her reservation value for the object is  $v = 1$  if the quality is HIGH, but the reservation utility  $v = 0$  if the quality is LOW. At the start all consumers are pessimistic about the quality so that no one is willing to pay a positive price. Hence, the only way the firm can generate sales is to give away free samples of the product, and hope that the consumers will pass on good information about the product. Consider a two period model, where in period 1 the firm chooses the number of samples to give away for free  $x \in [0, 1]$ , and in period 2 it chooses the price to charge,  $p \geq 0$ . Moreover, to simplify matters, suppose that there are no direct costs of producing the good, which implies that the only cost is an indirect one, via the loss of potential sales. Given that consumers only buy if they are informed that the product is HIGH, it is optimal for the firm to set price  $p = 1$  in the second period.
- (a) Show that the payoffs to a firm from a consumer with degree  $k$ , are then given by
- $$\phi_k(x) = (1-x)[1 - (1-x)^k].$$
- (b) Notice that  $(1-x)$  refers to the probability that a consumer has not been given the product for free in period 1.

- (c) Verify that  $\phi_k(x)$  is concave in  $x$  and it is increasing and concave in  $k$ .  
 (d) For a given distribution,  $P$ , show that the expected profits under strategy  $x$  as:

$$\Pi(x|P) = (1-x) \sum_{k \in O} P(k) [1 - (1-x)^k]$$

- (e) The monopolist chooses  $x$  to maximize profits. Show that the effects of changes in  $P$  on the optimal strategy depend on how marginal returns change with respect to  $k$  as in the model in the chapter.
5. Next consider the following variant of the model. Suppose that  $\psi(k, s) = s/\bar{k}$ , for all  $s, k \in O$ : here the probability that a consumer buys the product is increasing in the number of neighbors who have already the product, but it is independent of the consumer's neighborhood size.
- (a) Under this assumption, show that the expected profits to the firm from a degree  $k$  buyer are:
- $$\phi_k(x) = (1-x)x \frac{k}{\bar{k}}.$$
- (b) Verify that  $\phi_k(x)$  is increasing and linear in degree and exhibits increasing (decreasing) marginal returns in degree, for low (high)  $x$ .
6. This question explores a setting in which consumers all have the same out-degree but have different indegrees. Let  $I = \{1, \dots, \bar{l}\}$  and let  $H : O \rightarrow [0, 1]$ , be a probability distribution, where  $H(l)$  indicates the fraction of individuals in  $\mathcal{N}$  who are sampled by  $l$  others. The mean of  $H \hat{l} = \sum_{l \in I} H(l)l$ . If an individual is sampled by  $l$  other individuals this means that there are  $l$  "links" pointing to individual  $i$ . Note that  $P$  and  $H$  satisfy the condition  $\hat{l} = \hat{k}$ . For simplicity we focus on the case where  $P(\hat{k}) = 1$ , in other words everyone draws a sample of the same size (and so the out degree distribution is degenerate).
- (a) For a given strategy  $x \in [0, 1]$ , show that the expected net profits are:
- $$\Pi(x|P) = [1 - (1-x)^{\hat{k}+1}] - \frac{\alpha}{2}x^2, \quad (15.40)$$
- (b) Suppose  $H'$  first order stochastically dominates  $H$ . Show that profits under  $H'$  are higher than profits under  $H$ .
- (c) Next consider targeted strategies. Suppose the firm knows the in-degree of individuals. Let a targeted strategy be denoted by  $\mathbf{x} = \{x_1, x_2, \dots, x_{\bar{l}}\}$ , where  $x_l$  is

the effort that firm targets consumers with indegree  $l$ . Let us denote by  $\tilde{H}(l)$ , the probability that a consumer  $i$  samples a consumer who has in-degree  $l$ . Using Bayes' rule, we can express  $\tilde{H}(l)$  as follows

$$\tilde{H}(l) = \frac{H(l)l}{\hat{l}}.$$

Given a targeted strategy  $\mathbf{x}$ , let  $\omega(\mathbf{x}) = \sum_{l \in I} \tilde{H}(l)x_l$ . Show that expected profits from strategy  $\mathbf{x}$  are:

$$\Pi(\mathbf{x}|H) = 1 - \sum_{l \in I} H(l)(1 - x_l)(1 - \omega(\mathbf{x}))^{\hat{l}} - \frac{\alpha}{2}(\theta(\mathbf{x}))^2,$$

and for any  $s \in I$  we have that

$$\frac{d\Pi(\mathbf{x}|H)}{dx_s} = H(s) \left[ (1 - \omega(\mathbf{x}))^{\hat{l}} + s \sum_{l \in I} H(l)(1 - x_l)(1 - \omega(\mathbf{x}))^{\hat{l}-1} - \alpha\theta(\mathbf{x}) \right].$$

- (d) Show that it is optimal to use an increasing cut-off strategy.

# **Part IV**

## **Broader Themes**

# Chapter 16: Networked Markets

## 16.1 Introduction

In the theory of general equilibrium and oligopoly the background assumption is that firms and consumers interact ‘anonymously’ and ‘uniformly/globally’ (anyone can buy and sell from everyone) through a price system. In practice, bounds of trust and cooperation lead to personalized relations and geographical distance and national boundaries place restrictions on who can undertake exchange with whom. These restrictions may be formulated in terms of (present or absent) ties within a network. This chapter presents models of networked markets that help us understand the ways in which prices and quantities are determined in such settings.

We start with a study of a group of sellers each wish to sell an indivisible good to a group of buyers. In a world where valuations of all sellers are 0 and the valuations of all buyers are 1, the standard model says that a law of one price obtains, with the price being equal to 1 if there are more buyers than sellers, and price is equal to 0 if there are more sellers than buyers. We examine how this prediction is affected if there are restrictions on who can trade with each others. We locate the buyers and sellers in a bipartite graph. The complete bipartite graph corresponds to the case where all buyers and sellers can trade with each other. Our analysis shows that the law of one price obtains only under very special circumstances: when the local environment facing sets of buyers and traders corresponds to the global ratio: in other words, a price of 1 obtains only if every buyer finds herself in a situation where she is connected to sellers who have an excess number of buyers to sell to. Similarly, a uniform price of 0 obtains only if every buyer finds herself in a situation where she is connected to sellers who have too few buyers to sell to.

We then take up pricing in chains of intermediaries between an initial seller and an eventual buyer. Examples of this model are supply chains and financial markets. We study price formation via three different protocols: posted prices, bargaining and auctions. The discussion draws attention to the complexity of the problem and reveals aspects of networks that will be important in shaping pricing and the distribution of surplus. We find

that the notion of ‘critical’ nodes is helpful in organizing our arguments. Roughly speaking, a node is critical in a network if it lies on all paths between the original seller and the eventual buyer. Critical traders earn larger payoffs than non-critical nodes.

The last part of the chapter takes up research collaboration ties among oligopolistic firms. Research alliances among firms are common and have been widely studied. Networks of research collaboration exhibit a number of distinctive features: the average degree is relatively small but unequal, the network has a core-periphery architecture (implying that the average distance between firms in the network is relatively small). We build on classical models of price (Bertrand) and quantity (Cournot) competition to propose a model of network formation that casts light on the economic forces that can help explain the emergence of these network properties. The analysis reveals that research collaboration among firms has powerful effects on the competitive position of firms. These effects are reinforced if firms are allowed to make transfers to other firms to form collaboration ties – as would be involved for instance in technology exchange agreements between a large firm and a start-up. The reinforcement of advantages can give rise to highly unequal networks.

## 16.2 Exchange and Price Formation

In a textbook model of buyers and sellers, the price is determined by the intersection of the demand and supply curves. This classical formulation assumes that all buyers and sellers can trade with each other. In practice, participation in trading may be restricted and some buyers may be able to trade with only a subset of sellers, and vice-versa. This could be due transport costs or restrictions imposed by national boundaries or due to high contracting costs. When trading options are limited, a seller may be able to charge more because many buyers are dependent solely on her, even if the aggregate picture is one in which sellers are on the long side and buyers are on the short side. This section studies the formation of prices and the allocation of trading surplus in such settings. We start with a model of bargaining and then take up auctions in networks. The exposition is based on Corominas-Bosch [2004] and Kranton and Minehart [2001].

We will consider a market comprising of buyers (numbering  $B$ ) and sellers (numbering  $S$ ). Each seller has a single indivisible good, which she values at 0; every buyer has a known valuation for the good equal to 1. The trading relationships are represented by a bipartite network (see Figure 16.1 for examples): in this network, a buyer and a seller have a link if and only if they can trade. The simplest cases of such networks involve a pair of buyer and seller, or two sellers and a single buyer (and vice-versa). Note that the complete bipartite network in which all sellers can trade with all buyers (and vice-versa)

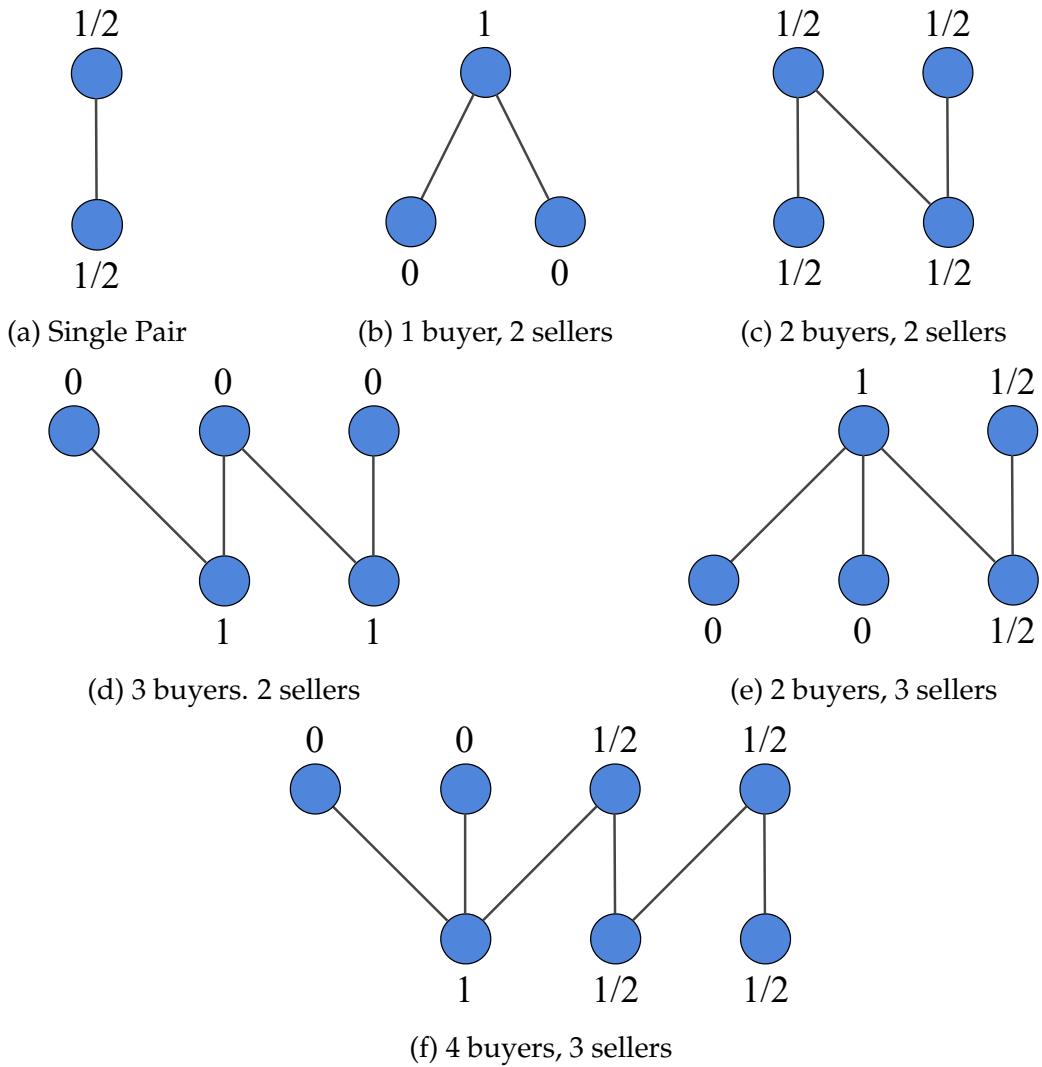

Figure 16.1: Examples of Bipartite Networks. Taken from Jackson [2008]

is an example of special interest as it corresponds to the classical market with no trading restrictions/frictions.

Let us start by recalling how prices will be determined in the textbook model: we can derive the demand curve and the supply curve by aggregating the individual schedules. Note that a price of  $p$  means the buyer's payoff is  $1 - p$  while the seller's payoff is  $p$ . As every buyer can trade with every seller, there must be a single price for all transactions. We will refer to this outcome as the competitive or the Walrasian benchmark (named after the French economist Leon Walras). In this outcome the equilibrium price is determined by the relative size of  $B$  and  $S$ . If  $B > S$  then the demand and supply curves will support the price of 1, while if  $B < S$  then the only price that can equate demand with supply is 0.

Let us next consider settings with trade restrictions. To facilitate an easy comparison

with the Walrasian model, we consider a simple and relatively ‘synchronized’ bargaining process. Time proceeds in discrete steps,  $t = 1, 2, \dots$ . In period 1 and all subsequent odd periods, every (remaining) seller makes an offer, which is observed by the (remaining) connected buyers. Buyers who wish to trade accept one of the prices that they see, those who do not wish to trade reject all prices that they observe. Those who have an agreed trade, exchange at the agreed price and leave the market (in case of a tie with two traders buying from one seller, we randomly pick one trade). In round 2 and all subsequent even numbered rounds, buyers make offers, and connected sellers respond. To focus on the network structure, let us suppose all traders discount the future at rate  $\delta \in (0, 1)$ . If a buyer (respectively seller) trades at time  $t$  he earns  $\delta^t(1 - p)$  (respectively,  $\delta^t p$ ). We study the relation between network structure and prices.

Consider the simplest network with a pair of traders or three traders. If two buyers are linked to a single seller then  $p$  is equal to 1; if two sellers are linked to a single buyer then  $p$  is equal to 0. In case of disjoint pairs of traders,  $p$  is equal to  $1/(1 + \delta)$  (this comes from the well-known Rubinstein-Stahl model of alternating offers).

Turning to richer and larger networks, there are indirect chains of links that are important in bargaining. For instance, a seller realizes that the response of her connected buyer depends on how many sellers she is connected to, and then on how many buyers they in turn are connected to (and so forth). The first step in the study of this problem is the following observation: every bipartite network can be ‘broken’ down into sub-networks in which either the buyers are in majority or the sellers are in majority or the two sides are in balance. This decomposition is helpful because prices in these sub-networks are either 1, 0 or (roughly) equal to  $1/2$ , respectively.

Let us develop this point formally. A seller-surplus local network  $g^s$  is one in which sellers are on the long side and every subset of sellers can be matched with buyers with cardinality at most as great as the seller. We refer to buyer-surplus local network by  $g^b$  and a balanced sub-network by  $g^e$ . Let  $N_g(V_0)$  be the set of vertices linked to a set of vertices  $V_0$ .

**Definition 16.1.** *A set of nodes  $V$  with  $V \subseteq S$  or  $V \subseteq B$  is non-deficient in network  $g$  if  $|N_g(V_0)| \geq V_0$  for every  $V_0 \subseteq V$ .*

Every bipartite network  $g$  can be decomposed into a number of subgraphs  $g_1^s, g_2^s, \dots, g_{n_s}^s$  (of seller surplus type)  $g_1^b, g_2^b, \dots, g_{n_b}^b$  (of buyer surplus type) and a third category  $g_1^e, g_2^e, \dots, g_{n_e}^e$  (of balanced type). Moreover, a seller in a  $g_i^s$  is linked only to buyers in some  $g_j^s$ , a buyer in a  $g_l^b$  is linked only to sellers in some  $g_x^b$ . Finally, a given node always belongs to the same type of sub-graph, across all possible decompositions.

This decomposition can be implemented as follows:

1. Start with two or more sellers who are linked ONLY to the same buyer. Ignore the other links of this buyer. The buyer gets 1, and the sellers get 0. Take these traders out of the network.
2. Now consider the residual network and repeat step 1, but with the role of traders reversed.
3. Proceed inductively in the number of traders: identify  $k$  sellers who have links with at most  $k - 1$  buyers. Or identify  $k$  buyers who have links with at most  $k - 1$  sellers. Assign payoffs correspondingly.
4. We are left with balanced sets of traders,  $k$  buyers linked to  $k$  sellers.

We illustrate how this algorithm works by applying it to the last network in Figure 16.1. This yields us Figure 16.2: we identify a buyer surplus sub-graph and then identify a balanced sub-network. This yields us a decomposition of the network and a corresponding allocation of surplus.

This decomposition allows us to develop the following description of prices in the different types of sub-networks. There is a (sub-game perfect) equilibrium of the bargaining game in which price is 0 in subgraphs  $g^s$ , price in subgraphs  $g^b$  is 1, and price in sub-graphs  $g^e$  is  $1/(1 + \delta)$ .

Let us sketch the argument underlying this pricing outcome. Consider the profile in which all sellers in a  $g^b$  subgraph propose 1 and all buyers accept it. Suppose that a buyer rejects this proposal. Then in equilibrium the trade will take place among the remaining buyers and sellers in the sub-graph. So the buyer will be disconnected from all sellers in the original sub-graph  $g^b$ . So his only hope is a positive payoff from his links in other sub-graphs. But the decomposition we obtained tells us that this buyer is only linked to sellers in other  $g^b$  subgraphs. In such a sub-graph sellers propose 1 and the buyers linked to them agree to the proposal. The buyer will see all his links to sellers deleted at the end of the round. The buyer will therefore be isolated and will earn 0 from the deviation. Thus accepting a price of 1 is optimal for this buyer.

We summarize our analysis in the following result.

**Proposition 16.1.** *Consider a network with  $S$  sellers and  $B$  buyers and a decomposition as computed above.*

*If  $S > B$ , then  $g$  will support the competitive outcome if and only if every sub-graph is of type  $g^s$ .*

*If  $S < B$ , then  $g$  will support the competitive outcome if and only if every sub-graph is of type  $g^b$ .*

*If  $B = S$ , then  $g$  will support the competitive outcome if and only if every sub-graph is of type  $g^e$ .*

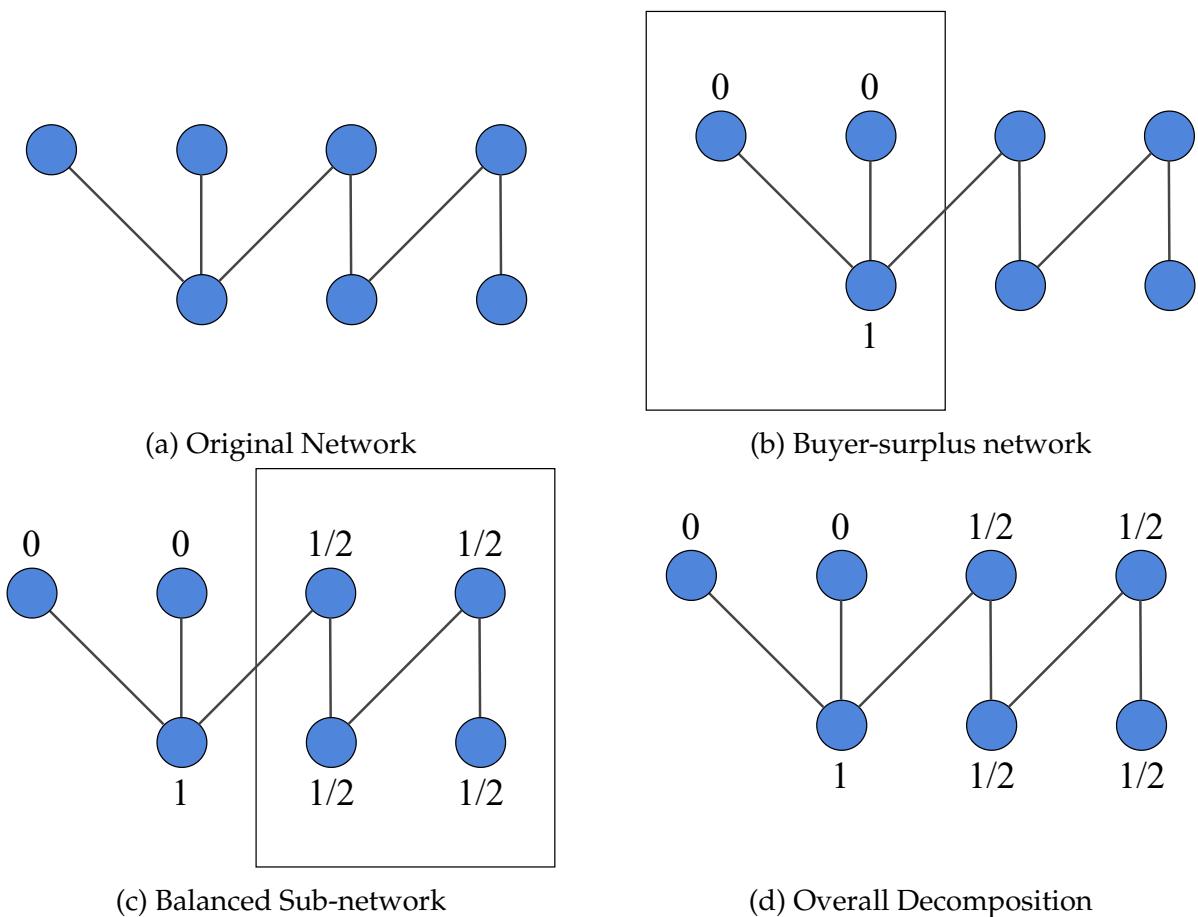

Figure 16.2: Implementing the Algorithm (the numbers indicate payoffs when  $\delta \rightarrow 1$ ). Taken from Jackson [2008].

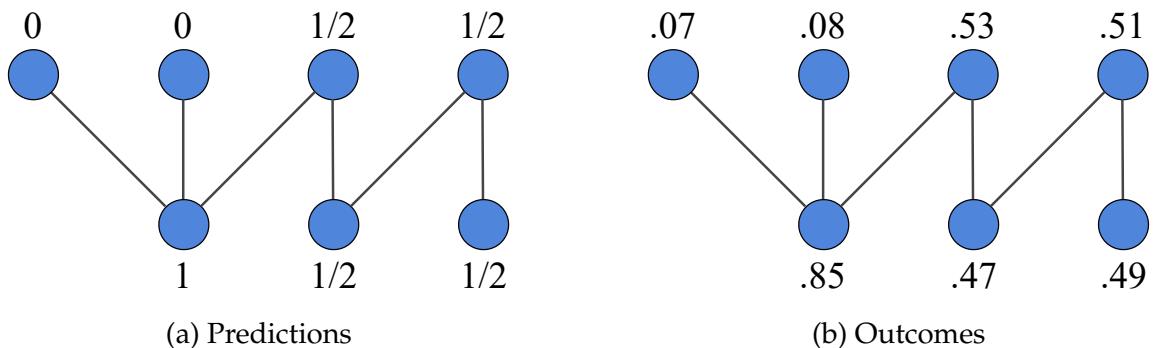

Figure 16.3: Experiments on Buyer-Seller Bargaining. Taken from Charness, Corominas-Bosch, and Frechette [2007]

These arguments are intuitive but the decomposition underlying the proof of the main result involves careful consideration of the direct and the indirect connections in the buyer-seller network. It is therefore very unclear if actual behaviour in such settings will conform to the theoretical predictions. With this observation in mind, we report the findings of an experiment with a small buyer-seller network (with 7 traders). The experiment is taken from Charness, Corominas-Bosch, and Frechette [2007].

Let us consider the following network: there are 4 sellers and 3 buyers. Sellers 1 and 2 linked only to buyer 1, seller 3 has links with buyer 1 and 2, while seller 4 has links with buyers 2 and 3. Sellers 1 and 2 and buyer 1 are in a sub-graph and sellers 3 and 4 and buyers 2 and 3 are in the other subgraph. The theoretical prediction is that sellers 1 and 2 make 0 while buyer 1 makes 1, sellers 3 and 4 and buyers 2 and 3 make  $1/2$  each. The network and the theoretical predictions are presented in Figure 16.3a.

The principal experimental finding concerns the average payoffs: seller 1 (0.07), seller 2 (0.08), seller 3 (0.53), seller 4 (0.51), buyer 1 (0.85) buyer 2 (0.47), buyer 3 (0.49). They are presented in Figure 16.3b. We conclude that the experimental outcome corresponds closely to the theoretical predictions of the model.

This paper provides an elegant micro-foundation for the Walrasian benchmark: it tells us the law of one price obtains only when all local markets reflect the global balance of buyer vs sellers. So, in a ‘market’ with surplus sellers the outcome may entail some sellers who make large profits because they are ‘locally’ in a buyer-surplus market.

We have taken the network as given so far, but given the trading outcome on any network, we can now take a step back and ask what sort of networks would form if buyers and sellers can build links with each other. A question at the end of the chapter works through the incentives to create networks in this setting.

We have examined price determination in a network via a process of bargaining: in

our model, everyone knows the network and also knows that all buyers value the good at 1, while all sellers value the good at 0. In practice, it is more natural to suppose that there will be limited information on valuations and the connections of others. The theory of bargaining in networks – with incomplete information on either of these dimensions – is very much a field of ongoing research. The interested reader is referred to the excellent survey paper by Manea [2016]. Prices may be determined by agents posting a price (as firms often do) and through an auction among connected buyers. A problem at the end of the chapter explores posted prices in networks. We conclude this section with a brief discussion of auctions in networks that also allows for link formation.

**Example 16.1.** Auctions in Networks (Kranton and Minehart [2001])

There are two stages. In stage 1, players choose to form links. The links determine potential trade patterns. In stage 2, buyers simultaneously make bids to the seller. The winner is determined using a second price auction. Assume that the valuations of the buyers are uniformly distributed on the unit interval.

To fix ideas, suppose that there are 2 buyers and 1 seller. In the single link network, the buyer will bid 0. In the two links network, buyers will submit valuations equal to their valuation, and so the expected price is the expected value of the second highest valuation. It maybe checked that the expected valuation of the winner is  $2/3$  (which is also the total value of surplus generated), while the expected price is equal to  $1/3$ . Each buyer expects to earn  $1/6$ , together they expect to earn  $1/3$ , the seller expects to earn  $1/3$ .

What are the incentives of the traders to form a network? Let us first characterize the efficient networks: observe that expected social value of one buyer is  $1/2$  while the expected social value of selling to two buyers is  $2/3$ . This implies that the empty network is efficient if  $c > 1/2$ , the single link network is efficient if  $1/6 < c < 1/2$ , and the two link network is efficient if  $c < 1/6$ .

Next consider stage 1 with unilateral links formed by buyers. Observe that the empty network is an equilibrium if no buyer has an incentive to form a link: simple computations reveal that if the cost of a link  $c > 1/2$  then the empty network is an equilibrium. Next consider the single link network. A buyer is willing to form a link so long as  $c < 1/2$  and the second buyer has no incentive to form a link if  $c > 1/6$ .

We have thus shown that a single link network is an equilibrium if  $1/6 < c < 1/2$  and the two link network is an equilibrium if  $c < 1/6$ .  $\square$

In this example the efficient and equilibrium networks coincide. A question at the end of the chapter explores the role of linking protocol – one-sided versus two-sided – in this result.

## 16.3 Intermediaries

The previous section considered direct ties between initial sellers and final buyers. But, as our examples in earlier chapters indicate, supply chains are a defining feature of the modern economy. They are prominent in agriculture, in manufacturing, in transport and communication, in international trade, and in finance. The routing of economic activity, the allocation of surplus and the efficiency of the system depend on the prices set by the different intermediaries. This section studies the formation of prices in a network of intermediaries. We start with models of posted prices and then take up models of bargaining and auctions. the exposition in this section draws on Condorelli and Galeotti [2016].

Motivated by the example of supply chains, let us consider a simple model in which intermediaries set a bid-price to buy upstream and an ask-price to sell downstream (as in Blume, Easley, Kleinberg, and Tardos [2009]). The intermediary has no consumption value for the object and is connected to subsets of buyers and sellers. This may be seen as a natural next step from the bipartite networks we considered in the previous section. In this model, a seller has one unit of an indivisible good, and every buyer demands one unit of the same good. The consumption value of buyers and sellers may differ but it is commonly known. The trading proceeds in two stages. In the first stage, an intermediary offers a bid-price to each seller to whom she is connected, and an ask-price to each buyer to whom she is connected. In the second stage, sellers and buyers choose the best offer from the offers of intermediaries open to them (it is possible that they choose not to buy or sell). A large penalty is imposed on an intermediaries if she sells more units than she has acquired. This assumption ensures that in equilibrium, intermediaries will not default on their price commitment to buyers. It is possible to show that every Nash equilibrium of this game results in an efficient outcome, i.e., every possible beneficial trade is realized. An intermediary makes a positive profit if and only if she is *essential*, i.e., if the intermediary raises social welfare. In the special case with only one buyer and one seller, an intermediary is essential if she lies on the unique path between them. A question at the end of the chapter works through equilibrium in specific networks in this model.

In this model there is only one layer of intermediation between initial sellers and eventual buyers. Let us move beyond this two step network to more complete multipartite networks with longer paths in which all traders post bid-and-ask prices simultaneously. In this case, the object then flows from the initial seller to the highest bidder in tier 1, and from the buyer in tier 1 to the highest bidder in tier 2, and so forth. The object stops moving either when it is acquired by an intermediary  $i$  and  $i$ 's ask is strictly higher than the best bid of any of her downstream buyers or if it has reached an eventual buyer. This formulation

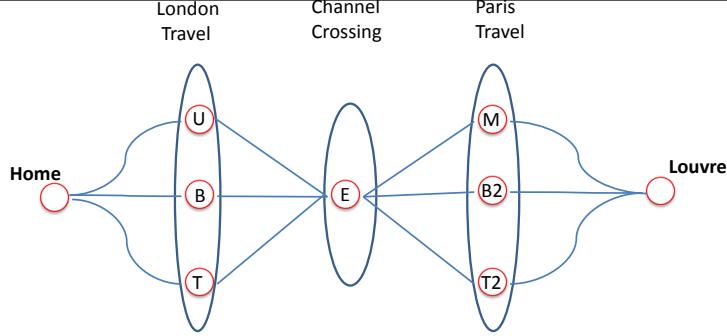

Figure 16.4: Traveling from Home in London to the Louvre in Paris

with bid-ask prices is explored in Gale and Kariv [2009]. We would like to study richer set of networks and this leads us to simplify the pricing process slightly. Our discussion will focus on a model of posted prices taken from Choi, Galeotti, and Goyal [2017].

By way of motivation for this model, let us consider a tourist who wishes to travel by train from London to see the Louvre in Paris. The first leg of the journey is from her home to the St.Pancras Station in London. She can use a taxi, a bus service or the London Underground to get to the station. Once at St.Pancras Station, the only service provider to Paris Nord Station is Eurostar. Upon arriving at Paris Nord Station, she again has a number of alternatives (e.g., bus, Metro and taxi) to get to the Louvre. We can represent the possibilities with the help of a network as shown in Figure 16.4: this network consists of alternative paths, each constituted of local transport alternatives in London and in Paris and the Eurostar Company. These service providers each sets a price with a view to maximizing their profits. The traveler picks the cheapest ‘path’. How does the network shape the prices and which route will the tourist eventually choose?

This example suggests the following model: there is a source node,  $\mathcal{S}$ , and a destination node,  $\mathcal{D}$ . A path between the two is a sequence of interconnected nodes, each occupied by an intermediary. The source node and the destination node and all the paths between them together define a network. The passage of goods (or people) from source to destination generates surplus. Let us suppose that the value is known and for simplicity set it equal to 1. Intermediaries (who each have zero cost) simultaneously *post a price*; the prices determine a total cost for every path between  $\mathcal{S}$  and  $\mathcal{D}$ . The tourist moves along a least cost path; so an intermediary earns payoffs only if she is located on it.

Every node  $i$  is called an *intermediary*; let  $N = \{1, 2, 3, \dots, n\}$ ,  $n \geq 1$ , denote the set of intermediaries. A path  $q$  between  $\mathcal{S}$  and  $\mathcal{D}$ , is a sequence of distinct nodes  $\{i_1, \dots, i_l\}$  such that  $g_{\mathcal{S}i_1} = g_{i_1i_2} = \dots = g_{i_l\mathcal{D}} = 1$ . The nodes  $N \cup \{\mathcal{S}, \mathcal{D}\}$  and the paths  $\mathcal{Q}$  define a network  $g$ . Every intermediary  $i$  simultaneously posts a price  $p_i \geq 0$ . Let  $p = \{p_1, p_2, \dots, p_n\}$  denote

the price profile. Throughout we will restrict attention to pure pricing strategies. The network  $g$  and the price profile  $p$  define a cost for every path  $q$  between  $\mathcal{S}$  and  $\mathcal{D}$ :

$$c(q, p) = \sum_{i \in q} p_i. \quad (16.1)$$

A *least-cost* path  $q'$  is one such that  $c(q', p) = \min_{q \in \mathcal{Q}} c(q, p)$ . Payoffs arise out of active intermediation: an intermediary  $i$  obtains  $p_i$  only if he lies on a feasible least cost path. Define  $c(p) = \min_{q \in \mathcal{Q}} c(q, p)$ . A path  $q$  is feasible if  $c(q, p) \leq 1$ , where 1 is the value of economic ‘good’ generated by the path. All paths generate the same value 1. If there are multiple least-cost paths, one of them is chosen randomly to be the active path. Given  $g$ , and  $p$ , we denote by  $\mathcal{Q} = \{q \in \mathcal{Q} : c(q, p) = c(p), c(p) \leq 1\}$  the set of feasible least-cost paths. Given a price profile  $p$ , intermediary  $i$ ’s payoff is:

$$\pi_i(p) = \begin{cases} 0 & \text{if } i \notin q, \forall q \in \mathcal{Q} \\ \frac{\eta_i}{|\mathcal{Q}|} p_i & \text{if } i \in q, q \in \mathcal{Q}, \end{cases} \quad (16.2)$$

where  $\eta_i$  is the number of paths in  $\mathcal{Q}$  that contain intermediary  $i$ .

We study (pure strategy) Nash equilibrium of the posted price game. A price profile  $p^*$  is a Nash equilibrium if for all  $i \in \mathcal{N}$ ,  $\Pi_i(p^*) \geq \Pi_i(p_i, p_{-i}^*)$  for all  $p_i \geq 0$ . An equilibrium is efficient (resp. inefficient) if trade occurs (resp. does not occur). An equilibrium  $p^*$  is said to be efficient if  $c(p^*) \leq 1$ ; otherwise, the equilibrium  $p^*$  is inefficient.

To build some intuition for how network structure affects pricing let us consider two simple networks. The first network has two paths between  $\mathcal{S}$  and  $\mathcal{D}$ , each with a distinct node. These two intermediaries compete in prices: this is very much like price competition between firms selling a homogenous product. Standard arguments tell us that the firms will set a price equal to 0. The second network contains a single line with two nodes between  $\mathcal{S}$  and  $\mathcal{D}$ . The outcome is a pair of prices that sums to 1; this is as in the Nash model of two players bargaining over a cake of size 1. Observe that in the first network the prices of the two competing firms are strategic complements, while in the latter network – when the two prices add up to 1 – they are strategic substitutes. These examples illustrate how classical models of price formation constitute special cases of our framework and also show how networks and the strategic structure are intimately related.

Let us build on these examples to make some observations on pricing in general networks. If there are multiple routes between source and destination then the players located on these nodes become competitors who are supplying a route, which is a homogenous product. If the routes are distinct – they have no common intermediary – then we should

expect that the outcome would be like the Bertrand outcome: all intermediaries set a price 0. It is possible to verify that this price profile constitutes a Nash equilibrium. However, it is not the unique equilibrium: to see why, consider a simple network with two paths with two intermediaries on each path. There is an equilibrium in which intermediaries on one path mis-coordinate and each sets a price 1, while the intermediaries on the other path each sets a price of 1/2.

Turning next to the case where some intermediaries are common to the paths, consider the special case where an intermediary lies on all paths. In this situation, we claim that the traveller must earn zero surplus. Suppose that she earns a positive surplus in equilibrium. This means that the cheapest path adds up to less than 1. But then the intermediary who lies on all paths can raise her price so that the prices add up to 1. This is a strictly profitable deviation for the intermediary and contradicts the claim that we were in equilibrium.

Building on the introductory chapter, let us define *betweenness centrality* of intermediary  $i$  as  $BC_i = \eta_i / |\mathcal{Q}|$ , where  $BC_i \in [0, 1]$ . Intermediary  $i$  is said to be *critical* if  $BC_i = 1$ .

**Proposition 16.2.** *In every network, there exists an efficient equilibrium. Any equilibrium  $p^*$  is either inefficient ( $c(p^*) > 1$ ), or allows intermediaries to extract all surplus ( $c(p^*) = 1$ ) or gives no surplus to intermediaries ( $c(p^*) = 0$ ). In a network with critical traders an efficient equilibrium results in full extraction by intermediaries.*

Let us sketch the proof for this result. We have seen in the example above that equilibrium may be inefficient. When equilibria are efficient only two outcomes are possible with regard to surplus extraction, either all surplus accrues to intermediaries or none of it does. To see why this is true note that if there is a critical trader then trade cannot occur at a price less than full surplus, because the critical trader can simply increase their price and thereby strictly increase their profits. If there is no critical trader then the argument is a little more complicated. If the feasible least-cost path is unique, then intermediaries in that path exercise market power and if intermediation costs are below the full surplus then an intermediary on that path could slightly increase his intermediation price while guaranteeing that exchange takes place through him. In contrast, when there are multiple feasible least-cost paths then there is price competition among intermediaries on these paths. In that case, whenever intermediation costs are larger than zero, an intermediary demanding a positive price gains by undercutting his price. Price competition drives intermediation costs down to zero.

Criticality dictates that all surplus must accrue to intermediaries, but the theory is permissive about how it is distributed among them. To see this point, consider the Ring with Hubs and Spokes network presented in Figure 16.5, and suppose that  $\mathcal{S}$  and  $\mathcal{D}$  are located

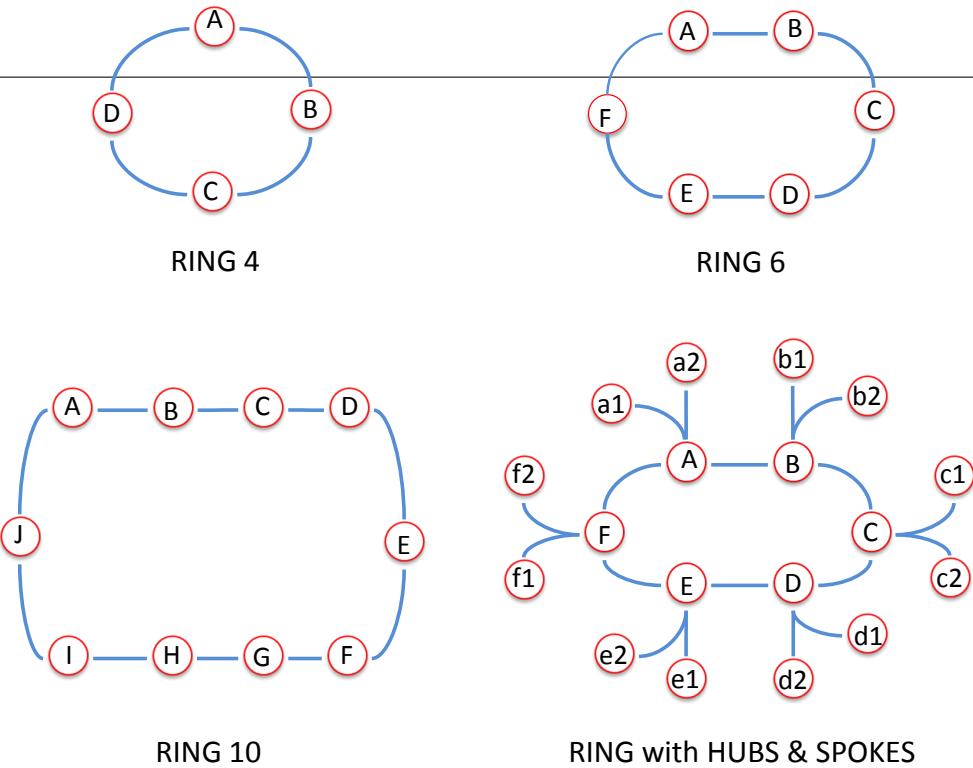

Figure 16.5: Examples of Networks

on  $(a_1, d_1)$ . Then, there exists an equilibrium in which all surplus accrues to the critical intermediaries, e.g.,  $A$  and  $D$  charge  $1/2$  and all other intermediaries charge 0. However, there is also an equilibrium in which the entire surplus is earned by non-critical intermediaries, e.g.,  $A$  and  $D$  charge 0,  $B$  and  $C$  charge  $1/2$ , and  $F$  and  $E$  charge 1.

The theoretical analysis suggests some broad patterns for how networks impact pricing but there remain open questions due to the multiplicity of equilibrium: we know for instance that mis-coordination can lead to the breakdown of trade and that even when trade occurs surplus may flow to non-critical traders. We conduct an experiment with networks that allow us to examine the roles of coordination, competition and market power (these are the networks in Figure 16.5).

The ring networks with four, six and ten traders allow us to focus on coordination and competition. For every choice of  $\mathcal{S}$  and  $\mathcal{D}$ , there are always two competing paths of intermediaries. In Ring 4, for any non-adjacent pair, there are two paths with a single intermediary each. Ring 6 and Ring 10 allow for situations with a higher (and possibly unequal) number of intermediaries on either path.

The Ring with Hubs and Spokes network allows us to study of the impact of market power: for instance, if  $\mathcal{S}$  is located at  $a_1$  and  $\mathcal{D}$  is located at  $a_2$ , intermediary  $A$  is a pure monopoly, while if  $\mathcal{D}$  is  $b_1$ , then the intermediaries  $A$  and  $B$  play a symmetric Nash demand game. This network also creates the space for both market power and competition to come into play. For instance, if  $\mathcal{S}$  is located at  $a_1$  and  $\mathcal{D}$  is located at  $e_1$ , then there are two

Network	minimum distance of buyer-sell pair				
	All ( $\geq 2$ )	2	3	4	5
Ring 4	1.00 (480)	1.00 (480)	--	--	--
Ring 6	1.00 (420)	1.00 (289)	1.00 (131)	--	--
Ring 10	1.00 (240)	1.00 (49)	1.00 (87)	1.00 (69)	1.00 (35)
Ring with Hubs and Spokes	0.95 (420)	1.00 (126)	0.94 (155)	0.90 (109)	0.90 (30)

Note. The number of group observations is reported in parentheses.

Table 16.1: Frequency of Trading. Taken from Choi, Galeotti, and Goyal [2017].

competing paths: a shorter path (through  $A$ ,  $F$ , and  $E$ ) and a longer path (through  $A$ ,  $B$ ,  $C$ ,  $D$ , and  $E$ ). Traders  $A$  and  $E$  are the only critical intermediaries.

The first finding is that the level of efficiency is remarkably high in all networks. Trading in Rings with four, six, and ten intermediaries occurs with probability 1. In the Ring with Hubs and Spokes, trading occurs with probability around 0.95. Table 16.1 summarizes the data.

We next turn to the issue of surplus extraction by intermediaries. Figure 16.6 presents a summary of the findings. As we move along the x-axis we cover the different networks. On the y-axis we have the share of surplus accruing to intermediaries. In the Ring with Hubs and Spokes, when  $S$  and  $D$  are served by a sole critical intermediary, surplus extraction is in the region of 99 percent. When  $S$  and  $D$  are connecting via one single path with two intermediaries, the game played by the two intermediaries is analogous to a symmetric Nash demand game. The intermediaries extract, in total, around 96 percent of the surplus and that they share it roughly equally. Finally, when there are two competing paths and critical traders, the intermediation cost ranges between 62 percent and 83 percent. In the case without critical intermediaries, this cost falls sharply to around 28 percent, which is comparable to the low-cost outcome found in Rings.

The final issue pertains to the sharing of surplus between critical and non-critical traders. Figure 16.7 summarizes the data. We cover the different possible distances and critical-noncritical configurations as we along the x-axis. The y-axis presents the prices. The figure reveals that in the Ring with Hubs and Spokes, critical intermediaries set higher prices and earn a much higher share of surplus than non-critical intermediaries.

To summarize: trading in network is generally efficient and critical intermediaries capture practically all the surplus.

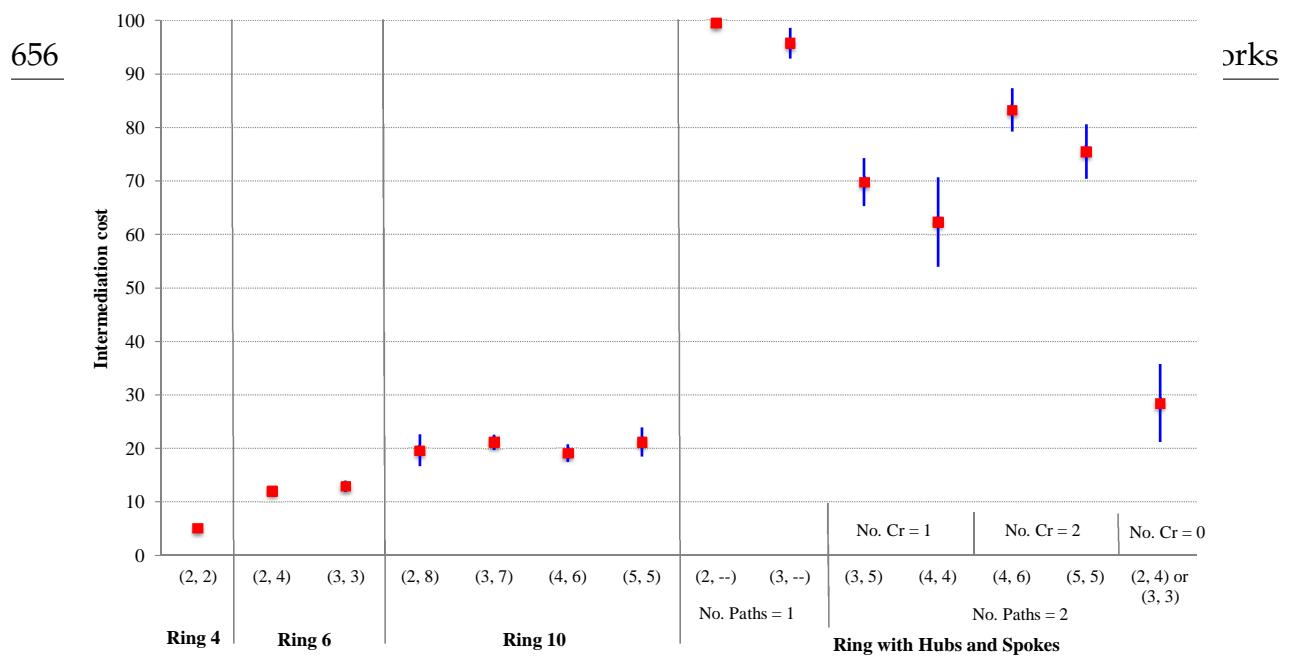

Figure 16.6: Costs of intermediation (numbers on x-axis indicate short and long paths between source and destination). Taken from Choi, Galeotti, and Goyal [2017].

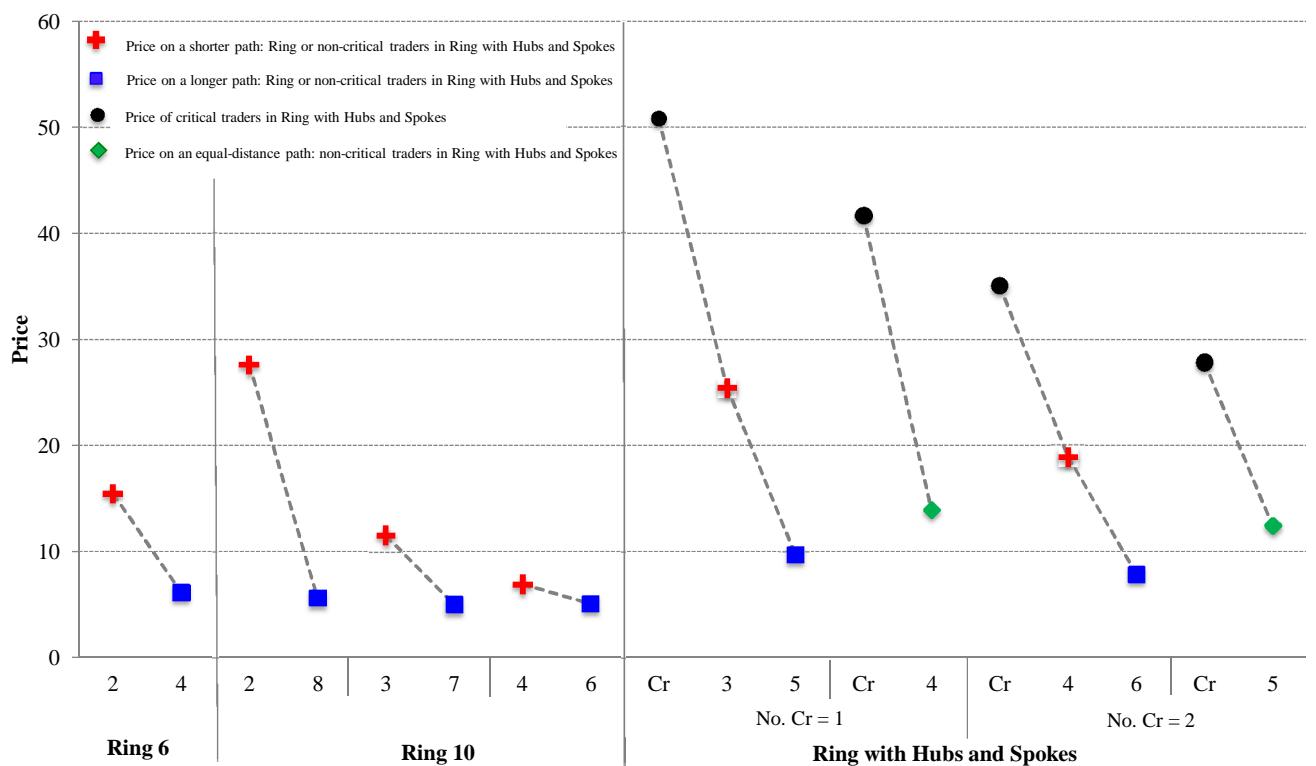

Figure 16.7: Competition among intermediaries. Taken from Choi, Galeotti, and Goyal [2017].

In this model there is full information on the size of the surplus. In practice, traders will normally not know the value of the surplus. Let us briefly discuss the implications of this imperfect information. Suppose to fix ideas that value is uniformly distributed on the unit interval. This defines a new game on a network: the strategies remain as before but the profits of intermediaries are altered due to the incomplete information on valuations.

To develop an idea of how incomplete information matters we discuss the two simple network examples as discussed above. In the two path case, nothing essential changes: prices are still set at 0. But in the line network with two nodes, there is an outcome where both intermediaries set a price equal to  $1/3$ , so there is no trade with probability  $2/3$ . It is easy to see that with three intermediaries the price will be  $1/4$  and so the probability of no trade is  $3/4$ . Thus individual prices are falling, aggregate price is rising and the probability of trade is falling in the number of critical traders. These points can be shown to hold in more general networks, a point that is developed in a question at the end of the chapter.

As in the previous section on bipartite networks, to deepen our understanding of pricing in networks, we will next explore price formation via bargaining. The model is taken from Manea [2018]. We consider the following setting: a seller owns a single unit of an indivisible good, which can be resold through a chain of intermediaries until it reaches one of several final buyers.

- At every stage, the current owner of the good selects a bargaining partner among his downstream neighbors in the network.
- The two traders negotiate the price of the good. With probability  $p$ , the current owner makes an offer and the partner either accepts or rejects the offer. With probability  $1 - p$  the downstream trader makes an offer. Irrespective of who makes the offer, once an offer is rejected bargaining in that stage ends. The current owner has an opportunity to select a new trader in the next stage (he may select the same partner again).
- If on the other hand, an offer is accepted, then the two traders exchange the good at the agreed price. If the new owner is an intermediary, he has an opportunity to resell the good to downstream neighbors following the same protocol. The final buyer consumes the good upon purchase.

Traders have a common discount factor  $\delta \in (0, 1)$ . At any point in the game, the strategy of an active trader conditions on current ownership: the strategy consists of an offer of a price to sell or an offer to buy at a price. The strategy of the respondent is to accept or reject. As past actions do not matter, we will study the Markov Perfect equilibrium of the

bargaining game. In words, the traders condition their offers and responses only on current ownership status and potential buyers downstream.

To draw out the role of the network architecture, let us assume that all traders have zero costs and that all buyers have a common value  $v > 0$ . A preliminary observation is the following: any seller/intermediary linked to two (or more) buyers will extract the full surplus of  $v$ , as traders become patient (this is reminiscent of our model of bargaining in bipartite networks). In the rest of the section, the discussion will proceed under the assumption that players are very patient, i.e.,  $\delta \rightarrow 1$ .

With these points in mind, let us consider the class of connected networks that are acyclic – these are networks in which there is a path leading from the original seller to every final buyer and there is a well-defined progression from the original owner downstream. Building on the discussion above, we will want to identify the sellers who act as a “gateway” to competing buyers without having to compete themselves to buy the good from upstream seller. We do this as follows: start with the final buyers: add all intermediaries who are linked to at least two buyers, then add all intermediaries linked to at least two traders already present, and so on, until no more traders have two or more links to traders already present in layer 0. This defines layer 0 in the induced network. Consider all the traders who do not belong to layer 0: start with traders who have only one link with a trader in layer 0, then add all intermediaries who have at least two links with intermediaries currently in layer 1 and repeat until there is no one with two or more links with traders in the emerging layer 1. This completes the construction of layer 1. Proceed recursively until all agents have been assigned to layers 0, 1, 2...

To develop a feel for the economic pressures at work in this environment, let us restrict attention to a special class of networks (inspired by the example of travel from London to Paris). We will consider complete multipartite networks. This is a network with a single initial seller and a single final buyer and  $L \geq 1$  intermediating tiers. Every node in a level is linked to every node in the adjacent levels above and below it. A node is critical if it is the unique member of a tier. Given the layer  $x$ , let  $k_x \in \{0, \dots, L - x\}$  be the number of downstream tiers that have critical traders. Let  $k$  be the number of ‘critical’ tiers in the entire network. Figure 16.8 presents examples of such networks. Note that in the competitive network there are multiple intermediaries at every tier of the network. By contrast, in the line network, there is a unique – critical – intermediary at both tiers 1 and 2.

The study of bargaining in these networks yields a clear set of predictions as summarized below. Recall that  $p$  is the probability that the current owner makes an offer to a partner.

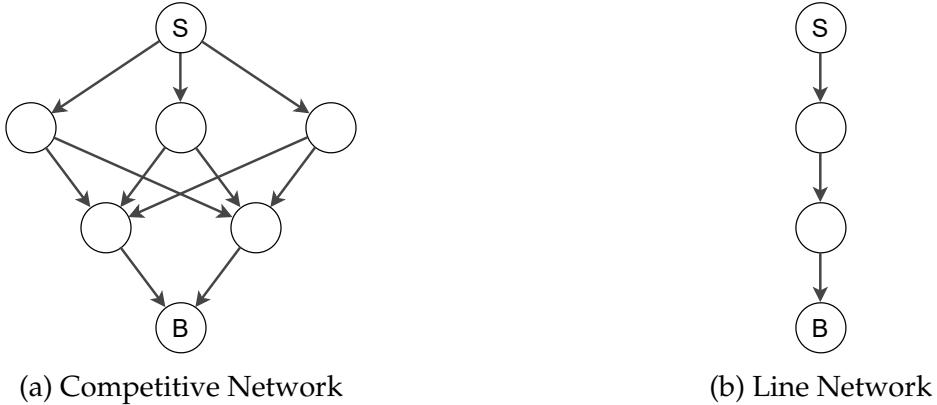

Figure 16.8: Complete Multipartite Networks. Taken from Condorelli and Galeotti [2016].

**Proposition 16.3.** Fix a complete multipartite network and let  $\delta \rightarrow 1$ . In equilibrium (i) the reservation value of intermediary  $i$  at level  $x$  converges to  $p^{k_x+1}v$ , (ii) the payoff of the initial seller converges to  $p^{k+1}v$  and payoff of the buyer converges to  $(1-p)v$ , (iii) the payoff of non-critical intermediaries converges to 0, while the payoff of critical trader at level  $x$  converges to  $(1-p)p^{k_x+1}v$ .

We start with part 1 of Proposition 1. The proof relies on a backward induction argument. When the object reaches an intermediary in the last tier, we have a standard two person bargaining game with a random proposer. In this game, when  $\delta \rightarrow 1$ , the intermediary obtains payoff  $pv$  and the buyer obtains  $(1-p)v$ . The resale value of an intermediary in tier  $L$  is then  $pv$ . Suppose next that the object has reached intermediary  $i$  in tier  $L-1$ . If tier  $L$  contains a critical trader  $j$ , then there is a standard bargaining game between intermediaries  $i$  and  $j$ : the total size of the cake is  $j$ 's resale value  $pv$ . In this game, intermediary  $i$  obtains an expected payoff of  $p^2v$ , which is his resale value. When tier  $L$  has more than one intermediary, the current owner,  $i$ , has multiple potential buyers in tier  $L$ , each with a resale of  $pv$ . We invoke the observation above to infer that competition among intermediaries will lead  $i$  to extract all surplus, i.e., his resale value is  $pv$ . Part 1 of the proposition now follows, by iterating backwards. Given part 1, it is straightforward to verify the other two parts.

We return to the networks in Figure 16.8 to appreciate the role of networks. Let us start with the line network. In this case, the resale value of intermediaries is as follows:  $p^3v$  for initial seller,  $p^2v$  for the first intermediary, and  $pv$  for the last intermediary. This suggests that the resale value is falling with distance from the final customer. As the equilibrium payoff of an intermediary  $i$  is  $(1-p)$  times his resale value, the ranking of equilibrium payoffs is the same as the ranking of their resale values. The payoff of the initial seller is decreasing in the number of intermediaries, while the payoff of the final buyer is  $v(1-p)$ .

In this model,  $p$  is naturally interpreted as a measure of the bargaining power of up-

stream traders. An increase in  $p$  leads to an increase in payoffs of the initial seller and a decrease in the payoff of the final buyer. Interestingly, the payoff of an intermediary changes non-monotonically with  $p$ : at first it increases and then it eventually decreases (this is due to the presence of multiple layers in the network).

Turning to the competitive network in Figure 16.8, we see that the number of critical traders is  $k = 0$ . Proposition 16.3 tells us that intermediaries have the same resale value, equal to 0, regardless of their location. The initial seller and the final buyer obtain  $vp$  and  $v(1 - p)$ , because the intermediary layers earn zero payoff. This suggests that horizontal mergers – that lead the competing traders in a tier to collude – are very profitable. For instance, if all intermediaries in one tier decide to merge, their total payoff would increase from 0 to  $pv(1 - p)$ ; the seller's payoff decrease from  $pv$  to  $p^2v$ .

Finally, we take up price formation through auctions in intermediation networks. Following Kotowski and Leister [2019], let us suppose that there is a single source and possibly multiple eventual buyers (each of whom values the good at value  $v > 0$ ). There are tiers of intermediaries between the original owner and buyers. In each tier, traders compete to provide intermediation services. The current owner conducts a second-price auction among the traders in the immediate downstream layer to sell his good. The new owner does likewise until the good arrives at a buyer. The network is common knowledge but intermediaries have private information on their own costs. If the cost of trading is High then the intermediary drops out of the network.

In this setting, trader behavior is determined by two network characteristics – the number of layers and the number of intermediaries in each layer – and the probability of High vs Low cost intermediaries. If there are two or more Low cost intermediaries in each layer the original owner will extract full surplus. Therefore, an intermediary earns rents only if it is the sole Low cost player in its layer, i.e., it is critical. With a greater probability of High cost, intermediate layers can in principle earn rents, in the event that their competitors in the same layer have turned out to be High cost. However, this possibility has correspondingly negative effects on the resale value for upstream traders. The authors show that the resale value is increasing in the probability of being Low cost and in the number of traders in each layer.

The models we have discussed in this section show how standard pricing protocols – posted prices, bargaining and auctions – can be used to study price formation and intermediation in networks. In all cases, critical traders appear to be central to shaping market power. Our discussion shows that location within a network and the structure of the network have powerful effects on patterns of trade and on earnings. In particular, we found that critical intermediaries earn larger payoffs than non-critical traders. So it pays to oc-

cupy a critical spot in a network. This suggests that traders have an incentive to create links so as to become critical. Similarly, other traders have an incentives to circumvent such critical traders by creating new ties. The chapter on platforms and intermediation studies this process and also presents experimental evidence on the role of pricing protocols in shaping network formation.

## 16.4 Research Alliances

Research alliances among firms are common: firms collaborate both with firms in their own industry as well as with those outside it and these alliances are non-exclusive so that a firm often takes part in multiple projects with different partners. Empirical research reveal the following stylized facts about R&D networks: the average degree is relatively small, the degrees are unequal, there is a core-periphery architecture and the average distance between firms in the network is small Konig, Liu, and Hsieh [2021]. This section studies the origins and the implications of these network patterns. We present a model taken from Goyal and Joshi [2003], Goyal and Moraga-Gonzalez [2001], and König, Tessone, and Zenou [2014]. Our exposition draws on Goyal [2007b] and Goyal [2017].

Firms produce services and products which involve the use of different bodies of knowledge. The complexity of technology means that an individual firm is at the frontier of some but not all the aspects of business. Research collaboration can be seen as a mechanism for firms to pool their distinct technological advantages. For firms producing goods that involve many different technologies, such as automobiles, there are many areas in which they can form potentially profitable collaboration partnerships.

Prior to competing in a market, firms can choose to collaborate on research. Collaboration lowers costs of partner firms. Lower costs is advantageous as it leads to larger market share and profits. On the other hand, collaboration with other firms involves resources and is therefore costly. So a firm compares the costs and returns from collaboration when deciding on how many links to form. At the heart of the analysis is the issue of how a collaboration link between two firms alters the incentives of other firms to form collaboration links (throughout we will assume that there is no collusion in the market stage among research collaborators).

There are two stages. In stage 1,  $n$  firms play a game of two-sided link formation. Every firm announces a set of firms  $s_i = \{s_{i1}, s_{i2}, \dots, s_{in}\}$  with whom it wishes to form links. A link is formed between two firms if they both announce an intention to form a link with each other. The collection of links formed defines an (undirected) network  $g(s)$ . Let  $N_i(g)$  be the collaboration partners of firm  $i$  in network  $g$ , and define  $\eta_i(g) = |N_i(g)|$ . There are  $K > n$

components in the product that firms produce and we will assume that all firms use the same  $K$  components. Let the cost for firm  $i$  of component  $k$  be given by  $c_{i,k}$ . The marginal cost of production for firm  $i$  is given by  $c_i = \sum_{k=1}^K c_{i,k}$ . The component-wise costs  $c_{i,l}$  take on a value of  $c^H$  or  $c^L$ , with  $c^H > c^L$ . Assume that for each firm  $i$  there is one and only one  $\hat{k}$  such that  $c_{i,\hat{k}} = c^L$ . Moreover, suppose that  $c_{j,\hat{k}} = c^H$ , for all other firms,  $j \neq i$ . Then it follows that if two firms form a collaboration link then they can both reduce their costs by  $c^H - c^L$ . Define  $\gamma = c^H - c^L$ .

It follows then that the marginal cost of firm  $i$  is given by

$$c_i(g) = \gamma_0 - \gamma\eta_i(g), \quad i \in N, \quad (16.3)$$

where  $\gamma_0 > 0$  is a positive parameter representing a firm's marginal cost when it has no links and  $\gamma > 0$  is the cost reduction from a link. The cost is a linear and declining function of the number of collaboration links with other firms. Given a network  $g$ , the profile of costs is  $c(g) = \{c_1(g), c_2(g), \dots, c_n(g)\}$ . In this formulation the cost reduction in each link is exogenously fixed.

In stage 2, firms compete in the market by choosing quantities or setting prices. Suppose that firms face an inverse linear demand given by  $P = 1 - Q$ , where  $P$  is the price and  $Q = \sum_{i=1}^n q_i$  is the total output produced by the firms. Define  $L(g_{-i}) = \sum_{j \in N} \eta_j(g) - 2\eta_i(g)$  as the total number of links of all firms in network  $g$ , *except* for the links that involve firm  $i$ . For a network  $g$ , using the standard formulae for Cournot models with heterogenous costs (see e.g., Vives [1999], the equilibrium quantity of firm  $i$  can be written as:

$$q_i(g) = \frac{(1 - \gamma_0) + (n - 1)\gamma\eta_i(g) - \gamma L(g_{-i})}{(n + 1)}, \quad i \in N \quad (16.4)$$

To ensure that each firm produces a strictly positive quantity we assume that  $(1 - \gamma_0) - (n - 1)(n - 2)\gamma > 0$ . It is easy to verify that the Cournot profits for firm  $i$  in network  $g$  are given by  $\pi_i^2(g)$ .

To complete the model, assume that every link involves a fixed cost  $c > 0$ . The net payoffs of firm  $i$  in network  $g$  are given as follows:

$$\Pi_i(g) = \left[ \frac{(1 - \gamma_0) + (n - 1)\gamma\eta_i(g) - \gamma L(g_{-i})}{(n + 1)} \right]^2 - \eta_i(g)c. \quad (16.5)$$

In the case of price competition, we will assume that all demand accrues to the lowest price firm; if there are multiple lowest cost firms, then the demand is equally shared among them. We study the architecture of pairwise equilibrium networks and payoff distributions (see chapter on costs and benefits of links for the definition of pairwise equilibrium).

In a market with a homogeneous product, a firm will attract demand only if it is a lowest price firm and if there are many lowest firms then they will share the demand equally. Anticipating this, in stage 1, a firm will only invest in costly links if it hopes to become a lowest cost firm. Either there is only one lowest cost firm or there are multiple lowest cost firms. In either event if there are costs to forming links, however small, then in both cases there will be firms who have formed links and who will make zero profits in the market: in other words, they will have negative earnings. Hence the empty network is the unique pairwise equilibrium.

By contrast, if firms compete in quantities, then an inspection of the equilibrium quantity in equation (16.4) reveals that profits are increasing in own links  $\eta_i(g)$ . This means that a firm has an incentive to form a link with every other firm so long as costs of links are sufficiently small. We conclude that the complete network is the unique pairwise equilibrium. Thus the nature of market competition – price versus quantity – has a decisive impact on the nature of collaboration networks.

As networks shape costs and quantities produced, they will determine the utility of consumers. Recall that social welfare in this market is the sum of firm profits and consumers surplus. Let us derive the efficient networks in the two markets. We first consider the nature of efficient networks under quantity competition. Let  $c(k)$  denote the marginal cost of a firm with  $k$  links. Social welfare is defined as:

$$W(g) = \frac{1}{2}Q^2(g) + \sum_{i \in N} \pi_i(g). \quad (16.6)$$

It is possible to show that the complete network is the unique network that maximizes social welfare. When two firms form a link, that lowers their costs and increases their market shares and profits. However, other firms lose out in market share. The computations show that aggregate quantity sold is increasing in links. The final step is to show that the gains of the firm with the additional links along with the increase in consumers surplus due to larger aggregate quantity sold are greater than the loss of the other firms.

Turning to the case of price competition. Let  $\underline{c}$  be the minimum cost attainable by a firm in any network; this is achieved when a firm has  $(n - 1)$  links. It is possible to show that a network maximizes social welfare if and only if two firms attain the minimum cost,  $\underline{c}$ . The argument is straightforward: with two maximally connected firms, costs attain their minimum value and price competition therefore pushes both firms to charge the minimal price. This maximizes consumption (and consumer surplus). It turns out that also maximizes total surplus. A question at the end of the chapter works through these computations.

To summarize, we have embedded a standard oligopolistic competition within a net-

work formation game and shown that market competition and networks interact in interesting ways: market competition shapes incentives to form links and create networks. These networks then shape the nature of the competition. The interaction between competition and networks can therefore have large effects on social welfare.

### 16.4.1 Large costs of linking

We next turn to the study the case of network formation when the costs of linking are large. Larger costs will reinforce the lack of incentives to form links in the pricing competition case. We therefore focus on quantity competition in the rest of this section.

As a firm will compare the marginal cost of a link with the marginal returns from a link, we need to understand the curvature of the returns as a function of the links in the network. We note from (16.5) that a firm's quantity and therefore its profits are declining in the links of other firms. Given a network  $g$ , the marginal (gross) returns from an additional link  $g_{i,j}$  are given by

$$\Pi_i(g + g_{i,j}) - \Pi_i(g) = \frac{(n-1)\gamma}{(n+1)^2} [\lambda(n) + 2(n-1)\gamma\eta_i(g) - 2\gamma L(g_{-i})] \quad (16.7)$$

where  $\lambda(n) = 2(1 - \gamma_0) + (n-1)\gamma$ . Thus the marginal (gross) returns from an additional link are increasing in the number of own links  $\eta_i(g)$  and decreasing in the number of links of other firms  $L(g_{-i})$ . The total cost of links is linearly increasing in the number of links. So any two firms that have a link must be linked with each other. Let us define a network with a dominant group as follows: there is a set of firms  $1 < k < n$  that constitutes a clique and all firms outside the group are singletons.

**Proposition 16.4.** *Suppose that payoffs are given by (16.5). A pairwise equilibrium network is either empty, contains a dominant group or is complete.*

The key to the proof is a simple observation: the marginal returns in own links are increasing and convex and marginal costs of links are constant, so if two firms have one or more links then in a pairwise equilibrium network they must also be linked to each other. As every pair of firms that has any connections must in turn be connected, the only possibility is that there is a clique of connected firms and some isolated firms. Figure 16.9 illustrates network architectures that can arise in pairwise equilibrium.

Let  $g^k$  refer to a dominant group network in which the dominant group has  $k$  firms. A firm in the dominant group should not have an incentive to delete any subset of its links. Given that payoffs are increasing and convex in own links it is sufficient to check if a firm has an incentive to delete all its links. Let  $Y(k)$  denote the difference in the payoff of a firm

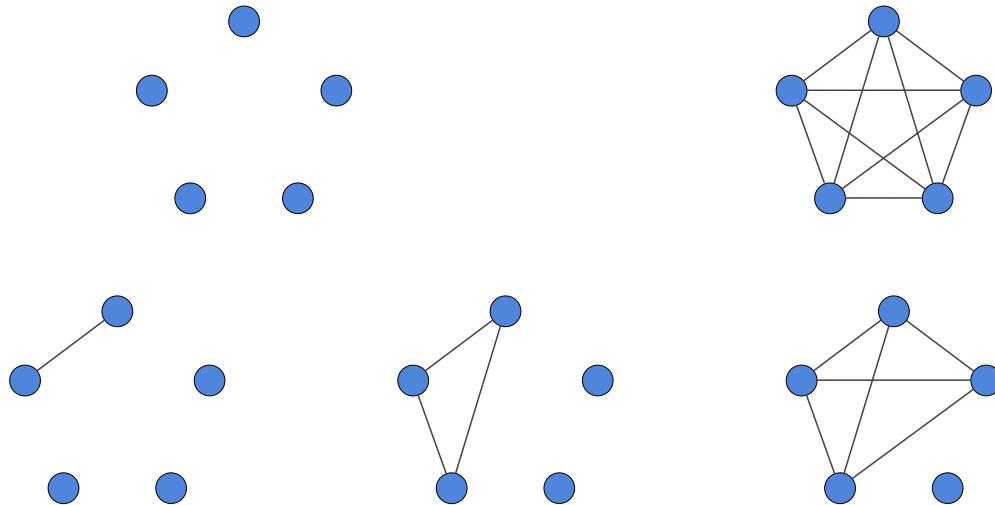

Figure 16.9: Pairwise equilibrium networks,  $n = 6$ .

in the dominant group of size  $k$  minus the payoff when the firm becomes isolated. Using equation (16.5) the incentive constraint may be written as follows:

$$Y(k) \equiv \frac{(n-1)\gamma}{(n+1)^2} [2(1-\gamma_0) + (k-1)(n+3-2k)\gamma] \geq c. \quad (16.8)$$

The left hand side of (16.8) reveals an interesting property of payoffs: the average returns from links are non-monotonic with respect to the size of the dominant group. They are initially increasing, until some critical size  $k^*$ , and declining thereafter. Due to increasing returns property, a firm in the dominant group would like to link with any isolated firms. So for the dominant group to be an equilibrium the isolated firm must find the link unprofitable. Let us define  $X(k)$  as the difference in payoff with and without a link. This yields us the following incentive constraint for isolated firms.

$$X(k) \equiv \frac{(n-1)\gamma}{(n+1)^2} [2(1-\gamma_0) + (n-1)\gamma - 2k(k-1)\gamma] < c. \quad (16.9)$$

We see that the marginal returns to the isolated firm are declining in the size of the dominant group. An increase in costs of forming links will make it smaller dominant groups sufficient to deter the isolated firms from forming a link. The left panel of Figure 16.10a illustrates the incentives of firms in the dominant group and the isolated firms as a function of the size of the dominant group.

In this figure, the terms  $F0, F1, F2$  and  $F3$  are defined as follows:

$$F0 = \frac{(n-1)\gamma}{(n+1)^2} [2(1-\gamma_0) + (n-1)(3-2n)\gamma]$$

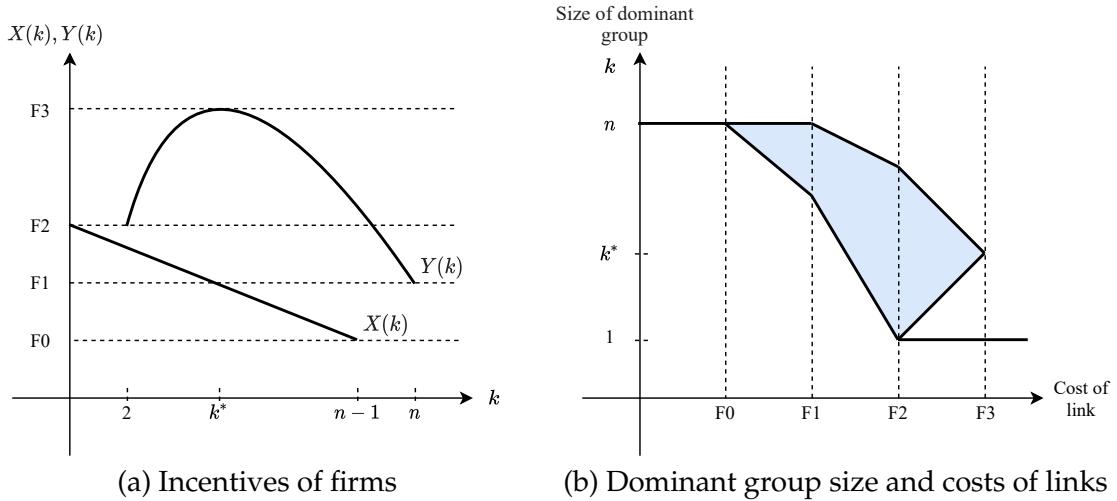

Figure 16.10: Dominant Group and Costs of Links. Taken from Goyal and Joshi [2003]

$$F1 = \frac{(n-1)\gamma}{(n+1)^2} [2(1-\gamma_0) + (n-1)(3-n)\gamma]$$

$$F2 = \frac{(n-1)\gamma}{(n+1)^2} [2(1-\gamma_0) + (n-1)\gamma]$$

$$F3 = Y(k^*)$$

We see that at low costs of forming links the incentive constraint of an isolated firm is binding. As the costs of links increase, smaller dominant groups are sufficient to discourage an isolated firm from forming a link. This suggests that larger costs of links will sustain a wider range of dominant group sizes. However, there is a complication: once we move beyond a certain cost level, the incentive constraint for a firm in the dominant group comes to bind. This implies that at high cost levels, small and large dominant groups are not sustainable and only medium sized groups are sustainable. The right hand panel of Figure 16.10b summarizes these findings.

Our discussion draws attention to a number of points. We see that for a wide range of costs of linking, equilibrium networks will contain a moderate sized dominant group. Networking opportunities give rise to asymmetries. These asymmetries are economically significant: firms in the dominant group have more links and lower costs than firms outside. In a model of quantity competition, this means they have a larger market share. We can go further and show that firms in the dominant group will also earn more profits. A question at the end of the chapter asks you to work through the computations.

The results in this section show how firms can use collaboration links as a strategy to create market dominance and increase profits. But the architecture of these networks differs from the empirically observed networks in one critical aspect: empirical networks

have a core set of firms that have links with a large number of firms who are relatively poorly linked. Let us re-examine the model to understand the forces that may push toward this architecture.

### 16.4.2 Transfers and Market Power

In our model, the marginal returns to a firm from an additional link are increasing in own links and declining in the links of others. When a high degree firm forms a link with a low degree firm, it earns a higher marginal payoff as compared to the low degree firm. Thus a high degree firm may have an incentive to offer transfers to a low degree firm to encourage link formation.

Let  $t^i = \{t_{i1}^i, \dots, t_{in}^i\} \in \mathcal{R}^n$ , with  $t_{ij}^i$  being the transfer from firm  $i$  to firm  $j$  on link  $g_{ij}$ . We will assume that  $t_{ij}^i \geq 0$ , for all  $i, j \in N$ , and that  $t_i^i = 0$ , for all  $i \in N$ . Once transfers are allowed a link is attractive for firms  $i$  and  $j$  so long as the joint marginal returns exceed the total costs of the link. Let us define a notion of stable networks that builds on the idea of pairwise equilibrium and incorporates this idea.

**Definition 16.2.** A network  $g$  is stable against transfers if:

1. For all  $g_{i,j} = 1$ ,  $[\Pi_i(g) - \Pi_i(g - g_{i,j})] + [\Pi_j(g) - \Pi_j(g - g_{i,j})] > 2c$ .
2. For all  $g_{i,j} = 0$ ,  $[\Pi_i(g + g_{i,j}) - \Pi_i(g)] + [\Pi_j(g + g_{i,j}) - \Pi_j(g)] < 2c$ .
3. There exist transfers  $t^i \in R^n$ ,  $i = 1, 2, \dots, n$  such that

$$\Pi_i(g) - \eta_i(g)c - \sum_{j \in N_i(g)} (t_{ij}^i - t_{ji}^j) \geq \Pi_i(g_{-i}). \quad (16.10)$$

where  $\Pi_i(g_{-i})$  refers to the profit of firm  $i$  after it deletes all its links. As payoffs remain as before, it follows that there can be at most one non-singleton component in a stable network. Note that the dominant group was sustained by the resistance of the isolated firm to forming a link. However, now a firm in the dominant group can offer a transfer to induce an isolated firm to form links. Moreover, once it forms a link with one isolate firm, the increase in total number of links among other firms lowers the marginal payoffs of any other isolated firm. However, the marginal returns to the dominant group go up, as it now has one more link. It turns out that the positive effect on the dominant firm dominates the negative effect on the isolated firm. As a result, once a dominant firm forms a link with one isolated firm it will go all the way and form a link with all isolated firms (by suitably raising the transfers). We state this as a property that we will invoke to establish results about networks that are stable against transfers.

**Property.** Suppose  $g$  is stable against transfers. If  $g_{i,j} = 1$  for distinct  $i, j \in N$  then  $g_{i,k} = 1$  for all  $k \in N$  such that  $\eta_k(g - g_{i,k}) \geq \eta_j(g - g_{i,j})$ .

This property helps us establish that the star network is stable against transfers.

**Proposition 16.5.** Let  $n \geq 4$ . Suppose that payoffs are given by (16.5). Then there exist  $F_H$  and  $F_L$ , where  $0 < F_L < F_H$ , such that the star network is stable against transfers if and only if  $c \in (F_L, F_H)$ .

Let us work through the details of the computations to appreciate the role of transfers in generating market power and augmenting the profits of well connected firms.

Suppose that  $g^s$  is a star network; denote the central firm by  $n$  and typical firms at the spokes by  $i$  and  $j$ . If firm  $n$  deletes all its links then the resulting network is empty,  $g^e$ . If firm  $i$  or firm  $n$  deletes a link, then we get the network  $g^s - g_{n,i}$ . They will wish to maintain their link if

$$[\pi_n(g^s) - \pi_n(g^s - g_{n,i})] + [\pi_i(g^s) - \pi_i(g^s - g_{n,i})] > 2c. \quad (16.11)$$

The requirement that firms  $i$  and  $j$  do not have an incentive to form a link may be written as follows:

$$[\pi_i(g^s + g_{i,j}) - \pi_i(g^s)] + [\pi_j(g^s + g_{i,j}) - \pi_j(g^s)] < 2c. \quad (16.12)$$

We wish to define transfers such that firms have no incentives to isolate themselves by deleting all their links. There exist transfers  $t_i$ , for  $i = 1, 2, \dots, n$ , such that

$$\begin{aligned} \pi_n(g^s) - (n-1)c + \sum_{j \in N_n(g)} (t_j^n - t_n^j) &\geq \pi_n(g^e) \\ \pi_i(g^s) - c + (t_n^i - t_i^n) &\geq \pi_i(g^s - g_{n,i}), \forall i \in N \setminus \{n\}. \end{aligned} \quad (16.13)$$

The (gross) profits for firms under different networks are:

$$\begin{aligned} \pi_n(g^s) &= \frac{[1 - \gamma_0 + (n-1)^2\gamma]^2}{(n+1)^2}, \quad \pi_n(g^e) = \frac{[1 - \gamma_0]^2}{(n+1)^2}, \\ \pi_n(g^s - g_{n,i}) &= \frac{[1 - \gamma_0 + (n-2)(n-1)\gamma]^2}{(n+1)^2}, \\ \pi_i(g^s) &= \frac{[1 - \gamma_0 + (3-n)\gamma]^2}{(n+1)^2}, \quad \pi_i(g^s - g_{n,i}) = \frac{[1 - \gamma_0 - 2(n-2)\gamma]^2}{(n+1)^2}, \\ \pi_i(g^s + g_{i,j}) &= \frac{[1 - \gamma_0 + 2\gamma]^2}{(n+1)^2}. \end{aligned}$$

After substitution and rearrangement, we can rewrite (16.11) as follows.

$$\frac{\gamma(n-1)[4(1-\gamma_0) + (n-1)\gamma(2n-3) - \gamma(3n-7)]}{(n+1)^2} > 2c.$$

Similarly, (16.12) can be rewritten as follows:

$$\frac{2\gamma(n-1)[2(1-\gamma_0) + \gamma(2-n+3)]}{(n+1)^2} < 2c. \quad (16.14)$$

Define:

$$F' = \frac{\gamma(n-1)[4(1-\gamma_0) + (n-1)\gamma(2n-3) - \gamma(3n-7)]}{2(n+1)^2},$$

$$F_L = \frac{2\gamma(n-1)[2(1-\gamma_0) + \gamma(2-n+3)]}{2(n+1)^2}.$$

Conditions (16.11) and (16.12) are satisfied if and only if the fixed costs are such that  $F_L < f < F'$ . It is easily verified that  $F_L < F'$  if  $n > 3$ .

Finally, let us construct the transfers. For the star to be stable it must be the case that the spokes do not have an incentive to form a link with each other. Given the symmetry in their situation, it follows that their marginal payoffs from the additional link are the same. This requirement taken along with increasing returns implies that if the star is to be stable then it must be the case that each of the spoke firms also do not have an incentive to form a link with the central firm. Thus transfers have to be made by the central firm to each of the spokes. The minimum value of this transfer is given by:

$$t_n^i = \pi_i(g^s - g_{n,i}) - \pi_i(g^s) + c.$$

Given the above expressions we can rewrite this minimum transfer as:

$$t_n^i = c - \frac{(n-1)\gamma[2(1-\gamma_0) - \gamma(3n-7)]}{(n+1)^2}.$$

We wish to show that the central firm has an incentive to make such transfers to each of the spoke firms rather than delete all links. This incentive is satisfied if and only if:

$$\pi_n(g^s) - (n-1)(c + t_n^i) \geq \pi_n(g^e).$$

After some rearrangement this requirement can be expressed as:

$$\frac{(n-1)\gamma[4(1-\gamma_0) + (n-1)^2\gamma - \gamma(3n-7)]}{(n+1)^2} \geq 2c.$$

Define:

$$F'' = \frac{(n-1)\gamma[4(1-\gamma_0) + (n-1)^2\gamma - \gamma(3n-7)]}{2(n+1)^2}.$$

It can be checked that  $F'' > F_L$ , for all  $n > 3$ . Define  $F_H = \min\{F', F''\}$ . ■

Transfers are critical to the emergence of a star network. If the marginal returns of a peripheral firm from the link with the central firm are positive then it follows, from the property of increasing returns in own links, that the peripheral firm would also want to form links with all the other peripheral firms. Thus a star is only stable in a situation where the links in the star are not individually profitable for the peripheral firms. In other words, all the links between the central firm and the peripheral firm are sustained by transfers from the central firm! The network is sustained by transfers from the central firm. It is possible to show that in spite of these transfers, the central firm earns a larger payoff as compared to the peripheral firms. A question at the end of the chapter works through these computations.

The arguments above can be used to build a general description of networks that are stable against transfers. Consider a partition of firms (based on degrees)  $\{h_1(g), \dots, h_m(g)\}$  with  $h_l(g) \cap h_k(g) = \emptyset$  for  $l \neq k$ , and  $\cup_{l=1}^m h_l(g) = N$ . Following Mahadev and Peled [1995], we define a nested split graph as follows.

1. For  $i \in h_1(g)$ ,  $g_{i,j} = 1$  if and only if  $j \in h_m(g)$ .
2. If  $g_{i,j} = 1$  for  $i \in h_l(g)$  and  $j \in h_{l'}(g)$ , then  $g_{i,k} = 1$  for any  $k \in h_{l''}(g)$  where  $l'' \geq l'$ .
3. Suppose  $i \in h_{m-l}(g)$ . Then  $g_{i,j} = 1$  if and only if  $j \in h_k(g)$ , for  $k > l$ .

We note that as we move up the partition, the neighbourhood of a firm in layer  $l$  is nested within the neighbourhood of firms in layer  $l+1$ . Equipped with this definition, we establish the following result.

**Proposition 16.6.** *Let  $n \geq 4$  and  $g \neq g^c$  be a connected network. If  $g$  is stable against transfers then it has a nested split graph structure.*

Figure 16.11 presents nested networks that are stable against transfers for the case of  $n = 6$ . The reasoning underlying the nested split structure is as follows. Consider a connected network  $g$  that is stable against transfers. Suppose that firm  $i \in \mathbb{N}_{x_1}$ . Since the network is connected,  $\eta_i(g) \geq 1$ . It is possible to show that it does not form a link with any  $j \notin \mathbb{N}_{x_m}$ . If  $i$  did form a link then from Property 16.4.2 it follows that firm  $j$  would have a link with all firms, i.e.,  $j \in \mathbb{N}_{x_m}$ , a contradiction. Since  $\eta_i(g) \geq 1$ , it must form a link with  $k \in \mathbb{N}_{x_m}$ , but then from property 16.4.2 it follows that  $\eta_k(g) = n - 1$  and so  $x_m = n - 1$ . A

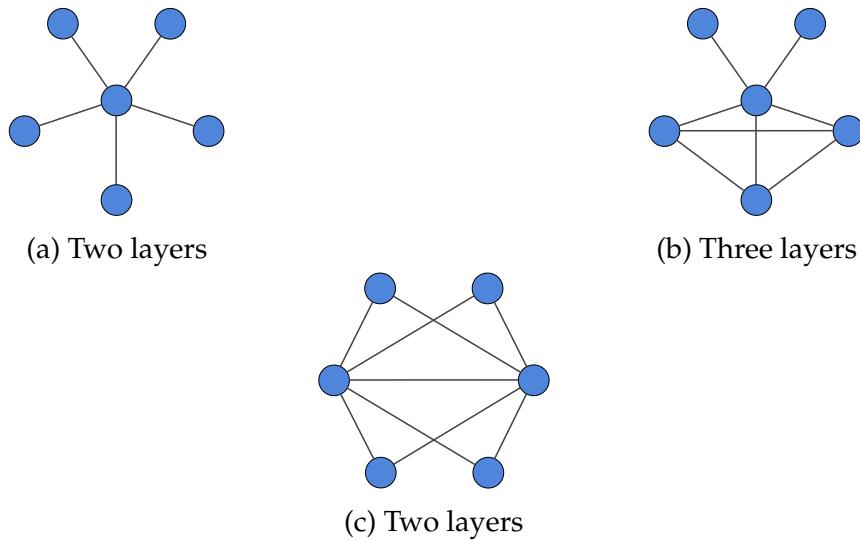

Figure 16.11: Nested-split graphs,  $n = 6$

question at the end of the chapter works through the arguments that show how stability against transfers satisfies the different properties of a nested split graph.

Let us summarize what we have learnt in this section. Research collaboration among firms has powerful effects on the competitive position of firms. These effects can be further reinforced if firms are allowed to make side payments and transfers – as would be involved for instance in technology exchange agreements between a large firm and a start-up. The reinforcement of advantages can give rise to nested-split graph structures. In these networks firms earn very unequal profits.

## 16.5 Reading Notes

The study of exchange and power in social networks has a long tradition in sociology; for early contributions see Homans [1961], Blau [2017] and Emerson [1976]. It was recognized early on by these authors that a network creates possibilities for trade and bargaining power and also gives rise to considerations of equity. Cook and Emerson [1978] present an early experiment on how network location shapes the division of surplus among the actors that prefigure some of the main themes of research and Cook and Emerson [1987] provide a good summary of the early work in this field. For an overview of some of the sociology research on economic exchange and price formation also see Granovetter [2005].

The issues of bargaining power were central to the early work on networks in economics, see e.g., Myerson [1977a]. The role of networks was also highlighted in early work by Kirman [1997], Weisbuch et al. [2000] and Tesfatsion [1997]. Starting with Corominas-

Bosch [2004] and Polanski [2007] a number of papers in the economics literature have explored the issue of bargaining power in networks. In the model of Corominas-Bosch [2004] the bargaining process is centralized: a single price is announced to all linked traders at the same time. In recent work, Abreu and Manea [2012] study a model with decentralized matching: in every period a single pair of linked traders is picked to bargain. They show that this change from centralization to decentralized trading can have large effects: bargaining may end in disagreement, a pair of traders may refuse to trade at one stage but agree to trade at a subsequent point. The interested reader is referred to Manea [2016] for an excellent overview of the research on bargaining in networks.

Price formation may be based on posted prices and auctions. We presented, very briefly, a discussion of auctions in networks. For an early and influential contribution to this subject, see Kranton [1996b]. Our discussion, both in the bargaining problem as well as in the auction case, draws attention to the role of link formation in shaping the architecture of networks and the efficiency of the trading system. For a systematic exploration on inefficiencies in bilateral trading networks, we refer the reader to Elliott [2015] and Elliott and Nava [2019]. Finally, it is worth noting that all the work we have discussed in this chapter assumes that traders know the network. The issue of price formation with imperfect information on valuations and networks remains an active field of research. For a sophisticated treatment of bargaining with incomplete information see Condorelli, Galeotti, and Renou [2017]. For an introduction to the study of behaviour with incomplete network information the reader should refer to the chapter on human behaviour in networks.

There is a large body of research on middlemen and intermediaries and it is clearly not possible to provide a good coverage of the main ideas within the space of a chapter. In our choice of material, we have focused on research where networks play a central role. Condorelli and Galeotti [2016] provide a very comprehensive overview of the theoretical literature. One way of organizing this large literature is to consider the “price” formation protocol used – auctions, bargaining or posted prices. We have presented models with posted prices and bargaining and (only briefly discussed) auctions. In addition to the papers mentioned in the chapter, we would like to mention the following other contributions. On posted prices see Acemoglu and Ozdaglar [2007], on bargaining see Gofman [2011] and Siedlarek [2015]. We have restricted attention to models where traders choose prices; for models where traders choose quantities the interested reader is referred to Babus and Kondor [2018], Malamud and Rostek [2017] and Nava [2015].

In the model of bargaining presented in the chapter it was assumed that every seller knows the value of the good to the buyers. In many settings, the value of the good is known to some but not to other traders. Condorelli, Galeotti, and Renou [2017] study a situation

where the good either has value Low or High to a trader. This valuation is independent of other's valuations and is private information. Trading proceeds as follows: the current owner makes a take-it-or-leave-it offer to a 'neighbor'. If the neighbor accepts then trade takes place, if not then he makes an offer to other neighbors. The process of bargaining can reveal the private information of traders. The authors show that in equilibrium High valuation traders always consume the product they own while Low valuation traders seek out potential trading partners. The novelty relative to the earlier bilateral bargaining literature, is that search for a high valuation trader will involve possibly many other traders (in the network). A trader that lies on all paths between a trader  $i$  and the original seller may be thought of as a 'critical' node: such nodes earn higher payoffs. For a general discount factor  $\delta \in (0, 1)$ , the analysis is intricate and trading exhibits complicated behavior: prices may be non-monotonic and trading inefficient. However, in the limit, as  $\delta \rightarrow 1$ , trading is efficient: the traders will locate a High valuation trader (if one exists).

Research collaboration among firms is widespread with potentially important implications for the performance of firms and the functioning of the economy at large. The traditional approach to collaboration is to consider coalitions of firms, notable early contributions include Bloch [1995] and d'Aspremont and Jacquemin [1988]. Following Goyal and Moraga-Gonzalez [2001] and Goyal and Joshi [2003] there is now also a large literature on R&D networks; for a study of efficient R&D networks see Westbrock [2010], for a systematic study of nested-split graphs see König, Tessone, and Zenou [2014], and for a detailed study of empirical patterns on R&D networks see Konig, Liu, and Hsieh [2021]. For a mathematical treatment of nested-split graphs the interested reader is referred to Mahaev and Peled [1995]. We discussed a simple model based on oligopoly competition to bring out the economic aspects of collaboration. Research collaboration among firms has also been extensively studied in sociology, organization theory, and business strategy. We mention three themes in this work that bear upon R&D networks.

In the model of R&D alliances we presented, the implicit assumption is that there is no informational asymmetry between firms – about skills and expertise or about the level of research effort. In practice, there will exist significant informational asymmetries that will give rise to a variety of incentive problems (and large transaction costs). To mitigate these pressures, a firm may prefer repeated collaboration with existing partners or to collaborate with firms about whom they can get reliable information via existing and past common partners. These considerations inform the social embeddedness perspective in economic sociology, see e.g., Granovetter [1985], Powell Walter [1990], Gulati [2007], Raub and Weesie [1990], Shan et al. [1994] and Podolny and Page [1998]. Networks also shape the nature of contracts and governance structures on collaboration links between firms. Collaboration

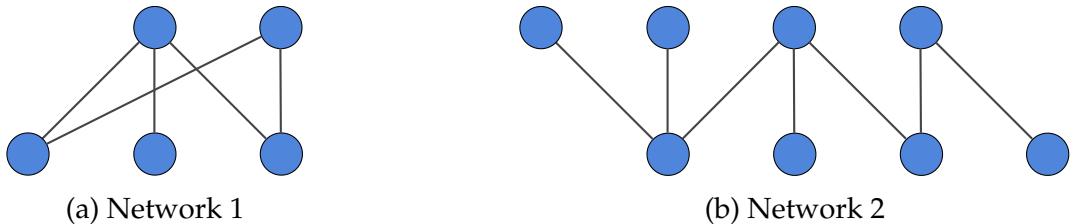

Figure 16.12: Buyer-Seller Networks

agreements become less formal if partners are embedded in social networks of previous collaboration links; for an overview of this research see Gulati [2007].

A second comment pertains to the theoretical modeling. We assumed that firms could join any number of alliances but these alliances were restricted to being bilateral. In actual practice, firms join multiple alliances and the alliances typically have more than 2 partners. This suggests that a more natural model would involve firms that join multiple alliances each of which may be of arbitrary size. The interested reader is referred to Ding, Dziubinski, and Goyal [2021] for a study of stable R&D alliance profiles in such a model.

Collaboration among scientists and academics raises somewhat related considerations and there is a parallel strand of work that explores the role of networks in that sphere; see e.g., Goyal, Leij, and Moraga-González [2006a], Fafchamps, Van der Leij, and Goyal [2010], and Ductor, Fafchamps, Goyal, and Van der Leij [2014]. Fafchamps, Van der Leij, and Goyal [2010] examine the formation of coauthor relations among economists over the period 1970-1999. They find that a new coauthor collaboration emerges faster between two researchers if they are “closer” in the pre-existing coauthor network among economists. This proximity effect on collaboration is strong: being at a ‘distance’ of 2 instead of 3 raises the probability of initiating a collaboration by 27%.

I would like to thank Michael Konig for discussions on R&D networks and Mikhail Safronov for comments on an earlier draft of the chapter.

## 16.6 Questions

1. Jackson [2008] Suppose that the assumptions of the Corominas-Bosch [2004] model hold. Apply the decomposition discussed in the chapter to compute the bargaining payoffs in the networks given in Figure 16.12.
  2. Consider the Corominas-Bosch [2004] model and suppose a link is two-sided and entails a cost  $c > 0$  for each trader. Show that if  $c < 1/2$  then the efficient network will entail a maximal set of disjoint pairs. Show next that, if  $c < 1/2$  and the discount

factor is close to 1, then pairwise stable networks (as defined in chapter on costs and benefits of links) coincide with efficient networks.

3. Let us consider a market with price setting firms. The sellers and buyers are located in a bipartite network. Every firm has a unit good to sell with reservation value 0. Consumers' utility from good is 1 and is known to firms. Every firm sets a single price and the network is commonly known.
  - (a) Show that if two sellers are linked only to a single consumer then they cannot set a price 1 in equilibrium.
  - (b) If there is a consumer who is linked to only one seller then the seller who is linked to this captive consumer can always make a profit of 1.
  - (c) Consider a network with 3 sellers and 3 consumers. Seller 1 is linked to consumers 1 and 2, seller 2 is linked only to consumer 2, while seller 3 is linked to consumers 2 and 3.
    - Compute the pricing equilibrium in this network.
    - Compute the outcome of the Corominas-Bosch [2004] bargaining game in this network.
    - How would you explain the differences in prices and allocation of surplus in these two games?
4. Consider the model of auctions in networks. Suppose that stage 2 is as in the example presented in the chapter but that in stage 1, linking is two-sided. Suppose a seller and a buyer have to both pay a cost  $c$  for a link to be created. Examine the incentives to create links and compare efficient and pairwise stable networks in that example.
5. In the bargaining model of intermediaries, suppose that final buyer has a valuation of 1 and that each trader has a small but positive transaction cost  $c$ . Consider the network in Figure 16.13. Using the ideas of critical traders and bargaining power, show that in equilibrium the object will move via intermediary 1 or 2 and the object reaches the final buyer via at least three intermediaries.
6. (Goyal and Joshi [2003]) Consider the two-stage model of network formation and price or quantity competition (as discussed in the chapter). Show that with small costs of linking complete network maximized social surplus with quantity competition, while a network with two maximally connected firms maximizes social welfare under price competition.

7. Consider the model of network formation and quantity competition as presented in the chapter. Show that firms in the dominant group network earn higher profits as compared to isolated firms.
8. Consider the model of network formation and quantity competition and allow for transfers among firms (as in the chapter). Show that in the star network the central firms earn higher profits as compared to the peripheral firms.
9. This question works through different properties of networks that are stable against transfers.
  - (a) Suppose  $g$  is connected and not complete. Show that it must contain firms with different degrees. Use property 16.4.2 to establish that there must be a difference of at least two degrees between any two firms who have different degrees.
  - (b) Note that if  $i, j \in h_1(g)$  and  $g$  is connected then  $\eta_i \geq 1$ . Next show that  $i$  cannot be connected to a firm outside  $h_m(g)$ . So it must be connected to a firm in  $h_m(g)$ . Then apply Property 16.4.2 to show that a firm with highest degree must have degree  $n - 1$ .
  - (c) Apply Property 16.4.2 to establish part (ii).
  - (d) Property (iii) is proved using an argument by induction. Start with  $l = 1$  and show that if  $i \in h_{m-1}(g)$  then  $g_{i,j} = 0$ , for  $j \in h_1(g)$ . Next suppose that the hypothesis is true for  $\hat{l} \geq 1$  and show that it also holds for  $\hat{l} + 1$ .
10. Consider the model of linking with competing firms. Suppose that the firms initially have different costs of production. Discuss how this might alter incentives for linking and shape networks.
11. Consider the model of linking with competing firms. Suppose next a setting in which firms have different costs of linking. A natural way to model such differences is to suppose that firms can be divided into groups – based cultural, legal, market, or geographical proximity. The costs are low within a group but high across the groups. Reason about how such differences in costs of links can shape networks.

# **Chapter 17: Communities and Economic Growth**

## **17.1 Introduction**

Modern economic growth of nations has two distinctive features: in *all* cases it involves a sustained and substantial rise in product per capita, and in *almost all cases* it involves a sustained and substantial rise in population. .... implying even higher rates of growth of total product. (Page 14, Kuznets [1961])

It has long been the majority view among sociologists, anthropologists, political scientists, and historians that .. (economic) behavior was heavily embedded in social relations in premarket societies but became much more autonomous with modernization. This view sees the economy as an increasingly separate, differentiated sphere in modern society, with economic transactions defined no longer by the social or kinship obligations of those transacting but by rational calculations of individual gain. (Page 482, Granovetter [1985]).

This chapter studies the role of communities in the process of economic growth and development.

Sustained economic growth can have very large effects on incomes over time – a rate of increase of 20% per decade means a rise of 6.7 times the initial value over a century; over two centuries, this growth rate will lead to income level over 38 times the initial level! These rates appear to be high but were realized by a number of countries – such as Sweden, United States and France – over the period 1850-1900. Over the period 1950-1990, a number of other countries – such as South Korea and Japan – registered even higher growth rates. Finally, in the years since 1980, China (and in later years India) have recorded even higher growth rates. As economic growth is closely associated with changes in a number of quality of life indicators, its impact on human well-being over a period of time can be enormous.

However, one of the enduring facts about economic growth is that it remains very uneven. A number of countries have achieved sustained growth over the past two hundred years, but there still remain a fairly large number of countries where growth has been slow and there are also a few where growth has barely occurred. This unevenness leads to an examination of the sources of economic growth.

.. a rise in per capita product usually means an even larger rise in product per unit of labor input – since some of the extra product is ordinarily exchanged for more leisure, a concomitant of a higher standard of living. However, marked rises in product per labor unit, when population and therefore labor force are increasing, are usually possible only through major innovations, i.e., applications of new bodies of tested knowledge to the processes of economic production. .. But this also means structural change as new industries appear and old industries recede in importance – which, in turn, calls for the capacity of society to absorb such changes: society must be able to accommodate itself to and adopt the successive innovations that raise per capita productivity. (Page 14, Kuznets [1961]).

If development is about creating new knowledge and investing in its uses to create new products and services, differences in growth must lie in the different responses to new innovations.

We start by briefly recalling the common features of economic development across time and space. The discussion then zooms in to discuss specific cases – relating to migration, education and investments in trade and industry – where we can see different responses of societies to similar opportunities. We examine the role of communities in explaining these differences.

Communities. – and more generally social networks – perform a number of functions in developing countries. An important role is to support business activity: a small number of communities dominate trade and manufacturing sector in many developing countries – expatriate Indian communities dominated East African business during and even after British colonial rule until the 1970's; ethnic Chinese have controlled business in South East Asia and the dominance may have grown with trade liberalization. In India, a small number of Hindu castes and non-Hindu communities continue to dominate business activity. A second role for community connections is to find jobs for their members. Friends and members of the origin community in Europe helped secure jobs for migrants to the American Midwest during the 19th and early twentieth century. Caste-based working class formed in the Indian cities that grew under British colonial rule and they remain prominent to this

day. A third role for community based networks is to provide insurance for their members. Private sector and state provision of insurance is limited – agrarian economies face weather related uncertainties that generate fluctuations in income. Social arrangements provide wide ranging help to households in the face of such shocks in smoothing their consumption.

These functions of community based networks interact powerfully with the opportunities that the development process opens up for individuals: we present three empirical case studies – on migration, on patterns of education choice, and on the transition from agriculture to manufacturing – to illustrate this point. These case studies motivate an enquiry into the role of social structure in shaping individual responses.

We introduce a simple model that locates individuals in a social network and considers their level of engagement in a network activity and their take up of a market opportunity. Network activity involves personalized interaction and reciprocal exchange – the returns to an individual from taking part in it are thus increasing in the number of their ‘neighbours’ who are also active in networks. The market opportunity is anonymous and agents are price-takers. The key issue is the relation between network activity and market opportunity: we say that they are ‘substitutes’ if greater network activity lowers the returns from market opportunity and we say that they are ‘complements’ if greater network activity enhances the returns from market opportunity.

As returns from network activity are increasing in the number of neighbours who take it up, we can use our analysis of games of complements in chapter 4. We drew attention to the role of a *q*-core of the network as the maximal group of active individuals. Building on that analysis, we show that when networks and markets are substitutes, individuals within the *q*-core stay out while those outside it take up the market opportunity. By contrast, when the two activities are complements, individuals within the (relevant) *q*-core take up both the network and market activity, while those outside it remain inactive on both dimensions. Denser networks lead to larger *q*-cores: in the case of substitutes this will mean a lower take up of market opportunity and in the case of complements it will mean a higher level of take-up.

New market opportunities can in principle benefit or harm a society. Our analysis reveals that when network activity and market opportunity are substitutes, the appearance of markets can leave everyone worse off, due to negative externalities of people moving out of social networks. On the other hand, in the complements case, taking up market opportunity raises participation in the network and therefore creates positive spillovers for everyone, thereby necessarily raising social welfare. Our model also sheds light on the question of whether new market opportunities raise or lower inequality. In the substitutes

case, inequality in the traditional society is necessarily lowered; in the complements case, the converse holds.

We next turn to the effects of economic change on social structure. A key feature of the process of economic growth is the movement of labour from agriculture to manufacture and services. This is accompanied with a corresponding movement of people from the rural countryside to the cities. The salience of this large scale process has led many scholars to take the position that, while historically, economic life was bound up in with social relations (involving family and close relations), modern economic life is largely divorced from such social ties. We start by presenting case studies on bank accounts, microfinance, and community driven development programmes that illustrate the capacity of social ties to metamorphose and reconfigure during the process of change. In some cases, social ties weaken, while in other cases they strengthen. These case studies thus pose a challenge to the traditional perspective on the role of social ties in economic activity. We conclude by arguing that the economic principle of whether markets and social ties are complements or substitutes is also helpful in understanding these empirical patterns on the evolution of social networks over time.

## 17.2 The patterns of economic growth

We start by presenting basic statistics on per capita income for a group of countries in Table 17.1. The obvious point to note is that even in 2018, after almost a century of political movements and research on the determinants of economic growth, the differences in per capita incomes across countries remain very great. There are countries like Australia and United States and Germany with per capita incomes in excess of 55,000 USD, and at the same time we have several large countries such as Bangladesh, Congo, and Kenya with per capita incomes below 2000 USD.

These numbers give us a first impression of the range of income levels; this variation remains very great even after adjustments are made for price and commodity bundle differences across countries. For instance, even at Purchasing Power Parity (PPP), in 2018, a number of large countries have per capita income that is less than one tenth of the per capita income of the United States.

We noted in the introduction how even small rates of per capita growth can lead to a massive aggregate change if they are sustained over fifty years or a hundred years. The other side to this observation is that starting from a certain income today and moving back in time, a relatively short stretch of time will bring us to a point where income is very low. Indeed it would be difficult to sustain life if income were any lower. In other

COUNTRIES	US DOLLARS	PPP
Australia	57,396	51,036
Bangladesh	1698	4550

words, *sustained economic growth is very much a modern phenomenon*. It is this realization that inspires the hope that differences in per capita incomes can be bridged relatively quickly, if only there was a good understanding of the process of economic growth.

Table 17.2 presents growth rates of select countries over the past fifty and the past hundred years. There is enormous variation in growth rates – as noted in the introduction, some countries – like Japan and Korea – have sustained rates of growth of income of over 50% for every decade over the fifty years. Even more impressively, China’s per capita income has grown 65% every decade. On the other hand, a number of large countries have hardly registered any growth – for instance, Congo actually registered a decline in per capita income, Ghana grew by 8.5% and Argentina grew at the modest rate of 13% per decade, over the past fifty years.

COUNTRIES	PC INCOME 50 YRS	POPN 50 YRS	PC INCOME 100 Yrs	POPN 100 YRS

Table 17.2: Percent Change per Decade – past 50 and 100 years. Source: Bolt et al (2018).

It is important to bear in mind the difference in the environment for the first countries that created sustained economic growth – such as England and France – as compared to the situation faced by poor countries in the contemporary world, with a significant number of very much richer countries. This point is brought out by the next set of data on incomes of these countries over the past 25 years. Table 17.3 presents per capita income (in purchasing power parity) on the same set of countries but now expressed as a ratio of the US per capita. We see that while some countries like China have registered large gains but that other countries have registered little movement and several countries (e.g., Pakistan, Congo, and South Africa) have actually fallen further behind.

Table 17.3: Per Capita Incomes relative to US. Source: World Bank 2018.

The income levels may be seen as creating different levels of opportunity. But it is possible to look more directly at measures of human well being. We present data on life expectancy and adult literacy. Figure 17.1 suggests that literacy can range from 40% to 100% and life expectancy can range from 55 years to 85 years. This is an extraordinarily wide range. It is interesting to observe also that the two quality of life indicators are highly correlated with per capita income up to the point where a country attains an per capita income of around USD 20K. Robert Lucas sums up the power of these data very powerfully:

Rates of growth of real per-capita income are ... diverse, even over sustained pe-

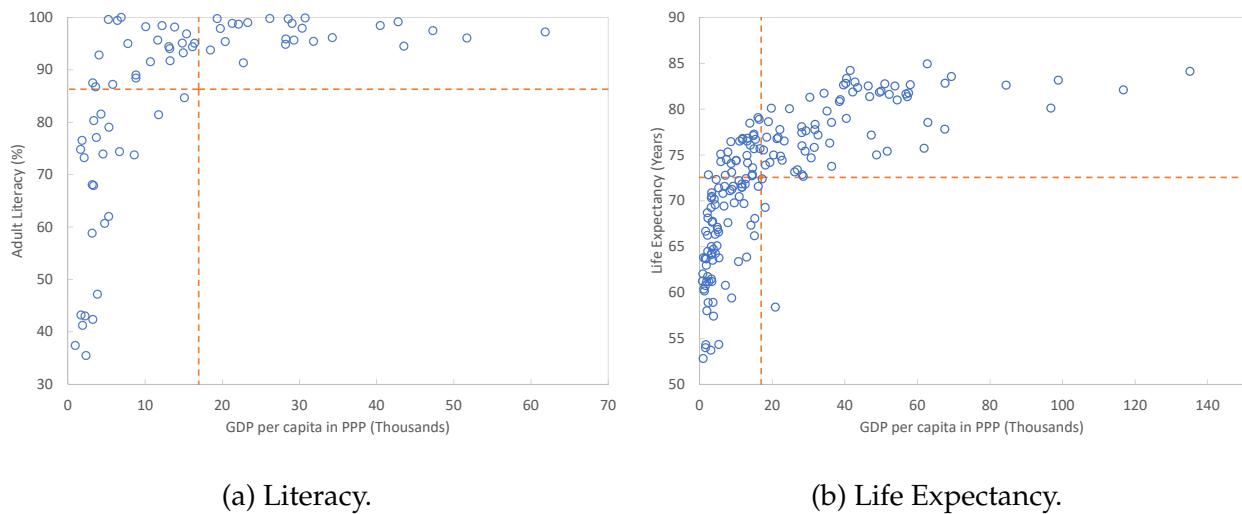

Figure 17.1: Quality of Life and Per-capita Income. Source: World Bank 2018

riods ... Indian incomes will double every 50 years; Korean every 10. An Indian will, on average, be twice as well off as his grandfather; a Korean 32 times.... We do not see how one can look at figures like these without seeing them as representing possibilities. Is there some action a government of India could take that would lead the Indian economy to grow like Indonesia's or Egypt's? If so, what, exactly? If not, what is it about the "nature of India" that makes it so? The consequences for human welfare involved in questions like these are simply staggering: once one begins to think about them, it is hard to think about anything else. Robert Lucas, 1985 Marshall Lectures, University of Cambridge.

One way to describe economic growth is to say that it involves a change in the types of economic activities that are undertaken by a society. This can be seen in the changes in allocation of labour force and aggregate output across broad sectors of the economy. It is customary to separate economic activity in three sectors – agriculture and related industries, such as forestry and fishing; mining, manufacturing and construction; and all other activities. Perhaps the most striking change in the process of economic growth is the change in share of agriculture. Figure 17.2 presents the relation between share of agriculture in labour force and share of agriculture in national income, in relation to the per capita income. We see that share of agriculture in labour force moves from 80% to 1%, and the share of agriculture in national income similarly moves from 50% to 1%, as we move from very poor to the richest countries. This is a very robust feature of economic growth – an increase in per capita income is accompanied by a significant fall in the importance of agriculture as a share of the national economy.

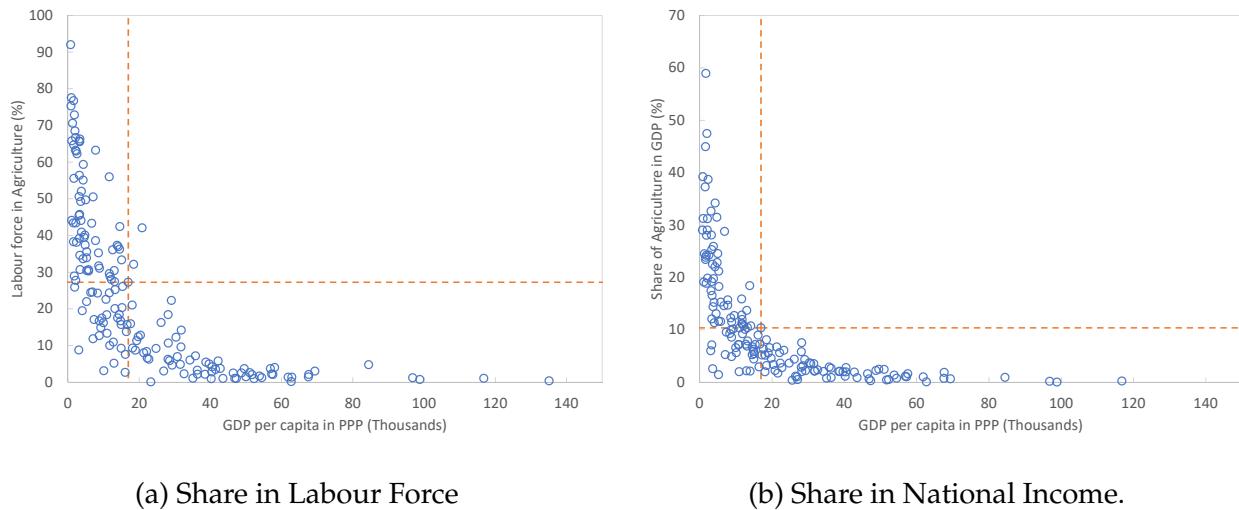

Figure 17.2: Agriculture in Economy. Source: World Bank 2018

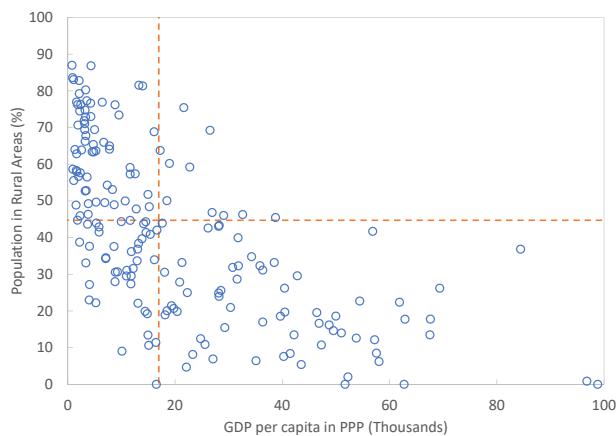

Figure 17.3: Share of Rural Population. Source: World Bank 2018

The rural-urban relation is central to the process of economic growth. There are two flows in this relation – the flow of labour from farms to factories and the flow of food from agriculture to cities to feed the workers who have left the farms. Figure 17.3 presents the relation between per capita income and share of rural population. We see that share of rural population falls progressively as we move up the income levels – all the way from 80% to less than 20%.

In the first half of the twentieth century the early theories of growth and development were deeply concerned about the relationship between agriculture and the rest of the economy. There was an early realization that agriculture must be able to spare labour and that productivity must grow in agriculture so that it could feed the labour that moved to in-

dstry. Fundamental to this process of growth therefore was the relocation of labour away from villages and countryside to cities – in other words, large scale migration.

However, this raises the question: once labour has moved on to manufacturing, what are the possibilities for further growth?

.... a rise in per capita product usually means an even larger rise in product per unit of labor input – since some of the extra product is ordinarily exchanged for more leisure, a concomitant of a higher standard of living. However, marked rises in product per labor unit, when population and therefore labor force are increasing, are usually possible only through major innovations, i.e., applications of new bodies of tested knowledge to the processes of economic production. .. But this also means structural change as new industries appear and old industries recede in importance – which, in turn, calls for the capacity of society to absorb such changes: society must be able to accommodate itself to and adopt the successive innovations that raise per capita productivity. (Page 15, Kuznets [1961]).

Ever widening circles of scientific discovery and continuous technological change are central to sustained economic growth.

Continuous technological progress and, underlying it, a series of new scientific discoveries are a necessary condition for the high rate of modern growth in per capita income combined with a substantial rate of growth in population. As evidence, we need only note the industries that loom large in an advanced economy: many of the electrical, internal combustion, and chemical fields were entirely unknown a hundred years ago, and even the older industries are permeated by processes whose origin lies in relatively recent scientific discoveries. (Pages 29-30, Kuznets [1961]).

We may therefore describe economic growth as a process of the sustained creation and ever deeper and wider use of new knowledge. This suggests that one way to understand the uneven rates of growth in different countries is to examine the ways that communities and social structure shape the take up of new opportunities.

### 17.3 Traditional society and new opportunities

We start by presenting specific historical experiences on the responses of communities to new economic opportunities – migration, education, and investment in trade and manufacturing. These case studies motivate an enquiry into general principles regarding the

role of social structure in shaping responsiveness of individuals and communities to new opportunities.

### **Example 17.1. Investments in Trade and Manufacturing**

China has witnessed the same degree of industrialization in three decades as Europe did over the course of two centuries; for a discussion on this growth see Greif and Tabellini [2017]. This economic transformation began in the early 1980's with the establishment of township-village enterprises (TVE's) and accelerated with the entry of private firms in the 1990's. Starting with almost no private firms in 1990, there were 15 million registered private firms in 2014 (they accounted for over 90% of all registered firms in the country). Alongside this growth in numbers, the share of registered capital held by private firms has grown sharply: by 2014, private firms held 60% of all registered capital in the economy. China's growth has had profound effects on the flow of goods and services and capital and on balance of political influence across the world.

Governments at the local (county), provincial, and central level played an important role in China's economic transformation. There still remains the question of how this growth in private firms occurred without effective legal systems and well functioning financial institutions, i.e., without the preconditions generally believed to be necessary for market-based development. How did millions of individuals who were born in rural areas transition into the role of entrepreneurs, set up and successfully run such a vast array of extraordinarily successful companies? ■

### **Example 17.2. Migration**

We have seen that a central element in the process of economic development is the transformation of the economy from one in which most people work in agriculture and live in villages to an economy in which most people work in manufacturing or services and live in cities. The pace of rural to urban migration is thus a key factor in economic development. There are big differences in this rate. Our discussion here draws on Munshi and Rosenzweig [2016].

In India, the rural-urban wage gap (after corrected for cost-of-living differences) was 25 percent in 2000 – this gap is large and it has remained so for decades. This gap is also significantly larger than the wage-gap in other large developing countries such as China and Indonesia – one estimate puts the difference to be as large as 16% higher for India. This large wage gap is accompanied by relatively low levels of rural-urban migration in India. For instance, the rate of rural-urban migration as a fraction of rural population was around 5.34% for India in 2005, while it was close to 14% for Brazil for 1997

The low migration mobility in India is reflected in its urbanization rates. For the period 1975–2000, consider the relative rates across four large developing countries: Indonesia, China, India, and Nigeria. Urbanization in all four countries was low in 1975 – around 15-20 percent of the population lived in cities. However, India fell far behind the rest by 2000 – the fraction of urbanized population is almost 15 percent lower than in the other three countries. What are the reasons for these differences in migration rates across these countries? ■

### Example 17.3. Education

One of the commonly observed features of economic growth is that literacy becomes universal and large sections of the population go in for secondary and post-secondary school education. There are major differences in the rate at which education is adopted by different countries and by different communities within a country. We briefly discuss take-up of English language education in Mumbai, to bring out the role of social networks in shaping take-up rates. The discussion here draws on Munshi and Rosenzweig [2006].

Mumbai was a leading manufacturing centre in India throughout the 20<sup>th</sup> century. In the last decade of the century, larger scale liberalization of the Indian economy led to a shift in the city's economy toward the corporate and financial sectors. Jobs in these sectors required a knowledge of English, unlike most jobs in the manufacturing sector. As these sectors expanded, returns to learning English grew substantially. Over the period 1980–2000, the returns to years of schooling increased only slightly for both men and women. On the other hand, the English premium increased sharply – rising from 15% in 1980 to 24% in 2000 for men, and from negligible in 1980 to 27% in 2000 for women.

This rise in returns to English elicited a strong response from families with children of school-going age children: enrollment rates in English-medium schools grew significantly for both boys and girls and for all castes. At the start, in 1980, there are large differences across castes in the take-up of English language schooling for both boys and girls. The fraction of high caste boys and other (medium and low) castes going to English language schools was 45% and 10%, respectively, while the fraction of high caste girls and other castes going to English language schools was 35% and 15%, respectively. Over the twenty year period, 1980–2000, the differences across caste persists for boys, but narrow significantly for girls: the fraction of high caste boys and other castes going to English language schools was 60% and 35% respectively, while the fraction of high caste girls and other castes going to English language schools was 45% and 35%, respectively. Why did the lower-caste boys fail to take advantage of the new economic opportunities as well as the girls? ■

We present a theoretical model to help us uncover general principles that can help us

understand the relation between social networks and market opportunities in these three cases.

## 17.4 A Theoretical Model

The model presented in this section is taken from Gagnon and Goyal [2017]. There is a community with  $n$  individuals. The social relations between these individuals are reflected in a social network  $g$ . Ties are binary (and undirected):  $g_{ij} \in \{0, 1\}$  for any pair of individuals  $i$  and  $j$ . Individuals can take part in network activity  $x$  – this could be sharing labour services or sharing income – and a market opportunity  $y$  – such as learning a language, migrating, or investing in a new enterprise. Suppose for simplicity that both  $x$  and  $y$  are binary –  $x_i \in \{0, 1\}$  and  $y_i \in \{0, 1\}$ . Let  $a_i$  denote the action choice of person  $i$  and let  $\mathbf{a}$  denote the profile of actions chosen. A key variable is the number of neighbours who choose the network opportunity. Let

$$\chi_i(\mathbf{a}) = \sum_{j \in N_i(\mathbf{g})} x_j \quad (17.1)$$

be the number of neighbours who choose the network action. Let  $\Phi_i(\mathbf{a} \mid \mathbf{g})$  denote individual  $i$ 's payoffs under action profile  $\mathbf{a}$  in a network  $\mathbf{g}$ . If an individual abstains from network exchange, then the network does not affect her payoffs: choosing  $x_i = 0$  may be thus interpreted as “leaving the network”. If an individual chooses inactivity,  $a_i = (0, 0)$ , then she earns 0. The payoffs to the market action by itself, i.e.,  $a_i = (0, 1)$ , are given by  $\pi_y \in \mathbb{R}$ . If individual  $i$ 's chooses  $a_i = (1, 0)$  her payoffs are given by  $\phi_0(\chi_i(\mathbf{a}))$  and if she chooses  $a_i = (1, 1)$  they are given by  $\phi_1(\chi_i(\mathbf{a}))$ . To summarize,

$$\Phi_i(\mathbf{a} \mid \mathbf{g}) = \begin{cases} 0, & \text{if } a_i = (0, 0) \\ \pi_y, & \text{if } a_i = (0, 1) \\ \phi_0(\chi_i(\mathbf{a})), & \text{if } a_i = (1, 0) \\ \phi_1(\chi_i(\mathbf{a})), & \text{if } a_i = (1, 1) \end{cases} \quad (17.2)$$

We note that payoff function  $\phi_i(\cdot)$  is the same across individuals. This is a useful starting point as it allows us to focus on network based differences between individuals. Towards the end of this section we will discuss how heterogeneity across individuals along other dimensions such as talent or wealth would interact with network differences.

Network based activity involves individuals carrying out favours or barter exchange. It is therefore reasonable to suppose that payoffs from the network action  $x$  display local

complementarity:

**Assumption 17.1.** Both  $\phi_0(\cdot)$  and  $\phi_1(\cdot)$  are strictly increasing in  $\chi_i(\mathbf{a})$ .

Turning to the relation between the network and market opportunities, the key idea is that the market action affects the marginal returns from network action: Define the function

$$\xi(\chi_i(\mathbf{a})) = \phi_1(\chi_i(\mathbf{a})) - \phi_0(\chi_i(\mathbf{a})) - \pi_y. \quad (17.3)$$

Observe that  $\xi(\cdot)$  is the difference between the marginal returns to  $x$  when  $y_i = 1$ ,  $\phi_1(\cdot) - \pi_y$ , and the marginal returns to  $x$  when  $y_i = 0$ ,  $\phi_0(\cdot) - 0$ .

Network and market actions are said to be *substitutes* if  $\xi(\cdot)$  is negative and (weakly) decreasing in  $\chi_i(\mathbf{a})$ . They are said to be *complements* if  $\xi(\cdot)$  is positive and (weakly) increasing in  $\chi_i(\mathbf{a})$ . Thus, our notion of substitutes combines a substitutes relation between an individual's network action and market action and a strategic substitutes relation between the network action of his neighbors and his own market action. The relation between social networks in traditional occupations with semi-skilled labour and markets for white collar jobs may be seen as example of substitutes. In a similar spirit, our definition of complements subsumes a complements relation between an individual's network and market action and a strategic complements relation between the network action of his neighbors and his own market action. Trust in traditional community ties may be seen as a complement to trading in products with high but uncertain valuation like diamonds.

**Assumption 17.2.**  $\xi(0) = 0$ . Network and market actions are either substitutes or complements.

We suppose that  $\xi(0) = 0$ : this is a simplifying normalization: if no one in the neighbourhood adopts action  $x$ , then the network is not “functioning”, and so the action  $y$  does not affect the marginal payoffs from action  $x$ . To develop intuitions underlying the arguments, it is helpful to consider the following example of a payoff function.

$$\Phi_i(\mathbf{a} | \mathbf{g}) = (1 + \theta y_i)x_i \chi_i(\mathbf{a}) + y_i - p_x x_i - p_y y_i \quad (17.4)$$

where  $p_x \geq 0$  and  $p_y \geq 0$ , respectively, are the prices of actions  $x$  and  $y$ . Observe that  $x$  and  $y$  are substitutes for  $\theta \in [-1, 0]$  and complements for any  $\theta \geq 0$ . We now study the nature of equilibrium and how it depends on the primitives of the model – the network  $g$  and the relation between market and network opportunities  $\theta$ .

To develop a feel for the economic trade-offs involved and how they shape individual choices let us work through an example with the linear payoffs example as in (17.4). Let us set  $\theta = -1.0$ ,  $p_x = 4.1$  and  $p_y = 0.5$ . This is the case of substitutes. Observe that

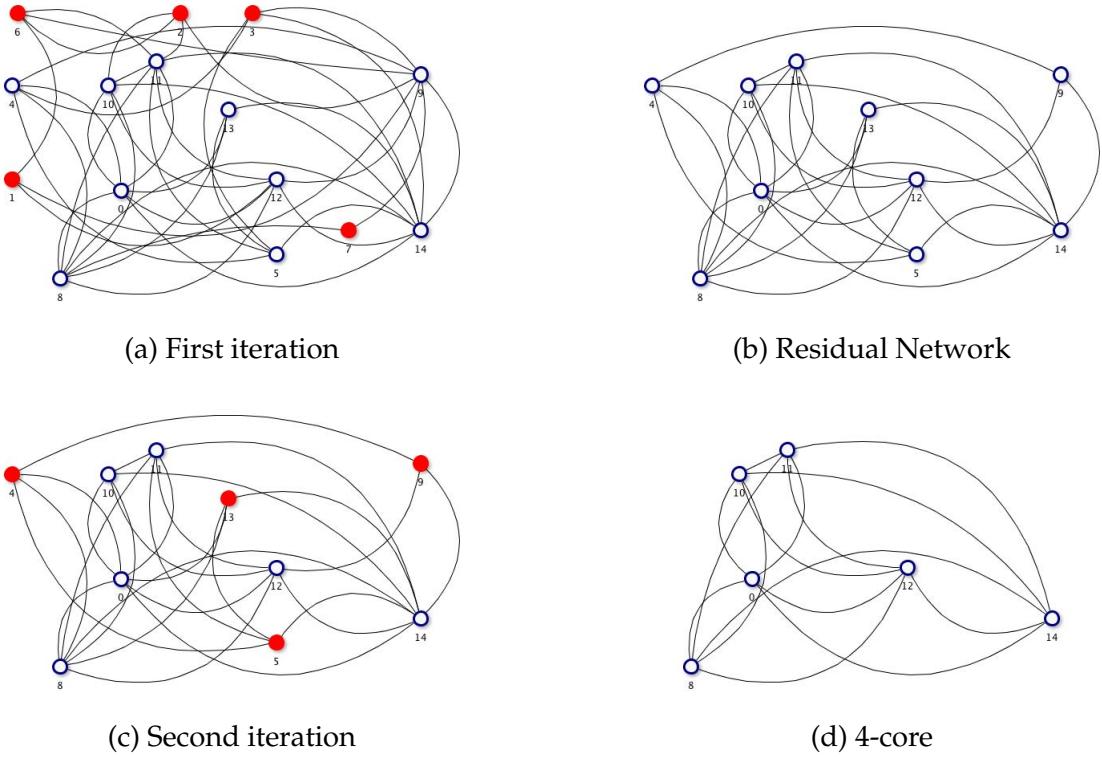

Figure 17.4: Algorithm to obtain q-core

$\pi_y = 1 - 0.5 > 0$ : market activity on its own is profitable and therefore that inactivity,  $a_i = (0, 0)$ , is never optimal. Next observe that  $a_i = (1, 1)$  is never optimal: the payoff from  $a_i = (1, 1)$ ,  $-p_x + 1 - p_y R$  is always smaller than the payoff from action  $a_i = (0, 1)$ ,  $1 - p_y$ . To compute the optimal action we therefore need to compare pure network activity with pure market activity. It is easily verified that pure network activity is more profitable if and only if  $\chi_i \geq 5$  (as this is the lowest integer greater than 4.1). So, for an individual to choose network activity she must have at least 5 neighbours also choose it. It now follows, from reasoning as in chapter on network games, that the maximal group of individuals who will choose network activity corresponds to 4-core of the network. Figure 17.4 illustrates the derivation of a 4-core. All individuals outside the 4-core will take up the market action.

Consider next the setting with complements: set  $\theta = 1.1$ , also put  $p_x = 7.5$  and  $p_y = 2$ . Market action is not profitable on its own as  $\pi_y = 1 - 2 < 0$ . Next observe that  $a_i = (1, 0)$  is never optimal: for it to be optimal the  $\chi_i - p_x \geq 0$ , which means that  $\chi_i > 0$ . However, payoff from  $a_i = (1, 1)$ ,  $(1 + 1.1)\chi_i - p_x + 1 - p_y$  is always larger than  $\chi_i - p_x$  because  $\theta = 1.1 > p_y - 1$ . To compute the optimal action we therefore need to compare action  $a_i = (1, 1)$  with the payoff from inactivity. Simple computations reveal that joint network activity and market action are optimal if and only if  $\chi_i \geq 5$ . So, for an individual to choose network activity she must have at least 5 neighbours choose the network activity. It now follows,

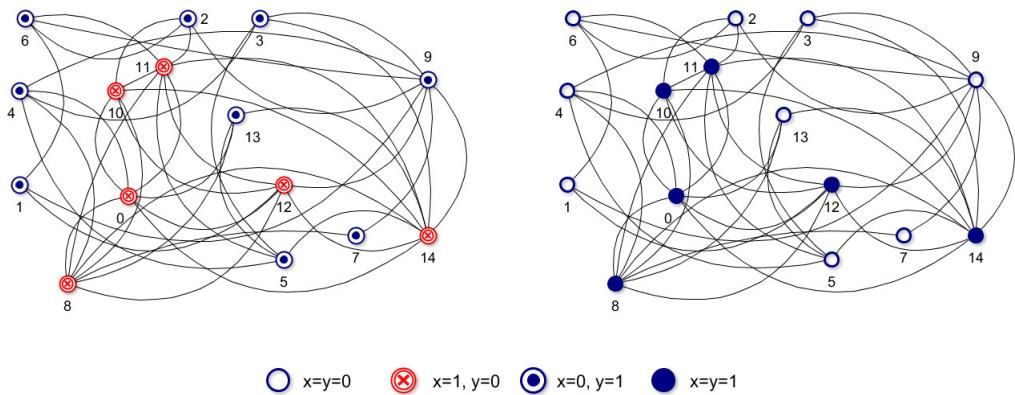

Figure 17.5: Adoption Patterns: Left – substitutes ( $\theta = -1$ ,  $p_x = 4$ ,  $p_y = 0.5$ ). Right – complements ( $\theta = 1.1$ ,  $p_x = 7.5$ ,  $p_y = 2$ ).

from reasoning as in chapter on network games, that the maximal group of individuals who will choose network activity corresponds to 4-core of the network. All individuals outside the 4-core will take up inactivity.

These computations serve as a basis for more general arguments concerning individual choices across a wide range of payoff functions. First, we observe that as in the weakest link game, the local complementarity in the network action,  $x$ , creates the potential for coordination failure and the possibility of zero activity outcomes. As the interest is on the interaction between network and market action, it is simplest to abstract from the coordination problem in the network activity. In what follows, in this chapter, we will therefore focus on the maximal equilibrium – an equilibrium  $a^*$  is said to be *maximal* if there does not exist another equilibrium that Pareto-dominates it. Restricting attention to maximal equilibrium is helpful as, for a given payoff function and a given network, there exists a unique maximal equilibrium.

**Proposition 17.1.** *Suppose that Assumptions 17.1 and 17.2 hold. For a given network  $\mathbf{g}$ , a maximal equilibrium exists and is generically unique.*

We begin with existence in the complements case: start from a profile with everyone choosing  $a_i = (0, 0)$ . Iterate through best responses: noting that actions are complements, any increase in action  $x$  by one individual provokes a further increase (weakly) in others' actions. As the action set is binary, the process must converge and the limit is an equilibrium. In the substitutes case, the argument is a little more involved and exploits the payoff structure more directly to construct different types of equilibrium in the cases where the market action alone is attractive and where it isn't. Existence of maximal equilibrium follows from noting that the set of strategies, and hence the set of equilibria, is finite.

Next consider the case of substitutes: it is helpful to separate the analysis into two parts.

1.  $\pi_y \leq 0$ : If  $\phi_0(0) > 0$ , then  $a_i^* = (1, 0)$  for all  $i \in N$  is an equilibrium. If  $\phi_0(0) \leq 0$ , then  $a_i^* = (0, 0)$  for all  $i \in N$  is an equilibrium.
2.  $\pi_y > 0$ : If  $\phi_1(0) \leq \pi_y$ , then  $a_i^* = (0, 1)$  for all  $i \in N$  is an equilibrium. Lastly, if  $\phi_1(0) > \pi_y$ , then  $a_i^* = (1, 1)$  for all  $i \in N$  is an equilibrium (due to complementarity in returns from action  $x$  across individuals).

Turning to uniqueness, suppose that there exist two distinct profiles  $\mathbf{a}$  and  $\mathbf{a}'$  that are both maximal equilibria. This means that there exist individuals  $i$  and  $j$  such that  $i$  does strictly better under  $\mathbf{a}$ , while  $j$  fares strictly better under  $\mathbf{a}'$ .

Consider first the case of complements. Define a new profile  $\hat{\mathbf{a}}$ , with  $\hat{x}_i = \max\{x_i, x'_i\}$  and  $\hat{y}_i = \max\{y_i, y'_i\}$  for all  $i$ . If  $\hat{\mathbf{a}}$  constitutes an equilibrium, then it follows that  $\hat{\mathbf{a}}$  Pareto-dominates  $\mathbf{a}$  and  $\mathbf{a}'$  as there is a strict inequality for at least a pair of agents. This contradicts the hypothesis that  $\mathbf{a}$  and  $\mathbf{a}'$  are maximal equilibria. If  $\hat{\mathbf{a}}$  does not constitute an equilibrium, then iterate using best responses starting from  $\hat{\mathbf{a}}$ . Observe that all actions are complements, so best responses can only lead to an increasing number of individuals choosing  $x = 1$  and/or  $y = 1$ . As in the existence proof, this process converges and the limit is an equilibrium. Note that at every iteration stage, the payoffs of every individual are weakly rising relative to  $\hat{\mathbf{a}}$ , which again contradicts the hypothesis that  $\mathbf{a}$  and  $\mathbf{a}'$  are maximal.

Finally, consider uniqueness in for the substitutes case. Construct a profile  $\hat{\mathbf{a}}$ , where  $\hat{x}_i = \max\{x_i, x'_i\}$  and  $\hat{y}_i = \min\{y_i, y'_i\}$  for all  $i$ . Suppose that  $\hat{\mathbf{a}}$  constitutes an equilibrium. Clearly, the payoffs of all individuals choosing  $x = 1$  under either  $\mathbf{a}$  or  $\mathbf{a}'$  must be weakly larger in  $\hat{\mathbf{a}}$  (due to local complementarity in  $x$ ). Note also that an individual  $k$  switches from  $y_k = 1$  (or  $y'_k = 1$ ) to  $\hat{y}_k = 0$  only if  $\min\{y_k, y'_k\} = 0$ . As the payoffs from  $y$  are independent of others' choices, this must entail a weak increase in individual  $k$ 's payoffs. Hence,  $\hat{\mathbf{a}}$  Pareto-dominates  $\mathbf{a}$  and  $\mathbf{a}'$ , a contradiction to the hypothesis that  $\mathbf{a}$  and  $\mathbf{a}'$  are maximal equilibria. The case where  $\hat{\mathbf{a}}$  does not constitute an equilibrium can be studied by iteration as in the complements case above: details are omitted.

■

We now turn to understanding the relation between networks and equilibrium behaviour. An individual chooses between four possible opportunities, namely  $(0, 0)$ ,  $(1, 0)$ ,  $(0, 1)$ , and  $(1, 1)$ . Recall that both  $\phi_0(\cdot)$  and  $\phi_1(\cdot)$  are strictly increasing in level of network activity. Assuming that these payoffs increase sufficiently, there exist  $q_1 \geq 0$  and  $q_2 \geq 0$  such that

$$\phi_0(\chi_i) > \max\{0, \pi_y\} \text{ if and only if } \chi_i > q_1 \quad (17.5)$$

$$\phi_1(\chi_i) > \max\{0, \pi_y\} \text{ if and only if } \chi_i > q_2 \quad (17.6)$$

Next, recall from the definition of substitutes, in equation (17.3), that  $\phi_0(\cdot)$  increases “faster” than  $\phi_1(\cdot)$  with respect to  $\chi_i \in \mathbb{N}_+$ . This means that there exists a  $q_3 \geq 0$  such that:

$$\phi_0(\chi_i) > \phi_1(\chi_i) \text{ if and only if } \chi_i \geq q_3 \quad (17.7)$$

Similarly, in the case of complements, there exists a  $q_4 \geq 0$ , such that

$$\phi_1(\chi_i) > \phi_0(\chi_i) \text{ if and only if } \chi_i \geq q_4 \quad (17.8)$$

The network and market opportunities are strong substitutes if they are substitutes and  $q_3 < q_1$ . They are strong complements if they are complements and  $q_4 < q_2$ . Observe that strong substitutes rule out cases where  $a_i = (1, 1)$  is optimal for any  $\chi_i \in \mathbb{N}_+$ . Following a similar logic, we note that strong complements rules out action  $a_i = (1, 0)$  being optimal for any  $\chi_i \in \mathbb{N}_+$ . It can be verified that in the payoff function example 17.4 presented the network activity,  $x$ , and the market action,  $y$ , are strong substitutes if  $\theta \in (-1, 0)$  and  $\theta(n - 1) < p_y - 1$ ; they are strong complements if  $\theta > 0$  and  $\theta > p_y - 1$ .

In the case of strong substitutes, only individuals in the  $q_1$ -core will choose  $a_i = (1, 0)$ , while those outside it will either choose  $a_i = (0, 1)$ , if  $\pi_y > 0$ , or  $a_i = (0, 0)$ , if  $\pi_y \leq 0$ . To develop some intuition, consider the case where  $\pi_y \leq 0$ . Individuals therefore choose between  $a_i = (1, 0)$  and  $a_i = (0, 0)$ . They prefer the network action if they have at least  $q_1$  neighbours who choose  $x = 1$ . Observe that if all individual in the  $q_1$ -core do choose  $x = 1$ , then it follows that condition (17.5) is satisfied for all individuals in the  $q_1$ -core. Hence, players in the  $q_1$ -core all obtain larger payoffs by playing  $(1, 0)$  than by remaining inactive – the converse is true for players outside the  $q_1$ -core.

In the case of strong complements, only individuals in the  $q_2$ -core choose  $a_i = (1, 1)$ , while individuals outside the  $q_2$ -core choose either  $a_i = (0, 1)$  (if  $\pi_y > 0$ ) or  $a_i = (0, 0)$  (if  $\pi_y \leq 0$ ). Consider the case where  $\pi_y > 0$ . Individuals choose between  $a_i = (1, 1)$  and  $a_i = (0, 1)$  and prefer the former if and only if condition (17.6) is satisfied. If all individuals in the  $q_2$ -core choose  $x = 1$ , then (17.6) is satisfied for individuals in the  $q_2$ -core, and so all individuals in the  $q_2$ -core (and these individuals only) must strictly prefer  $a_i = (1, 1)$  to  $a_i = (0, 1)$ .

We summarize the discussion as follows:

**Proposition 17.2.** Suppose that Assumptions 17.1 and 17.2 hold. Let  $\mathbf{a}^*$  be the maximal equilibrium.

1. **Strong Substitutes.**  $a_i^* = (1, 0)$  if and only if  $i \in \mathbf{g}^{q_1}$ . If  $i \notin \mathbf{g}^{q_1}$ , then  $a_i^* = (0, 0)$  in case  $\pi_y \leq 0$ , and  $a_i^* = (0, 1)$  in case  $\pi_y > 0$ .
2. **Strong Complements.**  $a_i^* = (1, 1)$  if and only if  $i \in \mathbf{g}^{q_2}$ . If  $i \notin \mathbf{g}^{q_2}$ , then  $a_i^* = (0, 0)$  in case  $\pi_y \leq 0$ , and  $a_i^* = (0, 1)$  in case  $\pi_y > 0$ .

In words, if networks and markets are strong substitutes then all individuals in  $\mathbf{g}^{q_1}$  choose network activity only. Individuals outside  $\mathbf{g}^{q_1}$  choose the market action only if  $\pi_y > 0$  and choose inactivity if  $\pi_y \leq 0$ . If networks and markets are strong complements: all individuals in  $\mathbf{g}^{q_2}$  choose both network and market activity. Individuals outside  $\mathbf{g}^{q_2}$  choose the market action only if  $\pi_y > 0$  and choose inactivity if  $\pi_y \leq 0$ .

To develop a better understanding of the uses of Proposition 17.2, we present equilibrium outcomes in two familiar networks on Figure 17.6: the regular network with degree 3 and a core-periphery (CP) network (with an equal number of nodes and links). In the case of strong substitutes (top panel), peripheral individuals, who benefit the least from network exchange, choose the market action, while all other individuals choose the network action. Everyone chooses the network action in the regular network. In the case of complements, the opposite holds: for the given prices, only the best-connected individuals (in the core of the CP network) can afford to choose the market (and the network) action; all other individuals choose inaction. In the regular network, no one has sufficient connections: inactivity is pervasive.

Figures 17.5 and 17.6 help us appreciate the role of the topology of networks and the strategic relation between market and network activity in shaping behavior.

In the case of substitutes, the first thought would be that highly connected nodes should adopt the network action while less connected nodes adopt the market action. The analysis of the model goes beyond this intuition. Consider the network in Figure 17.5: node 9 has higher degree than node 10, and yet it chooses the market action while the latter chooses the network action. This is because node 10 forms part of the 4.5-core, while node 9 does not. Turning next to the impact of the strategic relation between network and market opportunities, let us compare behavior in the top panel (substitutes) and the bottom panel (complements) of Figure 17.6. In the substitutes case, it is the nodes lying *outside* the relevant  $q$ -core that choose market action, while in the complements case it is the nodes *within* the relevant  $q$ -core that choose this action!

We say that a network  $\mathbf{g}'$  is denser than another network  $\mathbf{g}$  if  $g_{ij} \leq g'_{ij}$  for any pair  $i, j \in N$ , and the inequality is strict for at least one such pair. We say that an individual

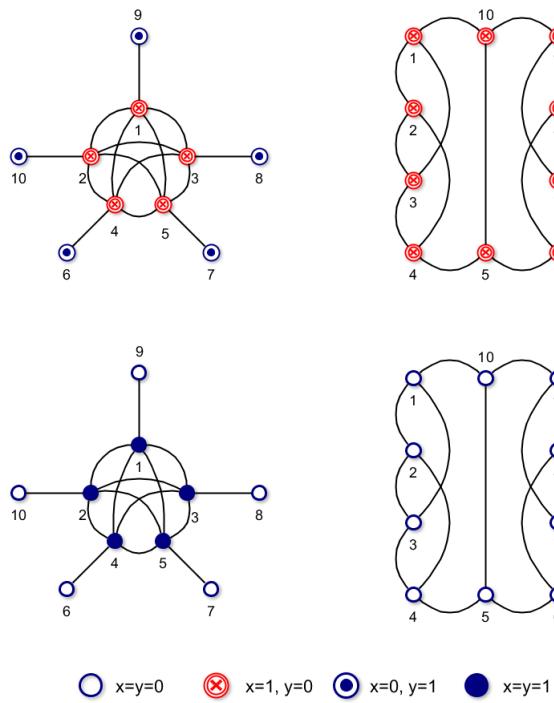

Figure 17.6: Core-periphery and Regular Networks: Top –substitutes ( $\theta = -1$ ,  $p_y = 0.5$ ,  $p_x = 2$ ). Bottom – complements ( $\theta = 1$ ,  $p_y = 1.5$ ,  $p_x = 6$ ).

is well connected if she lies in the appropriate  $q$ -core (e.g.  $q_1$ -core in the case of strong substitutes,  $q_2$ -core for strong complements).

Proposition 17.2 tells us that the key to market participation is the size of  $\mathbf{g}^q$  and the value of  $\pi_y$ . For instance, in the case of strong substitutes, if  $\pi_y > 0$ , then the set of market participants is simply the complement of the set  $\mathbf{g}^{q_1}$ . Similarly, in case of strong complements if  $\pi_y < 0$  then every individual in  $\mathbf{g}^{q_2}$  adopts the market action. This suggests that, loosely speaking, market participation is falling in the size of the core set in case of substitutes, while the converse is true in the case of complements. This suggests that market participation is (weakly) lower in denser networks when  $x$  and  $y$  are substitutes, and (weakly) larger when they are complements. Moreover, the market action  $y$  is adopted by less connected individuals in the case of substitutes, and by the well connected in the case of complements.

Our theoretical framework allows for an examination of the circumstances under which the introduction of markets is welfare-enhancing. To do so, we compare welfare in a society before and after the arrival of market action  $y$ . Given a network  $\mathbf{g}$  and action profile  $\mathbf{a}$ , aggregate welfare is given by:

$$W(\mathbf{a} \mid \mathbf{g}) = \sum_{i \in N} \Phi_i(a_i, \mathbf{a}_{-i} \mid \mathbf{g}). \quad (17.9)$$

In the case of complements, the introduction of  $y$  (weakly) facilitates the adoption of the network action  $x$ . The introduction of  $y$  thus implies (weakly) larger individual payoffs, for everyone, and hence a larger aggregate welfare. However, if  $x$  and  $y$  are substitutes, the effects of the introduction of the market are less clear. A switch away from the network activity to the market action by some individuals leads to a fall in the payoffs of the individuals who remain with the network action. This negative effect can dominate any gains the market participants enjoy. The following example illustrates this point. **question on welfare**

#### Example 17.4. When markets lower social welfare

Consider the core-periphery network in Figure 17.6, and suppose that the payoff function is as in Example 17.4 which we present here for easy reference.

$$\Phi_i(\mathbf{a} \mid \mathbf{g}) = (1 + \theta y_i)x_i \chi_i(\mathbf{a}) + y_i - p_x x_i - p_y y_i \quad (17.10)$$

In this payoff function, fix  $\theta = -0.9$  and  $p_x < 1$ . Prior to the introduction of  $y$ , all individuals choose  $x = 1$ . Suppose now that the market action  $y$  becomes available. If  $0 < 0.1 < p_y \leq p_x < 1$ , then all periphery individuals choose  $y = 1$ , while core individuals stick to  $x = 1$ . Periphery individuals increase their payoffs by  $0 < p_x - p_y < 1$  following their switch. On the other hand, a periphery individual's switch entails a decrease in the benefits of the core individual she is connected to of exactly 1. The net effect of the introduction of the market action is thus strictly negative.

We now turn to the impact of markets on inequality. To appreciate the issues in the simplest way, we examine the ratio of the highest payoffs to the lowest payoffs. Given network  $\mathbf{g}$ , this ratio is denoted by  $\mathcal{R}(\mathbf{p})$ :

$$\mathcal{R}(\mathbf{g}) \equiv \frac{1 + \max\{\Phi_i(a_i^*, \mathbf{a}_{-i}^* \mid \mathbf{g})\}_{i \in N}}{1 + \min\{\Phi_i(a_i^*, \mathbf{a}_{-i}^* \mid \mathbf{g})\}_{i \in N}} \quad (17.11)$$

where  $a^*$  is the maximal equilibrium in network  $g$ .

$\mathcal{R}(\mathbf{g})$  is close in spirit to other traditional metrics of inequality, including the *range*, the *20:20 ratio* or the *Palma ratio*. The range is the difference between the payoffs of the wealthiest and the poorest individuals of a population. The *20:20 ratio* and the *Palma ratio* reflect the payoff ratio of the wealthiest 20 percent to the poorest 20 percent, and the payoff ratio of the wealthiest 10 percent to the poorest 40 percent, respectively. While  $\mathcal{R}(\mathbf{g})$  has

the same structure as these two measures, it requires less information about the payoff distribution and, thus, about the network structure.

Let  $\mathcal{R}_0(\mathbf{g})$  denote the inequality prior and  $\mathcal{R}_1(\mathbf{g})$  its level after the introduction of market action. Note that a rising  $\mathcal{R}(\mathbf{g})$  implies increasing inequality.

In the case of strong substitutes, it is easiest to see the argument when we start from a pre-market situation where well-connected individuals choose  $x$ . The introduction of the market clearly offers the less connected individuals a potentially better option. Their switch to the market action can only lower the payoffs of the best connected who remain with the network action. Hence the minimum payoffs must (weakly) rise and the maximum payoffs must (weakly) fall, with the introduction of the market. Thus markets unambiguously lower inequality.

When  $x$  and  $y$  are strong complements, we can focus on two action profiles  $(0, 0)$  and  $(1, 1)$ . Individuals who benefit the most from network exchange will also benefit the most from markets. When market take-up is partial, markets will thus unambiguously raise inequality. When market penetration is complete ( $\mathcal{M}(\mathbf{g}) = 1$ ), the worst-off individuals may benefit relatively more or less as compared to the best-off individuals from the newly available market  $y$ , depending on the social structure and the payoffs to the two opportunities. The following example elaborates on this point.

### Example 17.5. Networks and Inequality

Consider the network in Figure 17.7 and the payoff function in (17.4). Fix  $p_x = 4.1$ . In such case, the best-off individuals before the introduction of  $y$  are individuals 1 to 6 with payoffs of 0.9, while all other individuals have payoffs 0. This means that inequality is given by  $\mathcal{R}_0(\mathbf{g}) = 1.9$ . Now suppose that  $y$  is introduced at a price  $p_y = 1.05$ . Then, the earnings of individuals 1, 7 and 3 to 6 are 5.85, while those of individuals 2 and 8 to 11, respectively, are 7.85 and 3.85. Consequently,  $\mathcal{R}_1(\mathbf{g}) = 1.825$ , which indicates falling inequality.

Next suppose that  $p_y = 2$ . Then, the payoffs to individuals 1, 7 and 3 to 6 is 4.9, while those of individuals 2 and 8 to 11, respectively, amount to 6.9 and 2.9. Consequently, inequality is given by  $\mathcal{R}_1(\mathbf{g}) = 2.026$ ; there is thus an increase in inequality with the arrival of a market.

We summarize the effects of social structure on social efficiency and inequality as follows.

**Proposition 17.3.** *Consider the interaction between networks and markets.*

- *In the case of strong substitutes, a new market opportunity may lower aggregate payoffs but it (weakly) decreases inequality.*

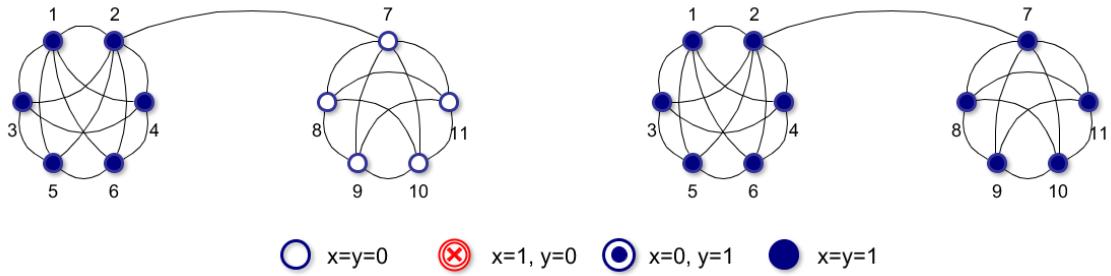

Figure 17.7: Prior to market:  $p_x = 4.1$ . Post Market:  $p_x = 4.1$ ;  $p_y = 1.05$  or  $p_y = 2$ .

- In the case of strong complements, a new market opportunity will raise aggregate efficiency. It will also raise inequality so long as take-up is partial,  $\mathcal{M}(\mathbf{g}) \in (0, 1)$ . If take-up is complete,  $\mathcal{M}(\mathbf{g}) = 1$ , then the effects on inequality are ambiguous.

In the discussion so far, we have assumed that individuals differ only with regard to network location. Individuals may be heterogeneous in other dimensions that affect the extent to which they can benefit from markets (e.g. human capital, initial wealth).

Suppose that the benefits from the market action,  $\pi_y$  are different across individuals. We assume that this heterogeneity does not affect the other determinants of the payoff function (i.e. returns to  $x$  and degree of complementarity between  $x$  and  $y$ ). To bring out the interaction between different types of heterogeneities, consider the following variation of the linear payoffs case:

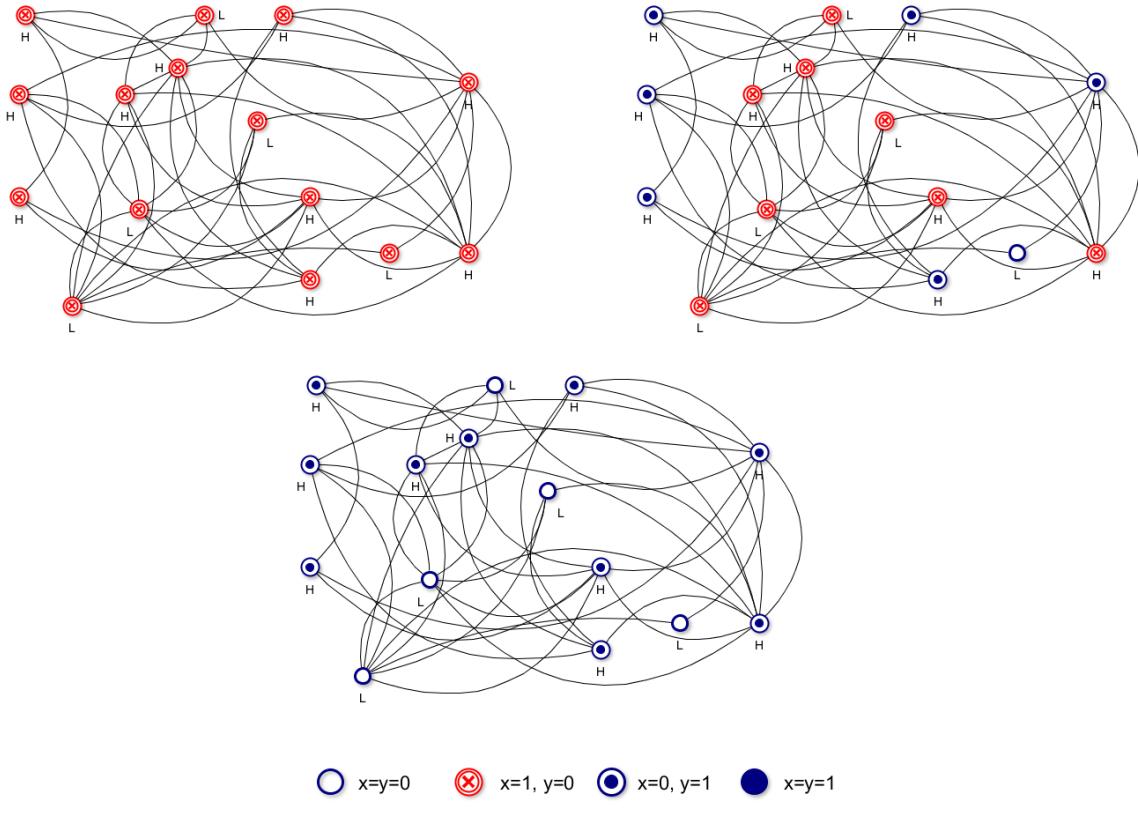

$$\Phi_i(a_i, \mathbf{a}_{-i} | \mathbf{g}) = (1 + \theta y_i) x_i \chi_i(\mathbf{a}) - p_x x_i + \pi_y^i \quad (17.12)$$

with  $\theta = -0.9$ . Suppose that individuals have either “high” or “low” returns from  $y$ , with  $\pi_y^H = 3$  and  $\pi_y^L = -1$ . The first thing to note is that high market value individuals require larger returns from network action  $x$  to remain in the network. Figure 17.8 illustrates the equilibrium adoption of  $x$  and  $y$  for different values of  $p_x$ .

We see that as we move to higher prices for network action, it is the higher value and not the lowest connected individuals who switch to market action (as in top right network). Further, it is possible for the market action to be adopted as a stand-alone by certain individuals, while others opt for  $a^* = (0, 0)$  (as in the bottom network).

Building on these observations, we can develop a general analysis of equilibrium actions with network and market value heterogeneity. A **question at the end of the chapter explores this point.**

Our results on inequality in Proposition 17.3 may change considerably. For instance if returns to market activity,  $\pi_y^i$ , is negatively correlated with membership in the  $q$ -core.

Figure 17.8: Implications of heterogeneity on market action:  $q_H = 2$  and  $q_L = 5$ 

To see this, recall that in our benchmark model, only poorly connected individuals, i.e. those out of the  $q_1$ -core, opt for the market action. These individuals are also the worst off in the pre-market situation, and this explains why inequality always goes down with the introduction of markets in the case of substitutes. But if these poorly connected individuals have high returns to  $y$  while others have no returns at all then the introduction of markets may make the poorly connected individuals the best-off individuals, indeed better off than the erstwhile rich individuals, and thereby exacerbate inequality.

Let us summarize what we have learnt from the theoretical model. We develop a model where individuals located in a social network choose a network action and a market action. The key to our results and to understanding the empirical patterns is the relation between the two activities i.e., whether they are (strategic) complements or substitutes. We show that equilibrium individual behavior can be described in terms of the  $q$ -core of the social network. We show that in the case of substitutes, it is the individuals who benefit the least from network exchange (i.e. individuals outside the  $q$ -core) who adopt markets.

Conversely, in the case of complements, well connected individuals find markets more attractive. Markets always raise aggregate welfare if the two activities are complements, but may lower welfare when the two activities are substitutes. Inequality in social networks is reinforced by markets in case of complements, but lowered in the case of substitutes. We now relate these empirical findings on rise of manufacturing and services, migration and take-up of modern education.

### 17.4.1 Using the model to understand the case studies

In this section we use the model as lens through which to better understand the case studies presented in section 17.3.

*Trading and Manufacturing in China:* In the absence of well functioning markets and legal institutions, how did large scale industrialization and urbanization of China take place? A number of authors have drawn attention to the role of communities in the Chinese growth process (Allen, Qian, and Qian [2005], Daiy, Mookherjee, Munshi, and Zhang [2020], Song, Storesletten, and Zilibotti [2011], Fleisher, Hud, McGuiree, and Zhang [2010], Nee and Opper [2012], Peng [2004], and Greif and Tabellini [2017]).

We start by noting the importance of the production clusters in the Chinese growth process (for a discussion of these clusters also see the chapter on social coordination). Thousands of firms, large and small, many specialized in a strictly defined production process, are agglomerated in a densely populated region, where a specific manufactured consumer good is churned out in very large quantities: these regions are sometimes referred to as the world's "socks city," "sweater city," "kid's clothing city," and "footwear capital". Members from clans and lineages migrate to production clusters in groups. It has been argued that informal mechanisms based on reputation and trust have been at work to allow millions of entrepreneurs, most of whom were born in rural areas, to establish and grow private companies.

Let us briefly discuss lineages in China. Patrilineal lineages – also referred to as clans – have long been associated with Chinese society. Almost a hundred years ago, Max Weber observed that clan organization was well preserved in China (Weber [1951]). A clan rests on blood ties, confers cultural identity, and has clearly nominated leaders. Clans are characterized by rules on obligations that have high ethical standing. Upon taking power in 1949, the Communist Party took a number of steps to suppress lineage organizations: it confiscated clan communal land and properties, deprived clan elders of their power, repealed clan codes, and injected the ideology of class consciousness and class struggle to diffuse clan identity. In spite of an official policy against clans during the communist pe-

riod, there is evidence to show that clans persisted, albeit in a dormant form through the communist period and that they revived greatly after the market reforms of 1979. There is strong empirical support for role of lineages and clans in furthering private enterprise and economic activity in the production clusters.

Seen through the lens of our model, in the setting of China with its limited legal and market institutions, activity in social ties may be seen as complementary to entrepreneurial market activity. In line with our theoretical work, lineages or clans that have dense networks are able to better leverage social connections to grow private enterprises.

*Migration:* Why are levels of rural-urban migration in India much lower than other comparable developing economies? Migration could be low because formal insurance in cities is very weak and/or because informal insurance works particularly well in villages. There is little evidence to suggest that formal insurance is significantly better in other developing countries as compared to India. In addition, research has documented evidence for very high levels of informal risk-sharing throughout the developing world, not just in India.

It would appear that the key is the size of networks that engage in informal insurance: if the group or network is small then consumption will still fluctuate appreciably as the group is too small to smoothen all shocks. On the other hand, if the group is very large then the smoothing would be much more effective. It would seem that what is exceptional about India is the size (and the spatial spread) and scale of caste-based insurance network: as the network is very large and spread out and comprehensive in its coverage, it has the ability to smoothen individual level and even village level shocks a great deal more effectively than in other countries. To put it in the language of our model – in India, villagers are members of networks with larger “q-cores” as compared to villagers in other developing countries. Proposition 17.2 suggests that villagers in India are less likely to take up the market opportunity of migration. This is consistent with the empirical record.

*English Language Education:* Turning next to the education example, the developments can be understood in terms of the theoretical framework as follows: a significant fraction – 68% – of men in blue-collar jobs found their current job through a relative or a member of their sub-caste. Thus network connections appear to be important for blue collar jobs in manufacturing. On the other hand, the prospects of getting a white-collar job appear to depend on number of years of schooling and proficiency in English. Thus networks are relatively unimportant for white-collar jobs. Parents choose the language of instruction: a Marathi language school may be interpreted as action  $x$  in the model, and English language school as a market action  $y$ . These choices are mutually exclusive: in other words, we are in a setting with perfect substitutes, viz.  $\theta$  is close to  $-1$  in Example 17.4.

In lower ranking sub-castes, as girls are not part of the network, they do not expect to secure blue-collar jobs through their network. The situation is very different for boys, as they are part of well functioning networks. Proposition 17.2 suggests that this difference in access to networks will lead girls to take-up English language education more than boys. This difference is consistent with the empirical record. This differential take-up of English education has implications for overall social well being and inequality. Proposition 17.3 suggests as girls move into white-collar jobs their families will withdraw from lower caste networks and that would erode these networks over time. This is costly for those who remain in the networks and may lower welfare of these sub-castes. On the other hand, greater take-up of white collar jobs will raise incomes for girls relative to boys and that will help reduce gender inequality.

## 17.5 *La langue duree*

In the introduction and in section 17.2 we discussed large scale patterns of economic change in a historical context. A key feature of the process of economic growth is the movement of labour from agriculture to manufacture and services. This is accompanied with a corresponding movement of people from the rural countryside to urban living in the cities. Traditionally, the salience of this large scale process has led many scholars to take the position that, while historically, economic life was bound up in with social relations (involving family and close relations), modern economic life is largely divorced from such social ties. The three empirical cases in section 17.3 point in to the resilience and the persistent presence of social networks and point to a reassessment of this perspective.

In the context of migration, social networks can shape the overall rate of movement of people from villages to cities. But, over the past decades, millions of people have moved from villages to cities. A number of studies in India and in other parts of the world demonstrate the emergence and the great resilience of community based networks in shaping the functioning of labour markets in manufacturing and services in cities. Indeed, these community based networks were a major consideration in the second case study above – the adoption of English education: it was the presence of strong working class networks that discouraged the take-up of English education among lower caste men in Mumbai. This case study reveals that, almost a century after the setting up of large mills and factories in Mumbai, community based networks are highly effective – as they continue to exercise a decisive influence on the occupational choices of individuals. The transition from an agricultural rural economy to an urban manufacturing economy leads to an evolution of ties

that can take very different forms depending on the context: in some cases, ties are eroded (as when families leave the working class networks and move into white collar jobs), in other cases the relations are reconfigured and possibly strengthened (as when a community moves collectively into trade and manufacturing sector).

There is therefore a two way flow of influence between community networks and market activity: networks shape participation in markets and markets in turn shape the structure of social networks. This co-evolution of markets and social networks is a central aspect of the economic growth process and it takes place over long periods of time. We have discussed the impact of social networks on participation in markets in section 17.3; here we discuss the flow from markets to networks.

In recent years, a number of researchers have dug deeper into the details of how social ties - and indeed the topology of the network – is affected when traditional communities come in contact with new opportunities in a changing economy. We discuss case studies taken from this line of work to bring out the rich range of spillovers and interdependencies between formal institutions and market opportunities and traditional social ties.

### **Example 17.6. Bank Accounts and Social Ties**

Consider the effects of new bank accounts on the social network of informal ties of borrowing and lending. Our discussion is taken from Comola and Prina [2020].

In 2010, the accounts were offered randomly to women in 19 villages located in the vicinity of the town of Pokhara in Nepal. The bank did not charge any opening, maintenance, or withdrawal fees and pays interest comparable to the alternatives available in the Nepalese market. Customers can make transactions at the local bank-branch offices in the villages, which are open twice a week for approximately three hours, or at the bank's main office, located in downtown Pokhara, during regular business hours. The take-up and usage rates of the savings accounts offered to the treatment group were very high — 84% of the households offered the account opened it and used it actively, depositing an average of 8% of their baseline weekly household income almost once a week for the first year after the accounts. How did these bank accounts affect informal ties between the villagers?

The study of networks is based on a starting survey in 2009 (prior to the offer of the bank accounts) and an end survey in 2011 (conducted after the accounts were offered). In all, the sample included 915 households. In the survey, the female household head was asked to provide a list of people (inside or outside the village) who the household could rely on most (and/or who could rely on them most) for help in cash or in kind and with whom they regularly exchanged gifts and/or loans. Respondents could list as many names as they wished.

At the start, households reported having 1.42 partners, on average, of whom 0.64 lived in the village. The network was therefore very sparse – network density was low, only 2% of the potential within-village links are present – and it was also very fragmented with 312 households (34% of the sample) being isolated. The introduction of bank accounts leaves the number of binary links virtually unchanged: 656 links at start versus 658 at end point. However, there was an important reshuffling in the distribution of links – the probability of a tie between new bank account holders increased and that of ties between non-account holders declined!

### **Example 17.7. Community Development Projects and Economic Networks**

International donors, multilateral organizations, as well as national governments increasingly use bottom-up approaches, such as Community Driven Development (CDD) programs, that involve local communities in project design and implementation. The scale of these programmes is extensive – they represent between 5% and 10% of the overall World Bank lending portfolio; roughly US\$ 85 billion was allocated to supporting close to 400 programs in 94 countries during the decade 2000-2010. We discuss the impact of CDD on informal social ties. Our presentation draws on Heß et al. [2020] and Jaimovich [2015].

The Gambian CDD programme allocated funds for village level development projects to about a third of all rural villages in the country. The programme was implemented between 2008 and 2009 in close to 500 villages that were chosen randomly from a set of 900 eligible poor villages. The resource allocation was equivalent to one half of the households annual income. A major goal of CDD's is to encourage and facilitate community level interaction. To accomplish this, villagers are deeply involved at all stages from identification of the potential projects to their maintenance. A total of 38 meetings are mandated – 20 of which were intended to involve the whole village, while the other 18 involved meetings of community-based organizations. The most common sub-projects are: farm implements and inputs, milling machines, water pumps, seed stores and cereal banking, and draft animals.

Data was collected in 2014 from 56 villages, half of whom had been exposed to CDD. Ties were measured on six economic domains (land, labor, inputs, food, gifts, credit) and also on two social domains – friendship and kinship. The effect of the CDD is estimated by comparing the probability of a link between any two individuals between villages that were and were not exposed to the programme, respectively.

It is helpful to trace out, at a high level, a few channels through which CDD participation can shape informal social ties. One argument would be that by bringing together

villagers in a sustained interaction the programme would also increase informal ties. A second argument would be that CDD exposes the village to markets and uniform prices and this may lead to the substitution away from informal ties toward market relations. A third argument pertains to possibility of elite capture and very unequal benefits accruing from the programme: this could create disputes and disrupt social ties.

The empirical study reveals that the CDD programme led to a more formal economy – it eroded informal economic ties, eliminating roughly one out of six transactions between households, and it raised the number of transactions with individuals outside the village. The loss of ties in villages was higher in villages where the projects performed poorly and also in villages where the gains were shared unequally.

### **Example 17.8. The Market for Diamonds**

Investments in manufacturing or trading require financial and social capital that are often beyond the capacity of a single individual. Individuals may have to turn to their community to put together these forms of capital. We discuss how a historically disadvantaged sub-caste moved from agriculture into the international diamond business using its community network and how its entry led in turn to changes in the network in turn. The discussion is based on Munshi [2011].

Diamonds constitute one of the principal exports for India. But India does not produce rough diamonds. These diamonds are imported, cut and polished in domestic factories, and then exported. The diamond mines of Argyle (Australia) were discovered in 1979. At that time, two traditional Indian communities, the Palanpuris and the Marwaris, controlled the business end of the diamond, while the cutting and polishing was done by a lower caste of agricultural labour contractors, the Kathiawaris. After the supply shock, some of the Palanpuri businessmen, who had branches in Antwerp (in Belgium), helped their Kathiawari contacts enter the business by supplying rough diamonds to them. This initial group of Kathiawari firms encouraged more of their community members to follow: by 2005, there were hundreds of Kathiawari owned firms in the Indian diamond industry.

The first entry of Kathiawars into the market was made possible through connections with well established Palanpuri diamond merchants based in Antwerp. This is the first point where network connections come into play. The second entry occurs after the initial Kathiawari enterprises have established themselves: using strong caste-based community successive members of the entered the diamond market, and as they entered the base of Kathiawari community grew further. An examination of the patterns of transition reveal

that at the start in 1975, almost 70% of the new Kathiawaris who joined the diamond market had parental connections. However, over the next two decades, this fraction declined sharply: by 2004, only 20% of the newly joining Kathiawaris had paternal connections in the diamond industry: they were entering on the strength of the ties with the Kathiawari community.

So far we have discussed the consequences of social networks for behaviour and market entry, but the transition of a community from one activity to another also has consequences for the social network itself. An examination of the patterns of marriage relations within the communities reveals an interesting change: the frequency of intra-industry (and intra-caste) marriages increases significantly for the Kathiawaris. Practically none of the early Kathiawari entrants in the diamond market (those who entered prior to 1975) married within the industry. By 2004, almost 50 percent of the entrants were marrying within the industry. Their (intra-industry) marriage rate was higher than the corresponding marriage rates for the Palanpuris and Marwaris (that remained largely unchanged over this period). ■

### **Example 17.9. Microfinance and Social and Economic Networks**

Muhammad Yunus founded Grameen bank in Bangladesh in 1983. By 2007, Grameen bank had made loans of more than USD 6 billion to micro-entrepreneurs in developing countries. A distinctive feature of the scheme is that it targeted borrowers with no credit history, i.e., those who had limited access to traditional banking. Yunus would go on to win the Nobel Peace prize in 2006 for his work. In the period since 1986, microfinance institutions have grown rapidly: according to the Microcredit Summit (Microcredit Summit Campaign 2012), the number of very poor families with a microloan has grown more than 18-fold from 7.6 million in 1997 to 137.5 million in 2010. We study the impact of the introduction of microfinance (MF) on social networks. Our presentation is based on Banerjee, Breza, Chandrasekhar, Duflo, Jackson, and Kinnar [2021].

Microfinance brings people together in its application process and the repayment phrase. On the other hand, by providing loans it lowers the need for local loans within the village. It is therefore a priori whether the introduction of microfinance will erode or strengthen village informal sharing and related social networks within the village.

The study covers 75 villages in Karnataka, a state in Southern India. We discussed properties of these networks in chapter 1. Bharatha Swamukti Samsthe (BSS) offers a conventional group-based microcredit program: borrowers (who are only women) are formed into groups of 5 and are jointly liable for their loans. The starting loan is approximately 10,000 rupees (a little over US\$ 200) and is repaid in 50 weekly installments. Between 2007

and 2010, BSS entered 43 of these 75 villages. We call these the MF villages, the remaining villages will be referred to as the non-MF villages. The social network is studied at two points in time, 2006 (prior to the introduction) and 2012 (after the introduction of micro-finance).

The first finding is that the introduction of microfinance is associated with a 11% decline in (the probability of) a link between any two households in a MF village compared to a non-MF village. Turning to the composition of these link deletions, let us classify households in terms of those that took-up MF and those that did not take up MF. The second finding is that links between two non-MF type household fell by more than the links between two MF households. This is somewhat surprising as *a priori* the value of the link between two non-MF household has not changed. A third finding is that it is not just the financial ties of borrowing and lending that have eroded, but other social ties that involve advice and support have also dissolved.

■

Putting together these studies – on bank accounts, development projects, entry in diamond markets, and microfinance – together with the earlier studies in section 17.3 shows us that market opportunities can both substitute for social ties as well as complement social relations. In the diamond industry, market opportunities spurred on and strengthened social ties. Similarly, in the bank accounts case, access to formal financial institutions appears to reinforce social ties. However, in the development project and micro-finance case, opportunities arising out of formal institutions and greater market opportunities eroded informal economic ties based on borrowing and lending, and to the extent that other social relations are complementary to these ties, they also have a knock-on negative effect on the broader social network.

The theoretical model proposed in section 3 can be elaborated to make these ideas a little more precise. Suppose in addition to the choices of the network activity,  $x$ , and market action,  $y$ , individuals can also choose links. The links are costly. To pursue the reasoning, it is helpful to incorporate these costs of links within the linear example presented in equation 17.4. The augmented payoffs may be written as:

$$\Phi_i(\mathbf{a} \mid \mathbf{g}) = (1 + \theta y_i)x_i\chi_i(\mathbf{a}) + y_i - p_x x_i - p_y y_i - c(\eta_i). \quad (17.13)$$

where  $\eta_i$  is the number of links formed by  $i$  and  $c(\eta_i)$  is the total cost of links. It will be convenient to assume that  $c(0) = 0$  and that these costs are strictly increasing and are a convex function of number of links. An individual contemplating an additional link will earn extra payoffs only if she is choosing the network activity. In the event that she

is choosing only the network activity the return from an additional neighbour who also chooses the network activity is 1, while in the event that she chooses both the network and the market action the additional reward is  $1 + \theta$ . It follows that an individual will forms links until the point that the marginal reward and the marginal cost are equal. Recall that  $\theta < 0$  in case of substitutes and  $\theta > 0$  in case of complements. This means that the additional reward  $1 + \theta$  is larger than 1 in case network and market are complements and it is less than 1 in case they are substitutes. As costs  $c(\cdot)$  are increasing and convex in number of links, it then follows that an individual will form more links in the case where these activities are complements. The number of links define the density of the network – thus networks will strengthen when individuals in a traditional community face new opportunities that complement the network activity, while they will weaken in the case that they are substitutes.

## 17.6 Reading Notes

At the mid-point of the twentieth century, with the decolonization process in full swing, the sources of economic growth and the reasons for its uneven spread across countries emerged as a major field of study. The work of Simon Kuznets provided an empirical foundation for this literature. We draw upon the discussion in the beautifully self-contained “Six Lectures on Economic Growth” (Kuznets [1961]). The fundamental role of sectoral transformation away from agriculture and toward manufacturing and services was the motivation for the theoretical models of economic growth inaugurated by the work of Lewis et al. [1954] and the models of migration initiated by Harris and Todaro [1970]. The exposition in section 2 draws on Debraj Ray’s textbook on Development Economics (Ray [1998]). We also touch upon themes from other older texts on economic development such as Myrdal [1972], Nurkse et al. [1966] and Hirschman [1958]. For overviews of the modern theory of economic growth, the reader is referred to the excellent books by Acemoglu [2009] and Aghion and Howitt [1998].

Section 2 discusses how social structure can help us understand individual and social responses to new opportunities. The discussion draws on the wide ranging research of Kaivan Munshi, Chang-Tai Tsieh, Guido Tabellini and Avner Grief and their collaborators). In particular, in this section, the case studies draw on Munshi and Rosenzweig [2006], Munshi and Rosenzweig [2016], Daiy, Mookherjee, Munshi, and Zhang [2020], Bai, Hsieh, and Song [2020a], Bai, Hsieh, Song, and Wang [2020b], and Greif and Tabellini [2017].

The theoretical model is taken from Gagnon and Goyal [2017] – this model combines the traditional idea that markets and networks are substitutes (as in the early work of Kranton

[1996a]) with the possibility that they can be complements. Building on the research on network games and social coordination – these ideas are located within a social network. They suggest the concept *q-core* as an organizing principle. The exposition on the relation between social ties and market opportunities draws on the elegant essay on the relation between markets and social ties, by Hirschman [1997], the popular book by Sandel [2000], and on the survey paper by Goyal [2017].

The traditional perspective on social structure and economic growth sees the process as one in which the role of social ties in economic life is gradually eroded. Karl Polanyi's 'The Great Transformation' is a well known early work on this subject Polanyi [1944]). Section 17.5 discussed the enduring role of social networks in the process of change. It starts with a number of case studies on how new opportunities – such as markets and arrival of other formal institutions – lead to changes in the social network. An important sphere in which social networks are especially important is informal risk sharing. There is a large body of research on the limits of such insurance: Our discussion on social ties draws on the extensive work of Marcel Fafchamps and his collaborators (Fafchamps and Lund [2003], Fafchamps and Gubert [2007]), Fafchamps [2011], Christopher Udry (Conley and Udry [2010], Udry [1994] and Ray Fisman (Fisman [2003] on informal insurance and social networks in developing countries. For recent work that takes on an explicitly networks perspective see Ambrus, Mobius, and Szeidl [2014], Ambrus and Elliott [2021], Bloch, Genicot, and Ray [2008], Bramoullé and Kranton [2007], and Munshi and Rosenzweig [2016]. Until recently, however, relatively little attention had been given to the interaction between formal insurance markets and informal risk-sharing in networks. A notable early exception is Arnott and Stiglitz [1991] who show that due to moral hazard problems a developed informal insurance system can hamper the development of formal insurance markets. For a recent study of formal and informal insurance in agriculture, see Mobarak and Rosenzweig [2013].

The case studies in section 17.5 are taken from recent papers on the relations between formal institutions and social networks – the study of micro-finance from Banerjee, Breza, Chandrasekhar, Duflo, Jackson, and Kinnan [2021], the study on bank accounts from Comola and Prina [2020], the study of the diamond market from Munshi [2011], and the study on community driven development projects from Heß, Jaimovich, and Schündeln [2020] and Jaimovich [2015].

Economic growth interacts with the environment and the base of natural resources. In many parts of the developing world, the lives of communities depend intimately on the quality of the local natural resources (examples include of which waterways, fisheries, pastures, and forests) that they can access. We do not cover this important interaction in

this book. For an introduction to the subject see Dasgupta [1993] and for a study of rules that communities use to manage natural resources see Ostrom [1990].

I thank Marcel Fafchamps for helpful comments on an earlier draft of the chapter.

## 17.7 Questions

1. Consider a  $n$  player game on a network  $g$ . Players simultaneously chooses a network action  $x_i \in \{0, 1\}$  and a market action  $y_i \in \{0, 1\}$ . Define  $a_i = (x_i, y_i)$ . Suppose that in a network  $g$  faced with a action profile  $a = (a_1, a_2, \dots, a_n)$ , the payoff function for player  $i$  is given by

$$\Phi_i(a|g) = (1 + \theta y_i)x_i \chi_i(a|g) + y_i - x_i p_x - y_i p_y \quad (17.14)$$

where  $\chi_i(a|g)$  is the number of neighbors in network  $g$  who choose the network action, and  $p_x \geq 0$  and  $p_y \geq 0$ , respectively, are the prices of actions  $x$  and  $y$ . We say that the actions  $x$  and  $y$  are substitutes if  $\theta \in [-1, 0]$  and complements if  $\theta \geq 0$ . A Nash equilibrium is said to be maximal if there does not exist another equilibrium that Pareto dominates it.

- (a) Suppose that  $\theta = -1$ ,  $p_x = 4$  and  $p_y = 0.5$ . Describe how the network shapes behavior in the maximal equilibrium.  
 (b) Suppose that  $\theta = 1$ ,  $p_x = 7$  and  $p_y = 2$ . Describe how the network shapes behavior in the maximal equilibrium.  
 (c) Assess the impact of markets on aggregate welfare (measured as the sum of individual payoffs) and inequality (measured as a ratio of highest versus the lowest income) in the two above settings.
2. Consider the model of networks and markets presented in section 19.4. Suppose that individuals are heterogenous with respect to the returns from market activity and that returns to market activity are negatively related to membership of the  $q$ -core. Reason how the arrival of markets may well increase inequality even if networks and markets are substitutes.
3. Consider the impact of the introduction of microfinance on social networks.
  - We found that ties between non-MF household fell by more than ties between MF households and finally that ties of advice also fell. How can we account for this change in social network?

- We found that informal ties of advice also declined. Use ideas from the theory of network formation – that links of different individuals may be strategic complements or substitutes – to reason about this change in social network.
4. When social networks and markets are substitutes there may arise the possibility of multiple equilibria: one with large social networks and small markets and another with small social networks and well developed markets. Moreover, once large social networks are in place, it may be difficult for markets to develop. Discuss and if possible provide examples of such outcomes.
  5. Social ties become less important with modernization because well-functioning markets provide services that are traditionally provided by social relations in traditional societies. Discuss.

# Chapter 18: Trust

## 18.1 Introduction

Virtually every commercial transaction has within itself an element of trust, certainly any transaction conducted over a period of time. It can be plausibly argued that much of the economic backwardness in the world can be explained by the lack of mutual confidence. Arrow [1972] page 357.

..an individual trusts if he or she voluntary places resources at the disposal of another party without any legal commitment from the latter, but with the expectation that the act of trust will pay off. Coleman [1994] page XYZ

Transactions in which trust is important include those in which goods and services are provided in exchange for future payment, employment contracts in which managers rely on employees to accomplish tasks that are difficult to monitor, and investments and savings decisions that rely on assurances by governments or banks that they will not expropriate these assets. In some situations, it is possible that the parties to the transaction will get to know one another and may carry out transactions in the future. However, in other situations it is more natural to imagine that the parties to a transaction are strangers and are unlikely to meet ever again – imagine, for example, a passenger arriving at an international airport and taking a taxi ride, the passenger and driver are unlikely to meet after the taxi drops off the passenger in town. In this chapter we will study both types of situations. In the former situation, we will think of trust as being local to a group of individuals, while in the latter case we will think of trust among strangers – generalized trust.

We start with an exploration of local trust. In this perspective, trust is viewed as a solution to a social dilemma – it is in the collective interest of individuals to cooperate and choose a certain course of action, but each individual has an interest in deviating from this course of action for their own material self interest. Good behaviour today is sustained by the anticipation of rewards tomorrow. The magnitude of rewards and the possibility of punishments implemented by connected others leads us to a study of social relations, in

particular the role of common neighbours in a network. These considerations lead us to the concept of *network closure*. To formally examine how direct and indirect connections come into play, we develop a model of links as *social collateral*. A relationship offers a stream of possible benefits in the future. Individuals can carry out transactions and trust each other to behave well because if they did not do so then they will forsake these future benefits. An investor may borrow money using the link as a collateral. This approach yields a key insight: the amount a person can borrow is given the level of trust and this trust is defined as the minimum cut of the network. We present evidence from urban Peru and rural India to illustrate the role of network closure.

We turn next to generalized trust. We start with a presentation of data on measures of generalized trust in different countries and we show how it correlated to economic performance. This sets the stage for a study of the determinants of generalized trust. As a first step we think of trust as arising out of beliefs and expectations on behaviour. We conceive of culture as describing these beliefs and expectations and we evidence on how two central elements of culture – religion and ethnicity – shape trust.

We then take up the connection between local and generalized trust. A recurring theme is the tension between group-based cooperation that underlines local trust (and excludes non-members) and the demands of generalized trust. We present a simple model of favoritism to bring out the origins of group based cooperation and its broader negative consequences. This is followed by a discussion of the role of formal institutions and social structure respectively in helping bridge the gap between local and generalized trust.

## 18.2 Local Trust

We start with a famous description of local trust

Wholesale diamond markets exhibit a property that to an outsider is remarkable. In the process of negotiating a sale, a merchant will hand over to another merchant a bag of stones for the latter to examine in private at his leisure, with no formal insurance that the latter will not substitute one or more inferior stones or a paste replica. The merchandise may be worth thousands, or hundreds of thousands, of dollars. Such free exchange of stones for inspection is important to the functioning of this market. In its absence, the market would operate in a much more cumbersome, much less efficient fashion. Inspection shows certain attributes of the social structure. A given merchant community is ordinarily very close, both in the frequency of interaction and in ethnic and family ties.

The wholesale diamond market in New York City, for example, is Jewish, with a high degree of intermarriage, living in the same community in Brooklyn, and going to the same synagogues. It is essentially a closed community. Observation of the wholesale diamond market indicates that these close ties, through family, community, and religious affiliation, provide the insurance that is necessary to facilitate the transactions in the market. If any member of this community defected through substituting other stones or through stealing stones in his temporary possession, he would lose family, religious, and community ties. The strength of these ties makes possible transactions in which trustworthiness is taken for granted and trade can occur with ease. In the absence of these ties, elaborate and expensive bonding and insurance devices would be necessary- or else the transactions could not take place. Coleman [1988], Page.

It is clear that a high degree of trust in others saves us from having to incur large costs in drawing up contracts with them and in having to monitor their activity. Coleman's description presents us with a context in which the overlapping social connections, reflected in trading links, in inter-marriage, common religious affiliation, and physical proximity, help in creating and sustaining trust and in facilitating the functioning of a very high value market.

We now turn to the sources of local trust.

If A does something for B and trusts B to reciprocate in the future, this establishes an expectation in A and an obligation on the part of B. This obligation can be conceived as a credit slip held by A for performance by B. If A holds a large number of these credit slips, for a number of persons with whom A has relations, then the analogy to financial capital is direct. These credit slips constitute a large body of credit that A can call in if necessary – unless, of course, the placement of trust has been unwise, and these are bad debts that will not be repaid. In some social structures, it is said that “people are always doing things for each other.” There are a large number of these credit slips outstanding, often on both sides of a relation (for these credit slips appear often not to be completely fungible across areas of activity, so that credit slips of B held by A and those of A held by B are not fully used to cancel each other out)....This form of social capital depends on two elements: trustworthiness of the social environment, which means that obligations will be repaid, and the actual extent of obligations held. Social structures differ in both these dimensions, and actors within the same structure differ in the second. Coleman [1988] Page S102.

We now move forward from bilateral relations and locate individuals in a network. A central idea in the literature pertains to the notion of *network closure*. Network closure was first introduced in the context of drop out rates in high schools in the United States. They represented this idea as in Figure 18.1: in the network on the left individuals 1, 2 and 3 are linked together but 2 and 3 do not close the circle. In the network on the right, there is a link between 2 and 3 that closes the circle of connections. Let us discuss the drop out study and place network closure in that context.

The High School and Beyond (HS&B) is a national longitudinal study originally funded by the United States Department of Education's National Center for Education Statistics (NCES) as a part of their longitudinal studies program. The HS&B is part of the National Education Longitudinal Studies program that seeks to document the "educational, vocational, and personal development of young people ... following them over time as they begin to take on adult roles and responsibilities."

Our discussion draws heavily on Coleman [1981]. The study uses the High School and Beyond data from 893 public schools, 84 Catholic schools, and 27 other private schools. Most of the other private schools are independent schools with no religious affiliation. The focus is on dropout rates of pupils as they approach the last year of high school. The dropout rates between sophomore and senior years are 14.4% in public schools, 3.4% in Catholic schools, and 11.9% in other private schools. The rate of drop out at Catholic schools is one quarter of the rate at public schools and about a third of the rate in other private schools. These large differences persist after we adjust for differences in economic and demographic differences of families sending children to different schools. Interestingly, the drop-out rates of pupils from Catholic families are only slightly lower than those of non-Catholics at the public schools. What are the reasons for this large difference?

The low dropout rates of the Catholic schools, the absence of low dropout rates in the other private schools, and the independent effect of frequency of religious attendance point to the importance of social network in the adult community surrounding it. The difference in this structure of this community can be understood with the help of Figure 18.2. The vertical lines represent relations across generations (between parent and child) while the horizontal lines represent relations within a generation. The point labeled P1 in both Figure 18.2 (left) and Figure 18.2 (right) represents the parent of child C1, and the point labeled P2 represents the parent of child C2. The lines between C1 and C2 represent the relations among pupils in the school. There exist a rich set of connections between pupils as they see each other at school and this develops a set of expectations and norms about each other's behavior. The two communities differ, however, in the presence or absence of links among the parents of children in the school. The network of parents in school II has

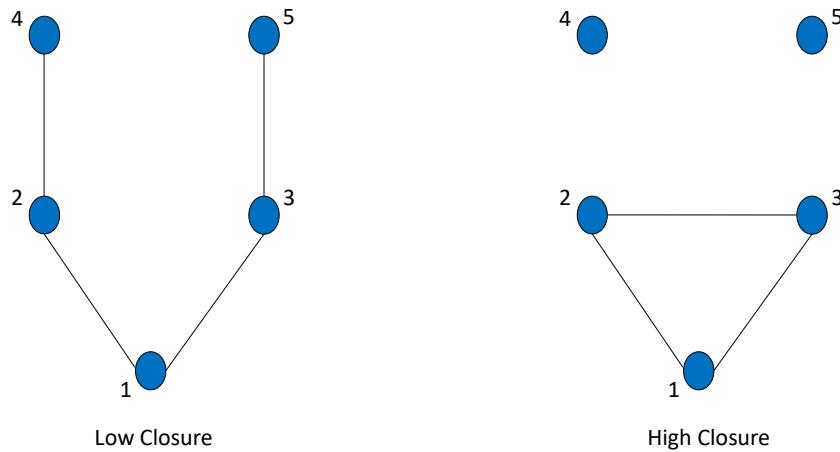

Figure 18.1: Network Closure

intergenerational closure – the parents' friends are parents of their children's friends. The social network of parents in school I, on the other hand exhibits no closure. Thus in school II, parents P1 and P2 can discuss their children's activities and come to some consensus about standards and coordinate sanctions. This is not possible in the network of school I. Network closure helps the community of parents develop shared norms and to more effectively impose sanctions in case of deviations of norms. Parent P1 is reinforced by parent P2 in sanctioning his child's actions; beyond that, parent P2 constitutes a monitor not only for his own child, C2, but also for the other child, C1. Parents and their children in Catholic schools were embedded in a network with inter-generational closure as in School II, while their public school counterparts were located in a network like School I.

We present two further examples of the use of social ties that serve to further bring out the role of network closure in supporting economic transactions. The examples are taken from Karlan, Mobiüs, Rosenblat, and Szeidl [2009].

The first example pertains to a Norwegian shipowner who was in need of a ship that had undergone repairs in an Amsterdam shipyard. The yard would not release the ship unless a cash payment was made of 200,000 pounds. The ship would remain tied up for the weekend, and the owner would lose at least 20,000 pounds. The shipowner did not have the 200,000 pounds available. He reached out to a London banker at Hambros, hoping that he would have contacts in Amsterdam. After hearing the situation, the Hambros man looked at the clock and said, "It's getting late but I'll see whether we can catch anyone at the bank in Amsterdam ... stay at the phone." Over a second phone he dictated to a secretary in the bank a telex message to the Amsterdam bank: "Please pay 200,000 pounds

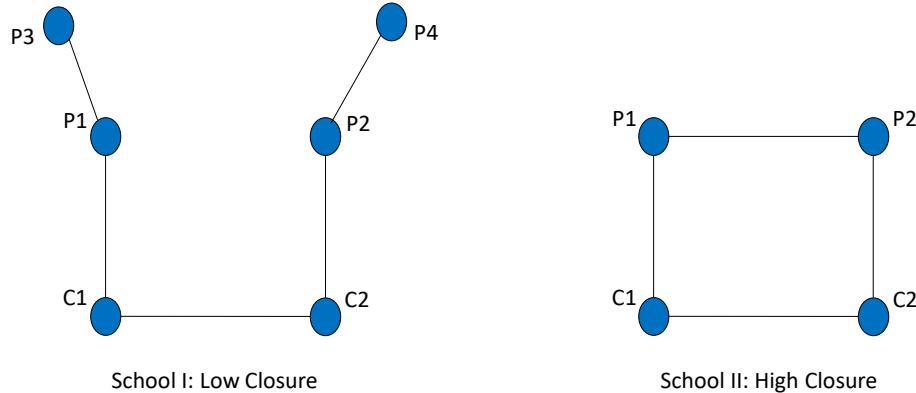

Figure 18.2: Intergenerational Closure

telephonically to (name) shipyard on understanding that (name of ship) will be released at once."

In this example, the shipowner borrowed 200,000 pounds from an Amsterdam bank with which he had no direct connection. He accomplished this by combining two relations: his connection with the London banker, and the connection between the London and Amsterdam banks. The London banker acted as a trust intermediary: he provided access and created the necessary trust for the transaction.

The second example on how networks generate trust is the guanxi system in China. Guanxi refers to a trusted relationship that can be used to obtain services either directly or indirectly from that person's social network. Consider the example of a buyer and a seller who share guanxi with a common acquaintance. This third person can act as a trust source – zhongjian ren – by introducing the buyer to the supplier. The intermediary vouches for the buyer by assuring the supplier that should the buyer exploit the supplier subsequently, he will compensate for any costs.

These examples illustrate ways in which activity between one pair of individuals can be supported by links with other individuals – that the pair knows in common. The intuitive appeal of the idea of network closure motivates a more general study that takes account of the overall structure of the network of connections. However before exploring this issue, we briefly comment on other non self-interest based approaches to local trust.

One route to trust proceeds as follows: an individual may act in a trustworthy way because this course of action is prescribed by his or her sense of identity. A core element in the theory of identity concerns the idea that our notion of the 'self' arises out of interactions with others. Our views of who we are and how we should act turns on what we learn from

others with whom we interact. Thus interactions with others may shape our notion of goals and aspirations and the appropriate way of behaving. Acting in a certain way that is consistent with one's sense of identity is to act by a different understanding as compared to that which is based on a computation of material costs and benefits. At a more general level, as we move away from instrumental to intrinsic motivations, identity may be seen as related to social norms. We will discuss the role of social norms at length in section 18.4, but at this point it is probably worth noting that social interactions may play a role of sustaining norms. We will return to this theme in section 18.6.

### 18.3 Social collateral

We consider a situation where a borrower needs the asset of a lender to produce social surplus. In the absence of legal contract enforcement, borrowing must be secured by an informal arrangement supported by the social network: connections in the network have associated consumption value, which serve as social collateral to enable borrowing. The discussion below and the theoretical model is taken from Karlan, Mobius, Rosenblat, and Szeidl [2009].

We start with three numerical examples to illustrate the basic logic of using relationships as collateral. In Figure 18.3 individual  $s$  would like to borrow an asset, like a car, from agent  $t$ . In Figure 18.3A, the network is as depicted and consists of just the two individuals  $s$  and  $t$ ; the value of their relationship is given by 2. This summarizes the total benefits – and may include social benefits from friendship or the discounted present value of future transactions. We take the view that these benefits may be used as a collateral by  $s$  to borrow from  $t$ : so  $t$  will only lend the car if its value does not exceed the relationship value of 2.

Let us enrich the situation slightly now and consider the network as in Figure 18.3B, where  $s$  and  $t$  have a common friend  $u$ . The value of the relationship between  $s$  and  $u$  is 3, and that between  $u$  and  $t$  is 4. Here, the common friend increases the borrowing limit by  $\min[3; 4] = 3$ , the weakest link on the path connecting borrower and lender through  $u$ . This common friendship raises the amount that can be borrowed by  $s$  from  $t$  to 5. The logic is that the intermediate agent  $u$  vouches for the borrower, and acts as a guarantor of the loan transaction. If  $s$  chooses not to return the car, he is breaking his promise of repayment to  $u$ , and therefore loses  $u$ 's friendship. Since the value of this friendship is 3, it can be used as collateral for a payment of up to 3. For the lender  $t$  to receive this amount,  $u$  must prefer transmitting the payment to losing the friendship with him. This logic also explains why we need to consider the weakest link.

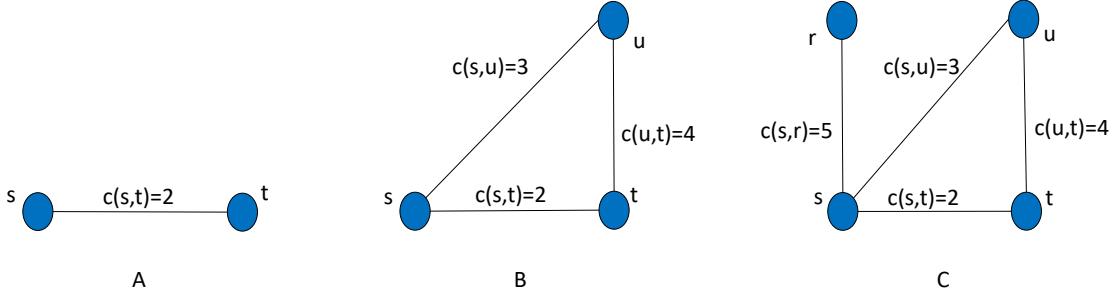

Figure 18.3: Social Collateral. Taken from Mobius and Rosenblat [2016].

Finally, Figure 18.3C considers a coalitional deviation. Assume that the borrower also has a cousin 'r' with whom he has a relationship valued at 5. In principle, r's cousin can act as a guarantor for s, raising the borrowing limit by an additional 5, to a total of 10. However, r's threat to break off her relationship with the borrower is not credible: for any loan amount exceeding 5 the borrower could propose a 'side-deal' to intermediary u and her cousin such that u can reimburse the lender for the guaranteed amount (which is at most 3) while transferring 0 to the cousin in case of default. Observe that as there is no onward link from cousin to any other individual, the cousin incurs no losses as a result of s reneging on his promise. Thus the intermediary u and the cousin are not worse off as a result of this side-deal. The borrower will use her friendship and therefore incur a combined loss of at most 5 (a loss of 3 to u and a loss of 2 to t). However, as she borrowed an amount exceeding 5 she is strictly better off under such a side-deal. Hence, the punishment of the borrower that involves individuals like the cousin who are unconnected to the lender is not credible.

We now develop this idea and apply it in general networks,  $G$ , with nodes  $N = \{1, \dots, n\}$ . For every pair  $i$  and  $j$  in  $N$ , there is a capacity given by  $c_{ij}$ . This capacity is zero if no link is present and positive if there is a link. For simplicity, suppose that capacity is symmetric, i.e.,  $c(u,v) = c(v,u)$ . A special case that is interesting arises when all positive links have the same capacity  $c > 0$ , so that  $\forall i, j \in N, c_{ij} \in \{0, c\}$ .

To understand the relation between networks and the limits of borrowing, it is helpful to explicitly define a sequence of actions that involve the borrower, the lender and the other individuals in the network.

- STAGE 1 Realization of needs. Two agents s and t are randomly selected from the

social network. Agent  $t$ , the lender, has an asset that agent  $s$ , the borrower, desires. The lender values the asset at  $V$ , and it is assumed that  $V$  is drawn from some distribution  $F$  over  $[0; 1]$ . The identity of the borrower and the lender as well as the value of  $V$  are publicly observed by all players.

- STAGE 2 Borrowing arrangement. The borrower publicly proposes a transfer arrangement to all agents in the social network. The role of this arrangement is to punish the borrower and compensate the lender in the event of default. A transfer arrangement consists of a set of transfer payments  $h(u; v)$  for all  $u$  and  $v$  agents involved in the arrangement. Here  $h(u; v)$  is the amount  $u$  promises to pay  $v$  if the borrower fails to return the asset to the lender. Once the borrower has announced the arrangement, all agents involved have the opportunity to accept or decline. If all involved agents accept, then the asset is borrowed and the borrower earns an income  $\omega(V)$ , where  $\omega$  is a non-decreasing function with  $\omega(0) = 0$ . If some agents decline, then the asset is not lent, and the game moves on directly to stage 5.
- STAGE 3 Repayment. Once the borrower has made use of the asset, he can either return it to the lender or steal it and sell it for a price of  $V$ . If the borrower returns the asset then the game moves to the final stage 5.
- STAGE 4 Transfer payments. All agents observe whether the asset was returned in the previous stage. If the borrower did not return the asset, then the transfer arrangement is activated. Each agent makes the promised payment  $h(u; v)$  in full or he pays nothing. If some agent  $u$  fails to make a prescribed transfer  $h(u; v)$  to  $v$ , then he loses his friendship with agent  $v$  (i.e., the  $(u; v)$  link goes bad). If  $(u; v)$  link is lost, then the associated capacity is set to zero for the remainder of the game. We let  $\tilde{c}(u; v)$  denote the new link capacities after these changes.
- STAGE 5 Friendship utility. At this stage, agents derive utility from their remaining friends. The total utility enjoyed by an agent  $u$  from his remaining friends is simply the sum of the values of all remaining relationships, i.e.,  $\sum_{v \in N} \tilde{c}(u; v)$ .

We study the (pure strategy) sub-game perfect equilibrium of game. In particular, we would like to understand the limits placed by the network  $G$  on the amount that  $s$  can borrow from the lender  $t$ .

In any equilibrium where promises are kept, transfers have to satisfy the capacity constraint

$$h(u; v) \leq c(u; v) \quad (18.1)$$

This inequality reflects the incentives facing an individual. If the borrower fails to return the asset, individual  $u$  has to decide whether to make his promised transfer payment  $h(u; v)$  to  $v$ . The cost of making the payment is  $h(u; v)$ , while the cost of not making the payment is the value of the relationship foregone. In any equilibrium where promises are kept,  $u$  must prefer the friendship over the monetary value of the transfer, leading to (18.1).

Consider the two agent network consisting of  $s$  and  $t$ . We argue that the extent of borrowing  $V \leq h(s; t)$ . To see why, suppose that the borrower  $s$  defaults. Then the lender receives the transfer payment  $h(s; t)$ , but he must break even and this requires that  $V \leq h(s; t)$ . On the other hand, for the borrower to prefer to return the asset, he must prefer not to default, which again requires  $V \leq h(s; t)$ . Combining this inequality with the capacity constraint (1) yields us

$$V \leq c(s; t) \quad (18.2)$$

showing that borrowing is limited by the total social assets available to  $s$  in this simple network. The value of the total social assets is referred to as the maximum flow in the network. It is also easy to see that when 18.2 is satisfied, there exists an equilibrium that implements borrowing: just set  $h(s; t) = V$ . Intuitively, the collateral value of friendship can be used to elicit payment and thus solve the agency problem.

The maximum flow is easy to infer in this two person network, but it is a much more complicated object in a general network with several individuals and with links having different capacities. As a next step let us consider a three agent network, with  $s$  and  $t$  and an intermediary  $u$ . A natural transfer arrangement that implements borrowing in this network is one where agent  $u$  acts as an intermediary who elicits and transits payments from  $s$  to  $t$  in the case of no compliance, and gets zero net profits. To formalize this arrangement, simply set  $h(s; u) = h(u; t) = V$ . For this arrangement to be in the interest of the individuals, the capacity constraint (1) must be satisfied for both links involved:  $V \leq c(s; u)$  must hold so that  $s$  delivers the transfer to  $u$ , and  $V \leq c(u; t)$  is needed to ensure that  $u$  passes on the transfer to  $t$ . Combining these yields the weakest link inequality

$$V \leq \min[c(s; u); c(u; t)] \quad (18.3)$$

Here the maximum flow is defined taking into account the different links that  $s$  and  $t$  have with the intermediary.

However, networks with more than two agents generally admit other (subgame perfect) equilibria that can implement borrowing even if (3) fails. To this in the simplest way, let us return to a network as depicted in Figure 18.3 and consider the network with four

individuals. Assume that the borrower  $s$  has a strong link to his cousin  $v$ , with a capacity value of  $c(s; v) = V + 1$ . The borrower might then propose an informal arrangement in which he promises to pay his cousin a transfer of  $h(s; v) = V + 1$  in case he fails to return the asset. This arrangement provides the right incentives to the borrower, and is a sub-game perfect equilibrium, even though (3) fails.

However, there is a potential problem in this arrangement: the borrower could circumvent the arrangement by entering a side-deal with his cousin, in which he steals the asset and shares the proceeds with the cousin (who in equilibrium would otherwise receive nothing). The lender conscious of such side deals will not lend to  $s$  if the loan is supported by transfer arrangements that are vulnerable to such side deals. To address this issue, we define subgame perfect equilibrium that is side-deal proof.

Consider the subgame starting in stage 2, after the identities of the borrower and the lender and the value of the asset are realized, and for any pure strategy  $\sigma$  let  $U_u(\sigma)$  denote the total utility of agent  $u$  in this subgame. We formalize the idea of a side-deal as an alternative transfer arrangement  $\tilde{h}(u; v)$  that  $s$  proposes to a subset of agents  $S \subset W$  after the original arrangement is accepted. If this side-deal is accepted, agents in  $S$  are expected to make transfer payments according to  $\tilde{h}$ , while agents outside  $S$  continue to make payments described by  $h$ . In order for the side-deal to be credible to all participating agents, it must be accompanied by a proposed path of play that these agents find optimal to follow.

Thus, a *side deal* with respect to a strategy profile  $\sigma$  is a set of agents  $S$ , a transfer arrangement  $\tilde{h}(u, v)$ , for all  $u, v \in S$ , and a set of continuation strategies  $\{\tilde{\sigma}_u | u \in S\}$ , proposed by  $s$  to agents in  $S$ , at the end of stage 2, such that

1.  $U_u(\tilde{\sigma}_u, \tilde{\sigma}_{S \setminus u}, \sigma_{-S}) \geq U_u(\sigma'_u, \tilde{\sigma}_{S \setminus u}, \sigma_{-S}), \forall \sigma'_u, \forall u \in S.$
2.  $U_u(\tilde{\sigma}_S, \sigma_{-S}) \geq U_u(\sigma_S, \sigma_{-S}), \forall u \in S.$
3.  $U_s(\tilde{\sigma}_S, \sigma_{-S}) > U_s(\sigma_S, \sigma_{-S}).$

In words, (i) says that all agents  $u$  involved in the side-deal are best-responding on the new path of play, i.e., that the proposed path of play is an equilibrium for all agents in  $S$  conditional on others playing their original strategies. Condition (ii) says that if any agent  $u \in S$  refuses to participate in the side-deal, then play reverts to the original path of play given by  $\sigma$ . Finally, (iii) ensures that the borrower  $s$  strictly benefits from the side-deal.

A pure strategy profile is a side-deal proof equilibrium if it is a sub-game perfect equilibrium that admits no side-deals.

We now introduce a few more pieces of notation that are helpful. An  $s \rightarrow t$  flow with respect to capacity  $c$  is a function  $f : G \times G \rightarrow \mathcal{R}$  that satisfies

1. Skew symmetry:  $f(u, v) = -f(v, u)$
2. Capacity constraints:  $f(u, v) \leq c(u, v)$ .
3. Flow conservation:  $\sum_w f(u, w) = 0$ , except if  $u = s$  or  $t$ .

The value of the flows is the amount that leaves the borrower:  $|f| = \sum_w f(s, w)$ . Let  $T^{st}(c)$  denote the maximum flow among all  $s \rightarrow t$  flows.

There exists a side-deal proof equilibrium that implements borrowing between  $s$  and  $t$  if and only if asset value  $V$  satisfies  $V \leq T^{st}(c)$ . Thus the maximum flow sets a limit to borrowing between  $s$  and  $t$ . Let us go through the argument underlying this result. A well known result on flows in graphs tells us that the maximum flow between  $s$  and  $t$  is equal to the minimum cut between them. So what is a minimum cut? A *cut* is a partition of nodes into two sets  $S$  and  $T$ , with  $s \in S$  and  $t \in T$ , and the value of the cut is given by the sum of all links between nodes in the sets  $S$  and  $T$ . A *minimum cut* is a partition which minimizes the value of the cut across all partitions.

To develop a feel for the idea of a minimum cut, let us consider a few examples. Consider the three networks in Figure 18.3. In a network with two individuals  $s$  and  $t$  there is only one link and so there exists a unique cut. The maximum flow is simply the capacity of the link. In a network with three individuals the minimum cut corresponds to the the partition with 1 in one set and 2 and 3 in the other set. The minimum cut is given by 5. Finally, consider the network with four individuals. It is easy to see that the existence of individual leaves the minimum cut unaltered, relative to the network with three individuals, so it is also given by 5.

Equipped with this result on maximum flow and minimum cut we can state a simple but powerful theoretical result: the size of the loan for  $s$ ,  $V$ , is limited by the maximum flow in the network.

First observe that any amount  $V \leq T^{st}(c)$  can be borrowed. Simply use the flows which define  $T^{st}$  to construct the transfers in stage 2. By hypothesis,  $V \leq T^{st}(c)$ , and so such a flow is incentive feasible. Also note that each intermediary node acts as a pure conveyor in such a flow. She merely passes on the transfers onward from borrower to lender. Next we argue that no loan larger than the maximum flow is feasible. Consider a loan that is larger than the maximum flow. This means that it also exceeds the minimum cut in the network. In other words, there exists a cut in the network  $S$  and  $T$ , such that the value of the cut is smaller than  $V$ . But then there exists a side-deal with the members of the set  $S$ , in which  $V$  is shared between the members of  $S$ . The side deal is attractive to members of  $S$ , as they get to keep  $V$  and it exceeds the sum total of anticipated rewards that they forgo from members of  $T$ .

Let us say that trust is equal to the size of the loan that can be taken. We can summarize our discussion so far as follows.

**Proposition 18.1.** *The maximum flow is given by the minimum cut of the network. The level of trust in the network borrowing is defined by its maximum flow.*

The maximum flow therefore defines payoffs in a network. The payoffs to  $s$  in a network  $G$  with capacities  $c$  are

$$\Pi^{st}(c) = \Pi^{st}(T^{st}(c)), \quad (18.4)$$

where  $\Pi(z) = \int_0^z \omega(v)f(v)dv$  (recalling that  $\omega(v)$  is the value to the borrower and  $f$  is the distribution of  $v$ ). This value is computed conditional on the pair  $(s, t)$  being picked.

We now examine how network structure shapes borrowing possibilities. A first remark is that an increase in capacities raises the maximum flow and therefore raises the borrowing potential in the network. Let us look at the deeper structure of the network next (while bearing in mind the idea of network closure).

At an intuitive level, networks have high closure if the neighborhoods of connected agents have a large overlap (as in Figure 18.1). However, there are also considerations that suggest that a network with low closure may be more advantageous. The idea here is that closure involves linking individuals who already have paths between them. Thus links are in some sense redundant. To the extent that links are costly and therefore scarce, closure is wasteful (Granovetter [1973] and Burt [1994]). Thus networks with low closure lead to higher performance, as they allow agents to reach many others through the network.

At an intuitive level, high network closure is associated with having multiple paths to a smaller set of agents. Using the concept of network flows, let us count the total number of paths of an agent. Suppose that all existing links have unit value, 1. Then the network flow  $T^{st}(c)$  is effectively the number of disjoint paths between  $s$  and  $t$ ,  $T^s(c) = \sum_{t \in N} T^{st}(c)$ .

We use Figure 18.4 to elaborate on the role of closure. In Figure 18.4,  $s$  has a total of four paths in both networks (where the background assumption is that the links each have capacity 1). In Figure 18.4A there are four paths that reach four different people, while in Figure 18.4B they reach only two people, but there are two paths connecting  $s$  with either of them. More generally, define  $P^s(n)$  as the share of paths  $s$  has with individuals to whom he has at least  $n$  paths. In the networks in Figure 18.4,  $P^s(2) = 0$  in Figure 18.4A and  $P^s(2) = 1$  in Figure 18.4B. Clearly,  $P^s(0) = 1$  always, and  $P^s(n)$  is (weakly) falling in  $n$ .

The important point to note is that higher closure ‘increases’ trust but reduces access. For example, in Figure 18.2B two people trust  $s$  with assets of value  $V = 2$ ; access is low as only two people are available for a loan, but loans of value 2 can be taken in this closed

Figure 18.4: Closure versus Access (taken from Karlan, Mobius, Rosenblat, and Szeidl [2009])

network. In contrast, in Figure 18.2A,  $s$  can borrow from four people, but the asset value can be at most 1: access has increased, but at the cost of a reduction in the size of the loan that can be drawn.

The attractiveness of closure depends on the ‘relative’ value of high versus low value loans. To formalize this trade-off between access and pairwise trust, define  $\tilde{\omega}(V) = f(V)\omega(V)$ , as the frequency-weighted profits from the ability to borrow  $V$ . Observe that  $\tilde{\omega}(V)$  depends on both the probability that an asset of value  $V$  is needed ( $f(V)$ ), and on the profits this asset generates ( $\omega(V)$ ). An economy is a high value environment if  $\tilde{\omega}(V)$  is increasing, and it is a low value exchange environment if  $\tilde{\omega}(V)$  is decreasing.

We will say that the network neighborhood of  $s$  has a higher closure than the neighborhood of  $s'$  if

1.  $T^s(c) = T^{s'}(c)$  so that  $s$  and  $s'$  have the same total number of paths; and
  2. For each  $n$ ,  $P^s(n) \geq P^{s'}(n)$ , so that a greater share of paths connect  $s$  to people with whom he has many paths.

Thus if the neighborhood of  $s$  has higher closure, then  $s$  is connected to fewer people through many paths. To facilitate a comparison of networks it is helpful to define payoffs of individuals as a function of the network.

Define  $q_s(j)$  as the proportion of paths of  $s$  with agents to whom he has exactly  $j$  paths. Note that

$$P^s(n) = 1 - \sum_{j=1}^{j=n-1} q^s(j) \quad (18.5)$$

Thus an increase in closure may be interpreted as a first order stochastic shift in density  $q_s(j)$ . Recall that there are  $N$  individuals in all, so  $s$  can have one out of  $N - 1$  individuals

as a potential lender (so  $N = 4$  in both panels of Figure 18.2). Let  $M$  be the total number of paths, observe that in both networks of Figure 18.2 we have  $M = 4$ . Now  $q_s(j)$  is the share of total paths that connect to agents with exactly  $j$  paths. So the number of paths that satisfies this criterion for  $j$  paths is  $Mq_s(j)$ . Next observe that the number of potential lenders who have  $j$  paths is given by  $Mq_s(j)/j$  (as there are  $j$  paths for each such individual). The probability of requesting a favor from any of them equals:

$$\frac{1}{N-1} \frac{Mq_s(j)}{j} \quad (18.6)$$

The payoff on meeting such an individual is  $\Pi(j)$ , and therefore the expected payoff to  $s$  in network is:

$$\frac{1}{N-1} \sum_j \frac{Mq_s(j)}{j} \Pi(j) \quad (18.7)$$

where we have assumed that all links have capacity 1. This in turn can be rewritten as

$$\frac{1}{N-1} \sum_j Mq_s(j) \frac{\Pi(j)}{j} \quad (18.8)$$

This expression is simply the expected value of  $\Pi(j)/j$  under density  $q_s(j)$ . In a high value environment,  $\Pi(V)$  is convex because the first derivative,  $\Pi(V)' = \tilde{w}(V)$  which is increasing. Since  $\Pi(0) = 0$ , it follows that  $\Pi(V)/V$  is non-decreasing in  $V$ . In this case a first order stochastic dominance shift in density  $q_s(j)$  increases the expected payoff. The converse holds in low value exchange environments.

These considerations allow us to state our main result on network closure.

**Proposition 18.2.** *In a high value exchange environment, a neighborhood with higher closure leads to a higher expected payoff to  $s$ . Conversely, in a low value exchange environment, a neighborhood with higher closure leads to a lower expected payoff to  $s$ .*

This result speaks to a classical question on the relative attractiveness of high closure and low closure networks. In a low value exchange environment, the access provided by low closure is more attractive, because knowing more people directly or indirectly increases the likelihood that  $s$  can obtain a low-value asset. This is consistent with theories put forward by Granovetter [1973] and Burt [1994] concerning the strength of weak ties and the benefits of a dispersed social network in providing access to assets such as small favors, information or advice. In contrast, in a high value exchange environment, network closure is better. Here, a reduction in access is more than compensated for by the fact that, through his dense connections,  $s$  will be able to borrow even high-valued assets. This would be

critical for parents bringing up children (where norms need to be established, monitoring needs to be carried out, and sanctions need to be applied) or for diamond merchants in New York (where the exchange of valuable stones requires high trust between dealers).

### 18.3.1 Empirical Evidence on social collateral

We present two case studies for the uses of social collateral that draw attention to the role of network closure. The discussion here is based on Karlan, Mobius, Rosenblat, and Szeidl [2009], Mobius and Rosenblat [2016] and Jackson, Rodriguez-Barraquer, and Tan [2012].

The first case study pertains to two Peruvian shantytowns in the Northern Cone of Lima. The data is from the year 2005. There are 299 households in all. The network describes, for each pair of households, how much time is spent with the friend or acquaintance per week and whether there were any loans made over the past one year. Households have, on average, 8.6 links, and the average geographic distance between connected agents (agents who have spent time together) is 42 and 39 meters in the two communities; this is considerably lower than the geographic distance between two randomly selected addresses, which is 132 and 107 meters, respectively. There were 254 informal loans; 167 borrowers in 138 households reported to have borrowed on average about 23 USD from 173 lenders during the past 12 months. Thus, informal borrowing is very common in these communities: 46 percent of all households have at least one household member who borrowed money in this manner.

The amount of time spent together provides a proxy for the strength of a relationship. This can be used to construct capacity of ties. Suppose that capacity of a link  $(u, v)$  is given by  $c(u, v) = c\tau(s, t)$ , where  $\tau(s, t)$  is the time spent together by s and t. To fix ideas let us consider only direct ties and indirect ties with one common intermediary. This allows for a simple decomposition of the trust flow between s and t as

$$T^{st}(c) = c\tau(s; t) + c \sum_{v \in N_s \cap N_t} \min(\tau(s; v); \tau(v; t)) \quad (18.9)$$

where the first term represents the direct flow and the second term is the indirect flow. Here  $N_s$  is the set of direct friends of agent s.

Table 18.1 groups all social links of each borrower into four categories, depending on whether the direct flow between borrower and lender is below or above the average direct flow, and whether the indirect flow between borrower and friend is below or above the average indirect flow. About 14.5 percent of the loans came from borrower/lender pairs with both below-average direct flow and below-average indirect flow. Observe that 22.5% of loans were made from above-average direct but below average indirect flow contacts.

Indirect Time Direct Time	Below Aver.	Above Aver
Above Aver	21	42
Below Average	14.5	22.5

Table 18.1: Social Relations and Propensity to Borrow. Data from Mobius and Rosenblat [2016].

About three times as many loans – 42% of loans involve lenders with both above-average direct and above-average indirect flow. Indirect flows thus play an important role in creating social collateral for borrowing.

The second case study is about favour exchange among households in rural Southern India. The study covers 75 villages in the Southern Indian state of Karnataka. These are the same villages that were covered in the rural networks discussion in chapter 1. The average number of households sampled in a village is 193.5. The average number of links per household 2.89. 18.2 summarizes the relation between having common friends and favour-exchange.

	Percentages
Favour exchange with common friends	59
Favour exchange without common friends	41
Favour exchange within subcaste	68
Favour exchange outside subcaste	32
Money or Kerorice favours with common friends	61
Money or Kerorice favours without common friends	39

Table 18.2: Common Friends and Favours

To get a first impression of the level of social collateral, we present the distribution of pairs with respect to number of common friends.

We consider the following types of favours:

1. Borrow kerorice: If you needed to borrow kerosene or rice, to whom would you go?
2. Lend-kerorice: Who would come to you if he/she needed to borrow kerosene or rice?
3. Borrow-money: If you suddenly needed to borrow Rs. 50 for a day, whom would you ask?
4. Lend-money: Who do you trust enough that if he/she needed to borrow Rs. 50 for a day you would lend it the him/her?

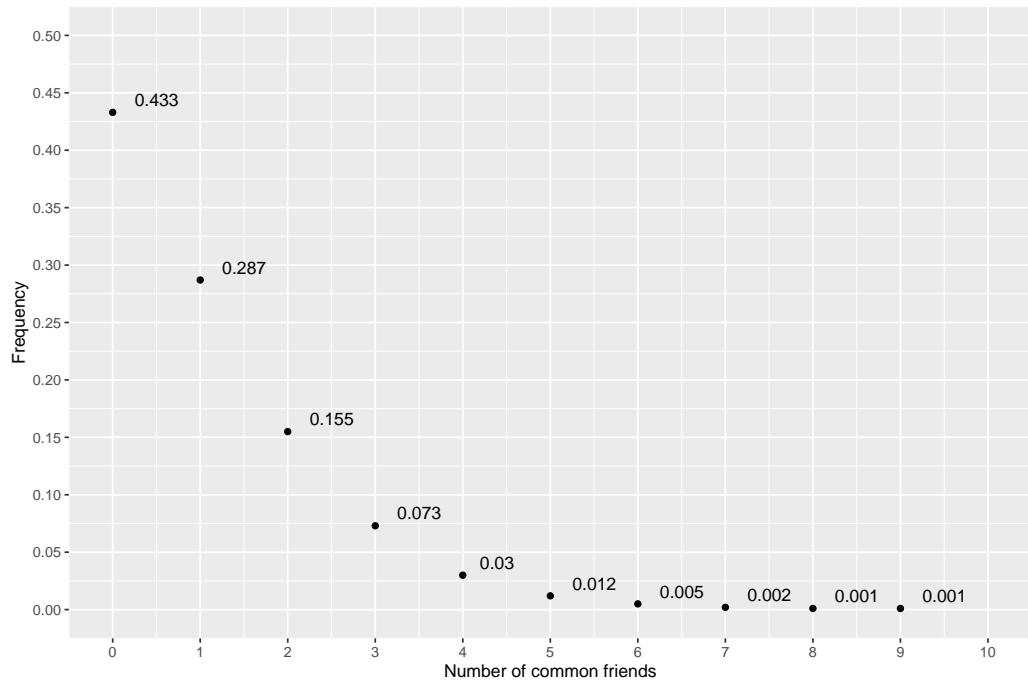

Figure 18.5: Distribution of Common Friends. Data from Jackson, Rodriguez-Barraquer, and Tan [2012]

5. Advice-come: Who comes to you for advice?
6. Advice-go: If you had to make a difficult personal decision, whom would you ask for advice?
7. Medical-help: If you had a medical emergency and were alone at home whom would you ask for help in getting to a hospital?

First, we consider the relation between common friends and any of the above seven favours. Figure 18.6 presents the relation between number of common friends and probability of favour exchange. This Figure shows that there is a positive relation: the greater the number of common friends, the higher the fraction of favour exchange (except in the case of 9 common friends, which is probably due to the very small number of such links). If we interpret number of common friends as higher social collateral, then this positive correlation is consistent with the theory: a greater number of common friends can support a wider range of favours and this raises the probability of a favour.

The size of the social collateral would probably matter for large favours as compared to small favours. With this idea in mind, we look at potentially higher value favours – money loans and loans of kerosine and rice. Figure 18.7 presents the fraction of large favour

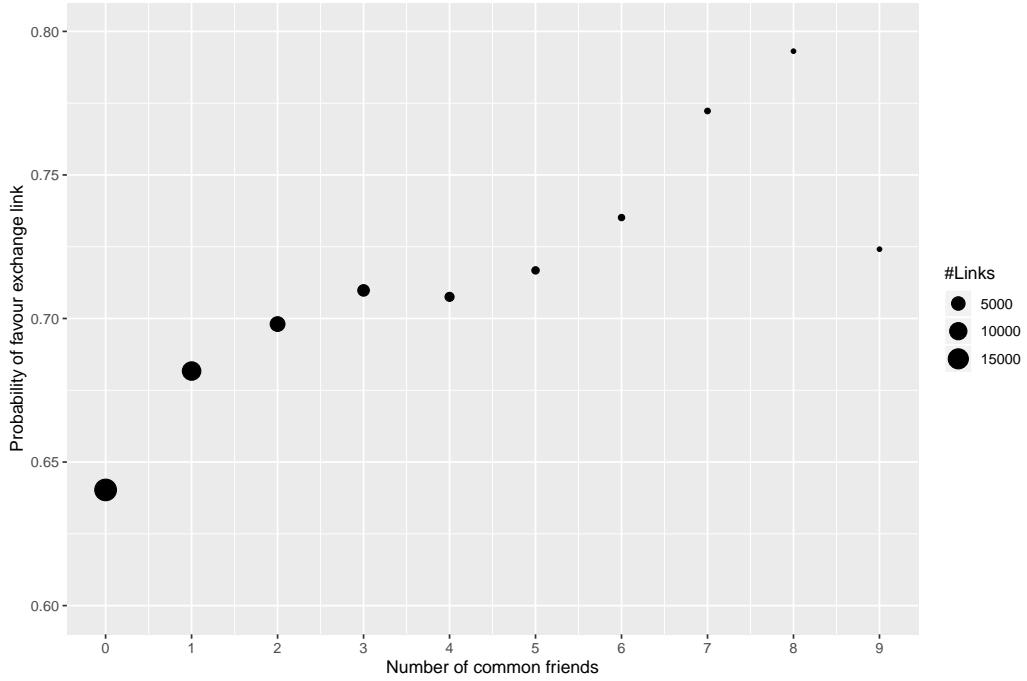

Figure 18.6: Common Friends and Favours. Data from Jackson, Rodriguez-Barraquer, and Tan [2012]

exchange pairs as a function of the number of common friends. It reveals that the fraction of pairs undertaking large favours increases in the number of common friends.

### 18.3.2 Repeated Interaction and Common Friends

The previous section presented a model of social collateral in which a link reflected anticipated future rewards. In this section we briefly elaborate on the repeated interaction implicit in these rewards. The discussion draws on a theoretical model due to Jackson, Rodriguez-Barraquer, and Tan [2012].

Consider a group of individuals,  $N = \{1, \dots, n\}$ , with  $n \geq 2$  that are connected together in an undirected network. The neighbors of  $i$  in network  $g$  are denoted  $N_i(g) = \{j | g_{ij} = 1\}$ . The degree of  $i$  is the number of neighbors, and is denoted by  $d_i(g) = |N_i(g)|$ .

Time proceeds in discrete periods,  $t = 0, 1, \dots$ . In any period, there is a chance that an individual needs a favor from a friend or will be called upon to do a favor for a friend. To be precise there is a probability  $p$  that individual  $i$  is called upon to do a favour for any one of his neighbours. It is assumed that at most one favor will be needed across all agents in any period, i.e.,  $n(n - 1)p \leq 1$ .

Doing a favor costs  $c > 0$  and the value of the favor is  $v$ . We will focus on the case where  $v > c$ . Thus value of a favor to the receiving agent exceeds the cost to the providing

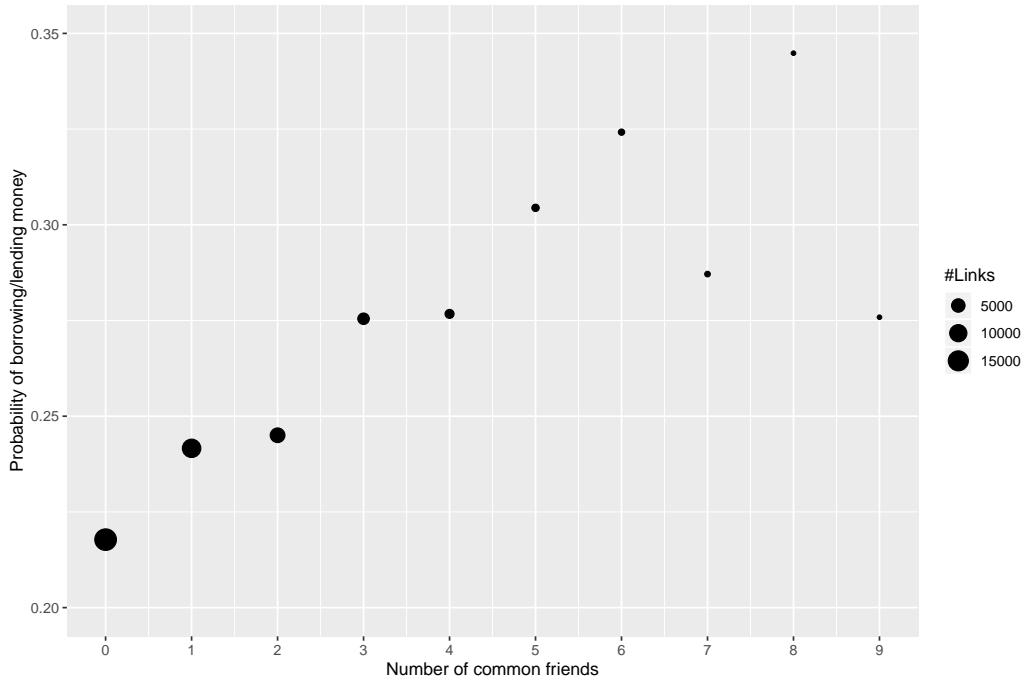

Figure 18.7: Common Friends and Large Favours. Data from Jackson, Rodriguez-Barraquer, and Tan [2012]

agent, so favour exchange is good for overall welfare. Individuals discount payoffs future payoffs using a factor  $0 < \delta < 1$ .

To develop a feel for the trade-offs involved, observe that in the situation with two individuals who do favours of each other, they would each expect a discounted payoff of

$$\frac{p(v - c)}{1 - \delta} \quad (18.10)$$

So an individual called upon to do a favour compared the cost  $c$  with the stream of benefits given by 18.10. Suppose that costs exceed these benefits – then two individuals cannot sustain favour exchange in isolation. How can the network help in this situation?

Consider individual  $i$  who is located in a network  $g$ . Suppose he refuses an offer to a friend  $j$ . Building on the idea of social punishments in the social collateral model a possibility is that  $j$  informs their common acquaintances and these common acquaintances all decide not to offer any favours to  $i$  in the future. Let  $N_{ij}(g) = N_i(g) \cup N_j(g)$  be the set of common acquaintances of  $i$  and  $j$  in the network  $g$ . Now, individual  $i$  located in a network  $g$ , compares the cost of doing the favour today,  $c$ , with the loss in stream of benefits from the common acquaintances and person  $j$ , i.e.,

$$\frac{(N_{ij}(g) + 1)p(v - c)}{1 - \delta} \quad (18.11)$$

This simple computation provides us with a simple rule of thumb: the size of favours that can be sustained in the network will grow with the number of common acquaintances between  $i$  and  $j$  an observation that is consistent with the evidence presented in section 18.3.

The discussion in this section focuses on the ways in which the structure of relations provides a form of collateral that allows for cooperative relations to exist. The social collateral argument rests on detailed information about transfers and the strength of ties being available to potential partners. In the introduction, we mentioned the role of trust in one off-interaction among strangers. The next section takes that up.

## 18.4 Generalized Trust

In this section, we start by presenting evidence on measures of generalized trust and then examine its sources. We will trust using the following “generalized trust question”:

- Generally speaking, would you say that most people can be trusted, or that you can't be too careful when dealing with others? The two possible answers are
  1. “Most people can be trusted”
  2. “Need to be very careful.”

We will measure trust in terms of the fraction of respondents who answered 1. The same question has been used by a variety of other surveys such as the European Social Survey, the General Social Survey, the World Values Survey, Latinobarometro, and the Australian Community Survey.

Figures 18.8 and 18.9 summarize the data for a set of countries for the years 1995 and 2017. They report the fraction of respondents who responded with ‘Most People can be trusted’. There are very great variations in level of trust across countries and these differences are fairly stable. For instance, in Sweden the trust level is 56% and 60%, while in Brazil the level of trust is 2.8% and 5.5%, respectively.

We next discuss the relation between this measure of trust and broad economic indicators. Figures 18.10 and 18.11 present a simple scatter plot on the relation between trust and per capita income for the years 1995 and 2017. We plot trust on the x-axis and the level of per capita income on the y-axis. We see that there is a clear positive correlation between

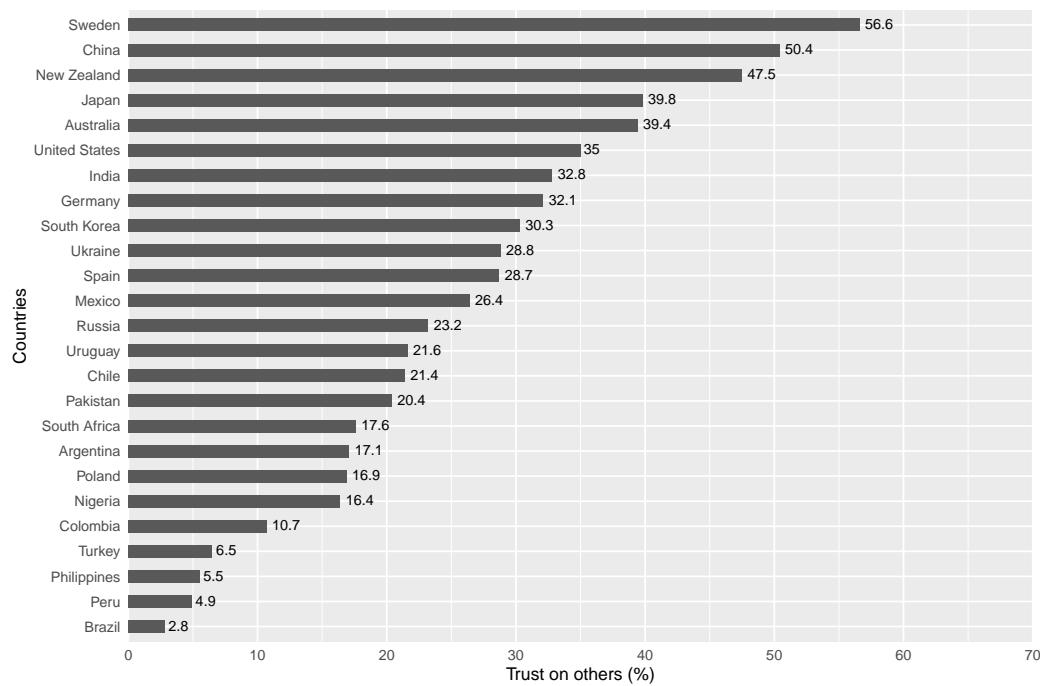

Figure 18.8: Trust Levels in 1995. Data from World Value Survey Wave 3.

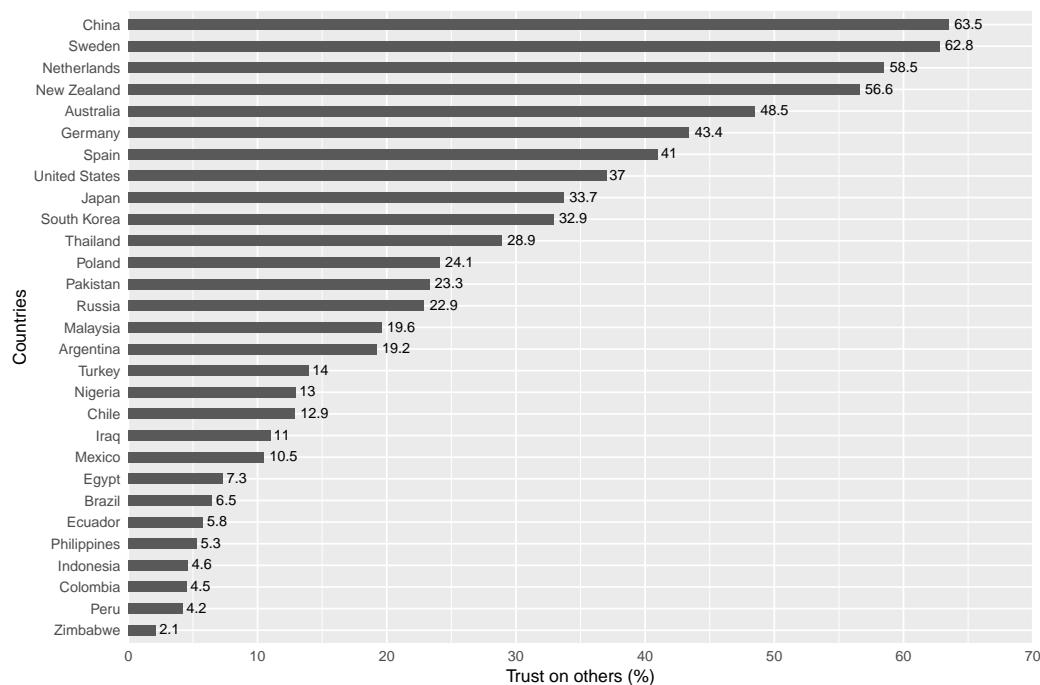

Figure 18.9: Trust Levels in 2017. Data from World Value Survey 2017

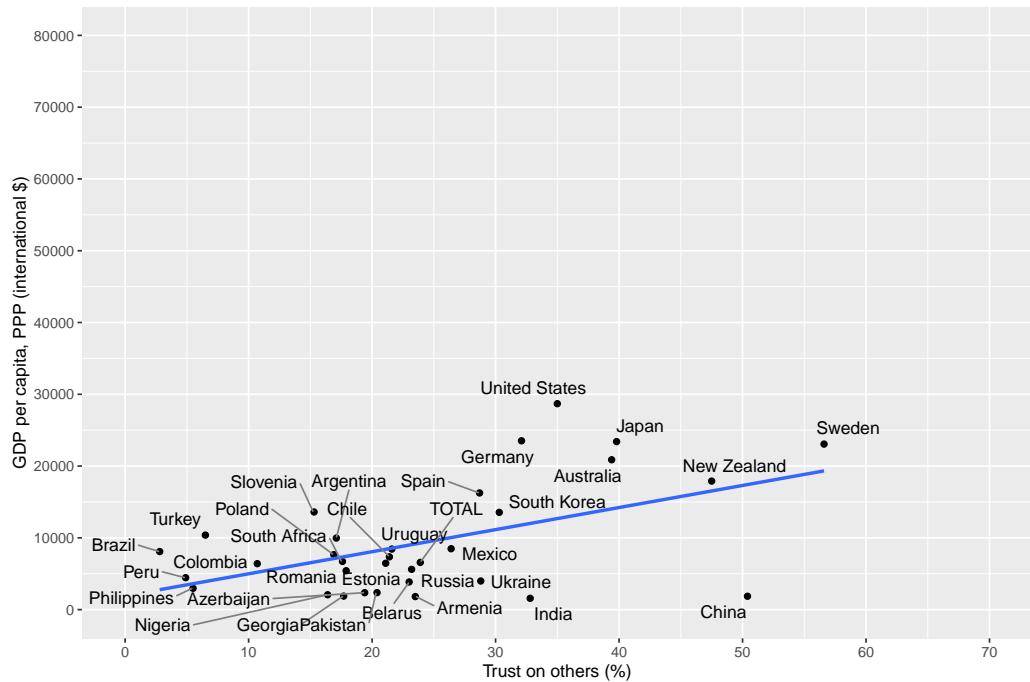

Figure 18.10: Trust and Income. Data from Data from World Value Survey Wave 3.

trust and income levels, for both years. These correlations motivate an examination of the sources of large differences in trust across countries.

We will trace differences in trust to culture. To appreciate the pathways through which culture may influence trust we start our discussion with the trust game: there are two players, a trustor and a trustee. The trustor has a sum of money  $M$ . In the first stage of the game, she can choose to pass on a part of this money,  $m$ , where  $m \in [0, M]$  to the trustee. Any amount passed on to trustee gains in value, so that the trustor receives  $3m$ . In the second stage of the game, the trustee can decide how much of this  $3m$  to return to the trustor. It is clear that if the trustor likes more money to less then she should retain all of  $3m$ . Anticipating this, the trustor will choose to transfer 0 in stage 1. Thus the money available to trustor and trustee will be  $M$  and 0. However, both the players are better off if the trustor and the trustee can agree to both transfer money to each other. For instance, if trustor transfers all of  $M$  and the trustee transfers one half of what she receives then both players will earn  $1.5M$  and they will both be better-off than in the no transfer outcome.

One resolution to this dilemma sees individual action as arising out of social obligations and expectations and norms. This perspective places emphasis on the role of the social context – how social relations and broader culture gives meanings to individual choice and thereby shapes action. In this line of thought, players solve this dilemma through trust. Trust can be thought of as

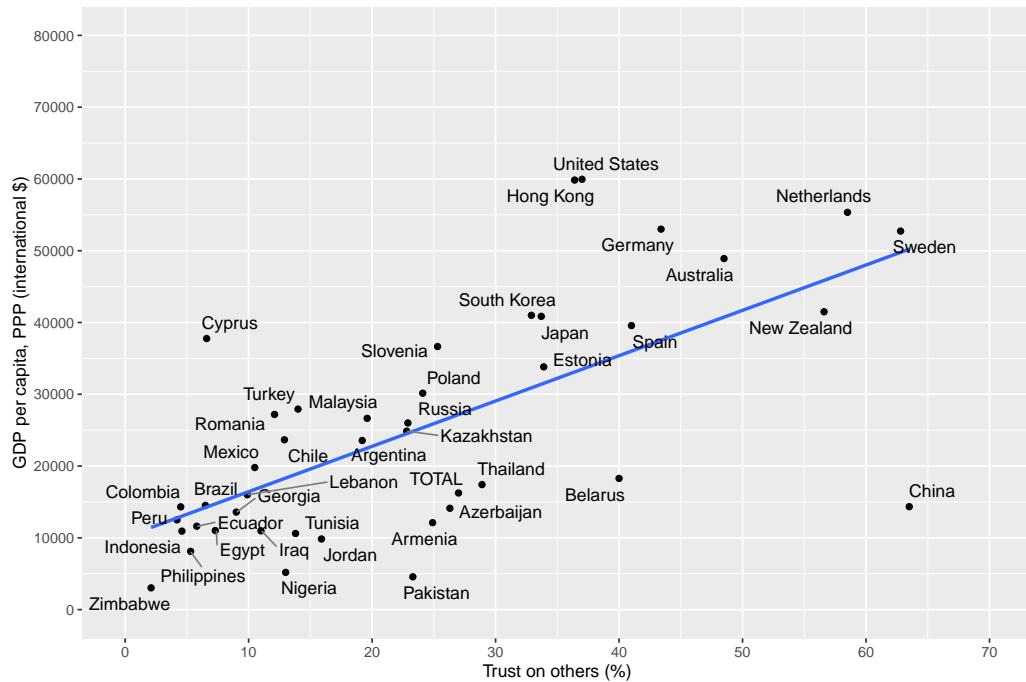

Figure 18.11: Trust and Income. Data from World Value Survey Wave 7.

..the subjective probability with which an agent assesses that another agent or group of agents will perform a particular action. Gambetta [1988]. Page number needed.

Individual A may trust B because she knows that B adheres to certain norms and these norms prescribe certain behaviour. These norms may entail trustworthy behaviour toward own group members or more generally toward everyone, even strangers.

A prescriptive norm within a collectivity that constitutes an especially important form of social capital is the norm that one should forgo self-interest and act in the interests of the collectivity. A norm of this sort, reinforced by social support, status, honor, and other rewards, is the social capital that builds young nations (and then dissipates as they grow older), strengthens families by leading family members to act selflessly in "the family's" interest, facilitates the development of nascent social movements through a small group of dedicated, inward-looking, and mutually rewarding members, and in general leads persons to work for the public good. In some of these cases, the norms are internalized; in others, they are largely supported through external rewards for selfless actions and disapproval for selfish actions. But, whether supported by internal or external sanctions, norms of this sort are important in overcoming

the public goods problem that exists in collectivities. Coleman [1988]. Page S104-105.

Thus a certain norm may be sustained through a combination of mechanisms (that involve the internalization of prescriptions that may form part of someone's identity, and a range of social pressures) In the previous section, we discussed the role of self interest and ongoing social relations in supporting cooperative behaviour in small groups. We now turn to the role of higher level social norms in shaping trust in large anonymous groups.

An important line of thought going back at least to Max Weber (Weber [2002]), argues for a central role for culture in shaping economic activity. Any new economic order – argued Weber – faces initial resistance. Economic incentives are not sufficient to motivate entrepreneurs to break apart from the pre-existing order. Weber argued that the Protestant Reformation came with the message that the pursuit of wealth should be regarded not merely as an advantage, but as a duty. This powerful injunction opened the way for individuals (and communities) to move beyond the earlier social order to create a new one, based on markets and the pursuit of economic accumulation.

The role of culture in its relation to trust and cooperative activity has been explored by a large literature. We now briefly discuss this work and then present empirical evidence on the relation between culture and trust. Culture may be said to be

.. those persistent and shared beliefs and values that help a group overcome the free rider problem in the pursuit of socially valuable activities. Guiso, Sapienza, and Zingales [2006a], pages 23-24.

The stability of culture and its effective intergenerational transmission through family upbringing is central to understanding the causal relationship flowing from trust on to economic growth. An important aspect of this work is that it shows that culture may provide a basis for different levels of trust. It does so by exploiting the intuitive notion that culture is persistent and this leads to a focus on dimensions of culture that are inherited by an individual from previous generations, rather than voluntarily accumulated.

Individuals have less control over their culture than over other social capital. They cannot alter their ethnicity, race or family history, and only with difficulty can they change their country or religion. Because of the difficulty of changing culture and its low depreciation rate, culture is largely a 'given' to individuals throughout their lifetimes. Becker [1998], page 16.

In this spirit, let us restrict attention to those cultural aspects like religion and ethnic background that can more reasonably be treated as invariant over an individual's lifetime.

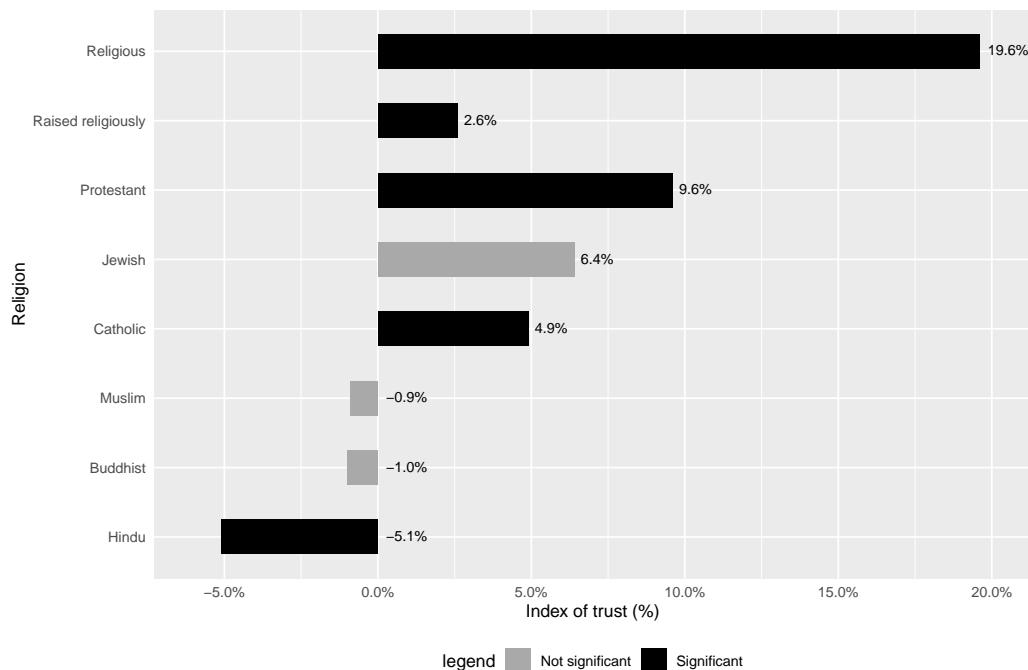

Figure 18.12: Religion and Trust. Data from Guiso, Sapienza, and Zingales [2006a].

Guiso, Sapienza, and Zingales [2003] present the effect of religion on trust using the World Values Survey. The dependent variable is a dummy equal to 1 if an individual replies “Most people can be trusted” to the question “Generally speaking, would you say that most people can be trusted or that you have to be very careful in dealing with people?”. The coefficients of interest pertain to religions shown in Figure 18.12 (where the omitted category is “no religious affiliation”). The figure suggests that being raised in a religious family raises the level of trust by 20% (this effect differs across denominations).

Similarly, ethnic origin has large effects on trust. To see this, let us replicate the same regression exercise within the United States, based on data from the General Social Survey. The General Social Survey measures ethnic origin of the respondent’s ancestors and allow us to study whether the culture transmitted by ancestors migrated from different countries plays a role in the beliefs of people living in the US. Figure 18.13 indicates a strong effect of ethnic origin: note that these effects are computed relative to Americans with British descendants. This suggests that the level of trust an American has toward others depends in part upon where the ancestors came from.

We conclude by showing that cultural traits are persistent. Figure 18.14 plots the impact of having ancestors from different parts of the world, relative to having British ancestors, and this is compared to the difference between the current level of trust in these parts of the world minus the trust in Great Britain from the World Values Survey. This figure

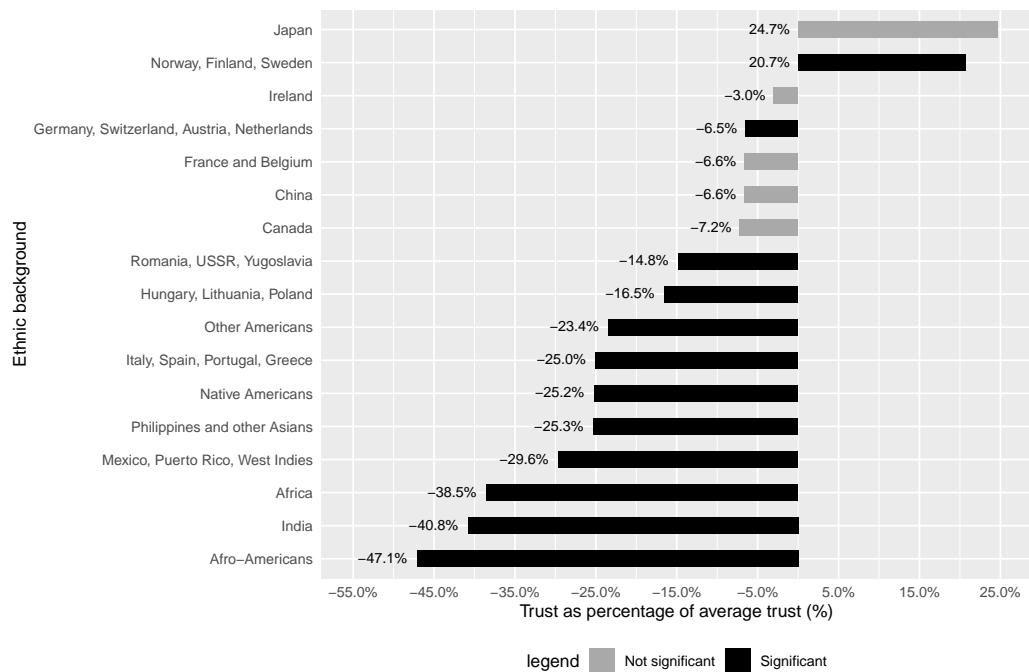

Figure 18.13: Ethnicity and Trust. Data from Guiso, Sapienza, and Zingales [2006a].

reveals a strong persistence in the differences in trust levels (the correlation is 0.6). This finding is consistent with the idea that beliefs about trust have a cultural component that is transported to the new world and continues to shape individual beliefs even in the new environment (several generations later).

## 18.5 Local and generalized trust

In our discussion of the diamond market, high trust within the small Jewish community that helps sustain economic activity will also make it difficult for individuals who do not belong to the community to participate in that market. This draws attention to a widely noted feature of network based trust – that it may inhibit wider exchange with outsiders and therefore it will be harmful to overall economic performance. In a wide ranging study on trust, Fukuyama [1995a] draws attention to a tension between different types of trust. He argues that prosperous countries tend to be those where loyalty to the (extended) family is not a dominant feature of social ties. Overweening family ties create rigidities and constraint the circle of trust. In particular, he argues that in countries like France and Italy (and Korea), social bonds are subordinated to family ties and other dysfunctional loyalties, creating rigidities, provoking state intervention, and dampening economic growth. By contrast, in Germany Japan and the United States, family ties are not dominant and

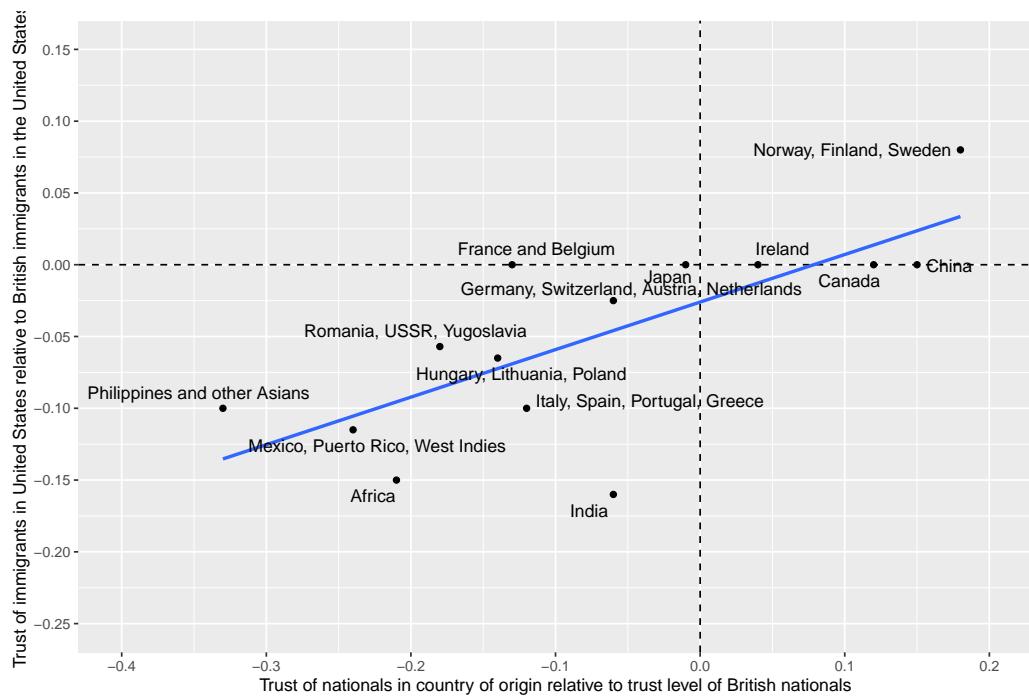

Figure 18.14: Persistence of Culture. Data from Guiso, Sapienza, and Zingales [2006a].

business relations between people can be conducted informally and flexibly on the basis of generalized trust.

This section starts with a simple model of group based favour exchange that helps us appreciate this tension between cooperativeness at the local level and overall economic performance. We then discuss features of formal institution that may help in addressing this problem; this issue is explored in greater detail in the next and final chapter of the book. We conclude this section by discussing the role of social structure in scaling up trust from the local level to larger collectivities.

### 18.5.1 A model of group based favours

Favoritism refers to the act of offering jobs, contracts and resources to members of one's own social group in preference to others who are outside the group. Over the years, a large literature has documented the prominent role of groups in the practice of favoritism in developing countries. For instance, in Tunisia members of the extended family of President Ben Ali and his wife routinely appropriated economic opportunities and granted each other special privileges; popular resentment against such favoritism played an important role in the Arab Spring in 2011. Appropriation of resources and contracts by dominant tribal groups in the African context, by caste groups in India, by dominant ethnic minori-

ties in many countries has been extensively documented. The aim of this section is examine the economic circumstances that give rise to favoritism and then to study its consequences for welfare.

We present a theoretical model taken from Bramoullé and Goyal [2016]. We consider a society with  $n$  individuals, who are partitioned in two groups  $\mathcal{A}$  and  $\mathcal{B}$  of respective sizes  $g_A$  and  $g_B$  with  $g_A + g_B = n$ ; we will assume throughout that  $n \geq 3$ .

One individual is picked uniformly at random and gets an economic opportunity. Call him the principal. To realize this opportunity, this principal needs to transact with an agent. One other individual is picked uniformly at random among the remaining individuals to be the expert. Thus the probability that a pair of individuals  $i$  and  $j$ , respectively are principal and expert is given by  $p$  and is defined as

$$p = \frac{1}{n} \frac{1}{n-1}. \quad (18.12)$$

If the principal interacts with the expert, the output produced is equal to 1. If the principal hires a non-expert, the output produced has a value of  $L \leq 1$ . We assume that there are no information problems: the principal and expert are commonly known once nature draws them. The value of  $L$  reflects the relative importance of the match quality.

We shall say that a principal practices *market behavior* if she always offers the job to the expert. By contrast, we shall say that a principal practices *favoritism* if she always hires someone from her group, *irrespective* of whether the expert is in her group or not. When a principal hires an inefficient group member, we say that he provides a favor. We will refer to the situation where a unique group practices favoritism as *limited favoritism* and the situation where both groups practice favoritism as *widespread favoritism*.

We now turn to the rules for the division of output. In the absence of frictions, competitive bidding provides a natural benchmark. Potential agents all bid for a contract; the expert is hired and earns  $1 - L$  while the principal earns  $L$  and non-experts earn 0.

To capture the role of frictions and rents, we adopt a two-stage model. In the first stage, a principal and an agent bargain over the division of output. If bargaining fails, the opportunity disappears with probability  $q \in [0, 1]$ . With probability  $1 - q$ , the second stage is reached and competitive bidding takes place. One interpretation of this probability is that it reflects the fact that bargaining takes time and, during this time, alternative competing opportunities may arise. An alternative interpretation is simply that it takes time to locate potential partners and in this period the exchange or economic opportunity may be superseded by alternatives. Payoffs in the first stage are determined via Nash bargaining. We now work out the payoff outcomes in this bargaining model.

Consider an interaction between the principal and the expert. Their reservation utilities are, respectively,  $(1 - q)L$  and  $(1 - q)(1 - L)$ . It then follows that their Nash Bargaining payoffs are then, respectively, equal to

$$L - q(L - \frac{1}{2}) \text{ and } 1 - L + q(L - \frac{1}{2}). \quad (18.13)$$

Consider next bargaining between the principal and a non-expert. The reservation utilities are  $(1 - q)L$  and 0. So their first period payoffs are given by  $L - \frac{1}{2}qL$  and  $\frac{1}{2}qL$ , respectively. As  $q$  increases, frictions worsen and payoffs get increasingly further away from the competitive benchmark.

This model provides a parsimonious representation of transaction costs and rents. We note that if  $L > \frac{1}{2}$  and  $q > 0$ , then experts earn more than under frictionless competition and their rents are equal to  $q(L - \frac{1}{2})$ . These rents are increasing in the level of friction,  $q$ , and falling in the (un)importance of match quality,  $L$ .

We denote by  $\pi_j(F, M)$  the expected payoff of an individual in group  $j \in \{\mathcal{A}, \mathcal{B}\}$  when his group practices favoritism while the other group practices market behavior; analogous notation is used for the other combinations. We will sometimes write  $\pi_j(F)$  when the behavior of outsiders is irrelevant.

The analysis starts with group incentives for the practice of favoritism. Suppose that group members can commit, *ex ante*, to a common norm of behavior. What are the circumstances under which they would choose to engage in favoritism?

When the expert is in the same group as the principal, in-group bias and efficiency are aligned. In this case, favoritism does not affect payoffs. Favoritism comes into play when the expert is an outsider to the group. A favor then costs  $\frac{1}{2}q(1 - L)$  to the principal, relative to market behavior, and yields  $\frac{1}{2}qL$  to the favored group member. The group gains  $q(L - \frac{1}{2})$  while the other group loses  $1 - L + q(L - \frac{1}{2})$  and society loses  $1 - L$ . This happens every time the principal is in the group while the expert is an outsider, hence with probability of  $p_{\mathcal{A}}g_{\mathcal{B}}$ . Therefore, the (expected) net group gain from favoritism is equal to  $p_{\mathcal{A}}g_{\mathcal{B}}(L - \frac{1}{2})$  while the other group loses  $p_{\mathcal{A}}g_{\mathcal{B}}(1 - L + q(L - \frac{1}{2}))$  and society loses  $p_{\mathcal{A}}g_{\mathcal{B}}(1 - L)$ . The per capita gain from a collective switch to favoritism is thus:

$$\pi_{\mathcal{A}}(F) - \pi_{\mathcal{A}}(M) = p_{\mathcal{A}}g_{\mathcal{B}}(L - \frac{1}{2}) \quad (18.14)$$

Observe that this equality holds no matter what the other group does.

**Observation 18.1.** *A group gains from favoritism if and only if  $q > 0$  and  $L > \frac{1}{2}$ . The rewards to favoritism for a group are increasing in both  $q$  and  $L$ .*

An important message is that if  $L > 1/2$  then *frictions* are both necessary and sufficient

for a group to desire favoritism. If the total payoff from an inefficient *within-group* match is higher than the fraction of an efficient match's payoff that stays in the group, then the group gains from favoritism. Therefore, groups may choose to practice favoritism even in the absence of informational frictions, social preferences or social dilemmas. When  $q > 0$  and  $L > \frac{1}{2}$ , experts earn rents in their economic transactions. Group gains from favoritism are precisely proportional to these rents, and are increasing in the extent of frictions  $q$  and  $L$ . As market frictions are greater and match quality less important (hence  $L$  is larger) in developing countries, this result also suggests that favoritism is more attractive in poor countries.

In addition, if a group faces discrimination or if there are other significant contracting costs with outsiders, principals in the group may not be able to get a fair reward for economic opportunities in dealings with outsiders. Terms of trade would then be group-specific, and our analysis easily extends to such situations. A group would then gain from favoritism when expert outsiders earn rents, no matter what happens for expert insiders. We finally observe, that under competitive bidding,  $q = 0$  and the principal's group is indifferent between favoritism and the market rule.

When  $L > \frac{1}{2}$  and  $q > 0$ , the game played by the two groups has the structure of a Prisoner's dilemma. Playing favoritism is a dominant strategy for each group.

Let us consider the economic consequences of the practice of favoritism. Suppose to begin that everyone abides by the market rule: principals hire experts. An individual is a principal with probability  $\frac{1}{n}$  and earns  $L - q(L - \frac{1}{2})$ . Similarly, he is an expert with probability  $\frac{1}{n}$  and then he earns  $1 - L + q(L - \frac{1}{2})$ . Therefore his expected payoff is:

$$\pi_A(M, M) = \pi_B(M, M) = \frac{1}{n} \quad (18.15)$$

As expected, the market generates equal payoffs across individuals. Moreover, total welfare is simply the sum of individuals utilities and is equal to 1.

Next, suppose that group  $\mathcal{A}$  practices favoritism while group  $\mathcal{B}$  abides by the market rule. Consider some individual  $i$  in  $\mathcal{A}$ . There are three possibilities. (1) With probability  $\frac{1}{n}$ , individual  $i$  is the principal. Then, the expert is a group member with probability  $\frac{g_A-1}{n-1}$ , in which case  $i$  earns  $L - q(L - \frac{1}{2})$ . Or, with the remaining probability  $\frac{g_B}{n-1}$ , the expert is an outsider and  $i$  provides a favor and earns  $L - \frac{1}{2}qL$ . (2) With probability  $\frac{1}{n}$ , individual  $i$  is the expert. Since the other group does not practice favoritism, he is always hired and earns  $1 - L + q(L - \frac{1}{2})$ . (3) Individual  $i$  obtains a favour: when the principal is another group  $\mathcal{A}$  member while the expert is an outsider. In addition, the opportunity to receive a favor is shared with all group members. So with probability  $\frac{(g_A-1)g_B}{n(n-1)} \frac{1}{g_A-1}$ , favored individual  $i$

earns  $\frac{1}{2}qL$ . Formally,

$$\begin{aligned}\pi_A(F, M) &= \frac{1}{n} \left( \frac{g_A - 1}{n-1} (L - q(L - \frac{1}{2})) + \frac{g_B}{n-1} (L - \frac{1}{2}qL) \right) \\ &\quad + \frac{1}{n} (1 - L + q(L - \frac{1}{2})) + \frac{(g_A - 1)g_B}{n(n-1)} \frac{1}{g_A - 1} \left( \frac{1}{2}qL \right)\end{aligned}\quad (18.16)$$

Regrouping and simplifying gives us the expected payoff to an individual  $i$  in group  $\mathcal{A}$  which practices favoritism, while group  $\mathcal{B}$  does not:

$$\pi_A(F, M) = p[n - 1 + qg_B(L - \frac{1}{2})] \quad (18.17)$$

In contrast, group  $\mathcal{B}$  loses  $1 - L + q(L - \frac{1}{2})$  per favor provided. So the individual's expected payoff is:

$$\pi_B(M, F) = p[n - 1 - g_A(1 - L + q(L - \frac{1}{2}))] \quad (18.18)$$

We see that  $\pi_A(F, M) > \pi(M, M) > \pi_B(M, F)$ . Starting from a market, a switch to favoritism by one group increases the payoffs of the group members at the expense of the payoffs of the outsiders. Interestingly, holding  $n$  constant, payoffs in the favoritism group are *decreasing* in its size. Benefits from exclusive favors are lower when they have to be shared with more individuals. Payoffs in group  $\mathcal{B}$  also decrease as group  $\mathcal{A}$  grows. Moreover, member in group  $\mathcal{B}$  lose more than what insiders gain, and the payoff advantage to group  $\mathcal{A}$ ,

$$\pi_A(F, M) - \pi_B(M, F) = p[qn(L - \frac{1}{2}) + g_A(1 - L)] \quad (18.19)$$

is positive and increasing in size of group  $\mathcal{A}$ .

Consider next a society with *widespread favoritism*. An expert in group  $\mathcal{A}$  is only hired when the principal is also a group member. Therefore,

$$\pi_A(F, F) = p[n - 1 - g_B(1 - L)] \quad (18.20)$$

and by symmetry  $\pi_B(F, F) = p[n - 1 - g_A(1 - L)]$ . Recall that  $\pi_A(M, M) = \pi_B(M, M) = p(n - 1)$ , and so individuals in *both* groups lose relative to the market!

Inequality is now a consequence of differences in group size. Since

$$\pi_A(F, F) - \pi_B(F, F) = p(g_A - g_B)(1 - L), \quad (18.21)$$

individuals in the larger group earn more than individuals in the smaller group. As both

groups are practicing favoritism, a larger group means more access to opportunities. Holding  $n$  constant, increasing the size of the larger group magnifies this effect: it raises payoffs in the larger group and lowers them in the other group.

Finally, consider aggregate social welfare. Recall that welfare drops by  $1 - L$  every time a favor is given. Total welfare loss is then equal to  $p_{AGB}(1 - L)$  under limited favoritism and  $2p_{AGB}(1 - L)$  under widespread favoritism. In either case welfare loss is maximal in a society with two groups of equal size.

We summarize these arguments as follows:

**Proposition 18.3.** *The welfare effects under:*

- *Limited Favoritism: individuals in favoritism group earn more than in the market, while individuals in the other group earn less than in the market. The payoff to favoritism group is declining in group size. However, payoff difference between the two groups is increasing in the size of the favoritism group.*
- *Widespread favoritism: all individuals earn lower payoffs as compared to the market. The individuals in the larger group earn more than those in the smaller group; this difference is increasing in the size of the larger group.*
- *Social welfare is lower under favoritism and is minimized in a society with two equal size groups.*

Thus, group based favoritism *always* reduces aggregate social welfare. We have provided a simple theoretical model of group based favour exchange that leads to lower economic performance. What can the groups and the society as a whole do to overcome the inefficiencies?

One way is to create formal legal and executive institutions that create and implement fair practice. These institutions involve innovations in institutional design and will entail costs. A simple way to think about the problem would be to say that there is a fixed cost  $F > 0$  to establish such institutions. The society as a whole would find it worthwhile to install such institutions if the returns were greater than the cost. Recall that the institution will help rectify principal and expert matching in situations where principal and expert are in different groups. The likelihood of this happening increases with an increase in the size of the smaller group and is maximized when the two groups are of equal size. Thus a society is more likely to install formal monitoring institutions when the two groups are of relatively similar size or equivalently, the greater the similarity in the size of the groups the higher the costs the society is willing to incur to prevent favoritism.

In this simple story, the assumption is that once established the formal institution can successfully prevent favoritism. But installing institutions is generally not enough: they have to be monitored for successful performance. The monitoring of institutions calls for effort and initiative from individuals. Therefore the extent to which formal institutions are able to address the problem of favoritism may depend on the associations and the broader culture of public spiritedness that exist in a society. The relation between formal institutions and social structure is studied in the next chapter.

## 18.6 Scaling up trust: role of social networks

...we need to understand the relationship between trust relations among individuals and in small communities and those in large networks of interaction.

This question has received little attention. Granovetter [2017a], page 85.

In our discussion of network closure and social collateral a recurrent theme is that particular forms of social networks can help sustain cooperation and local trust. In our discussion on generalized trust in the previous section, we mostly concentrated on the role of culture – interpreted in terms of expectations and beliefs concerning individual behaviour in matters regarding public goods – in sustaining trust. In this section we explore the role of social interactions and structures in sustaining such beliefs. In particular, we will examine ways in which the structure of the social network can help sustain social norms by providing a pathway from the small scale and local to the societal large scale.

Let us begin with a few empirical observations. Ermisch and Gambetta [2008], using trust games with a representative sample of the British population, find that people with strong family ties have a lower level of trust in strangers than people with weak family ties. They argue that this is because of the level of outward exposure: factors that limit exposure, limit subjects' experience and this also impairs their motivation to deal with strangers. Greif and Tabellini [2017] provide an historical analysis of this opposition by comparing the bifurcation of societal organization between pre-modern China and medieval Europe. Pre-modern China sustained cooperation within the clan, e.g. a kinship-based hierarchical organization in which strong moral ties and reputation among clan members played the key role. By contrast, in medieval Europe, the main example of a cooperative organization is the city, where cooperation is across kinship circles, and external enforcement played a bigger role. There is also empirical evidence on a negative relation between strong family based ties and political and social engagement, see e.g., Alesina and Giuliano [2010] and Alesina and Giuliano [2011].

Studies in this spirit lend support to a widely held and influential view that local group based favour exchange is incompatible with generalized trust. A number of prominent authors have written about this tension. As we noted in the previous section, Fukuyama [1995a] argues that strong favour exchange within kin based groups undermines generalized trust. Similarly, Henrich [2020] in his study of 'Weird' (acronym for Western, Educated, Industrialized, Rich, and Developed) societies argues for the distinctiveness of societies in which individuals hold on to abstract principles of fairness and are able to successfully undertake anonymous impersonal exchange in contrast to the majority of societies in the world where kin based norms are dominant (and that rely on favour exchange within groups). The model presented in the previous section offered a formulation of this tension: favour exchange within a group came at a the expense of losses at the aggregate level.

On the other hand, some authors have written about the possibilities of scaling up personalized trust through appropriate network structure. To see how this may be accomplished, consider the case of South Korea – a country that on the one hand conforms to a Confucian family system and on the other hand has an economy dominated by large professionally managed and highly successful companies (such as LG, Samsung, and Hyundai). Another prominent example of large professionally managed conglomerates controlled by a community is the Tata Group in India. A possibility is that kinship group can scale up its operations substantially by locating close members of the family in strategic positions of a network that is large. This is accompanied by cross-ownership among the relevant firms so as to ensure overlapping financial control.

The typical evolution was that an original family firm expanded not by getting larger but by setting up branches as independent companies or by buying already-established businesses. Authority, however, remained highly centralised across the component companies. Reputation and personal trustworthiness are crucial, contracts unimportant....These business groups can be very large and diversified, but control is maintained through pyramids – family firms that control other firms that control still other firms, etc – and dense interlocking directorates.

Thus family members who have strong trust relations with the central family group are strategically sprinkled through the many holdings in such a way as to knit the entire structure together. Employees who are not in direct touch with the core family members may nevertheless trust the motives of that group through their direct ties to the local family representatives and work harder and more effectively than if they had no commitment to the central group. Granovetter [2017a], Page 87-88.

In this example, it is possible that key members of the family were deliberately located at certain positions in the network to monitor and to collect information and to enforce norms.

To see how such a social structure can come about ‘organically’, in a large community, and without deliberate intervention, we turn next discuss a large community of researchers. We present data on research economists. Let us recall from chapter 1 the broad facts about this community: over the period 2000-2009, there were over 151,000 authors who published papers. The average number of coauthors, 1.95, was very small, but the most connected 100 authors had 25 coauthors on average. Somewhat remarkably, in spite of the very low average degree, the largest component contained over 67,000 nodes (this constitutes over 44% of all nodes) with an average distance of only 9.80. The key to understanding the average small distance is highly connected authors: the deletion of the 5% most connected authors completely fragmented it. Thus the most connected authors span the research profession and hold it together.

Van der Leij and Goyal [2011a] study the location of topology of the network and their interest is in the role of strong ties in sustaining it. They measure strength of a tie by the number of papers written together by the coauthors. They find that there is a positive correlation between the degree of authors and the strength of their tie. They also find that these strong ties are critical to holding the network together: in particular, the deletion of strong ties fragments the network at a much faster rate as compared to the impact of the deleting weak ties between authors.

We illustrate these points with the help of local network plots of leading economists. Figures 18.15-18.16 present the network of weighted links in the coauthor network around two leading economists over the period 1990-2009, Jean Tirole and Esther Duflo. These economists are connected with strong ties to key economists who in turn also have many links. The strong ties and the close access that a large set of economists have to Mr Tirole and to Ms Duflo (and therefore also to each other) facilitate the process of creating a tightly knit global community with shared norms on what are the important research questions and what are the appropriate methods to address them.

We bring these observations together by presenting a stylized network that illustrates these structural possibilities – highly connected nodes, strong ties between high degree nodes, small average distances – as in Figure 18.17.

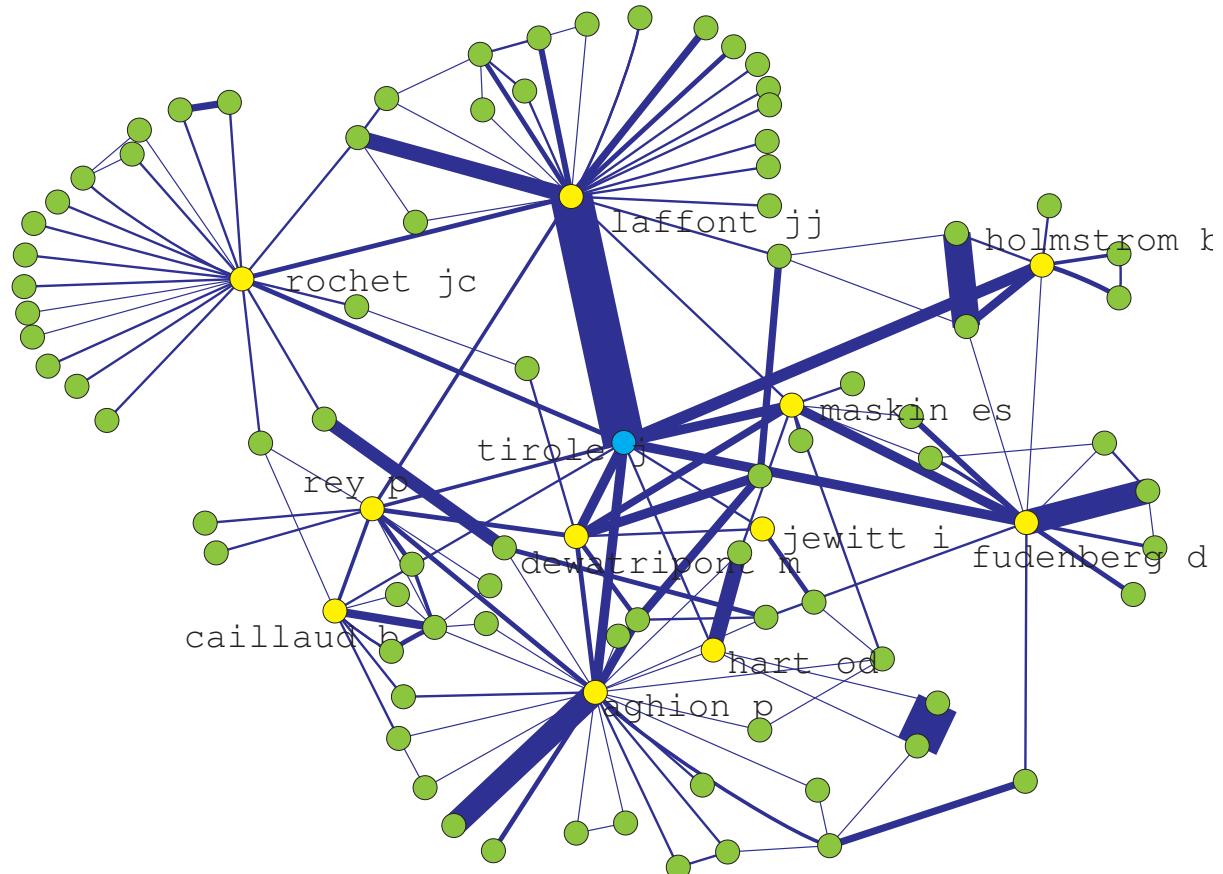

Figure 18.15: Local network of collaboration of Jean Tirole in the 1990s.

Note: The figure shows all authors within distance 2 of J. Tirole as well as the links between them. The width denotes the strength of a tie. Some economists might appear twice or are missing due to the use of different initials or misspellings in EconLit. The figure was created by software program *Pajek*.

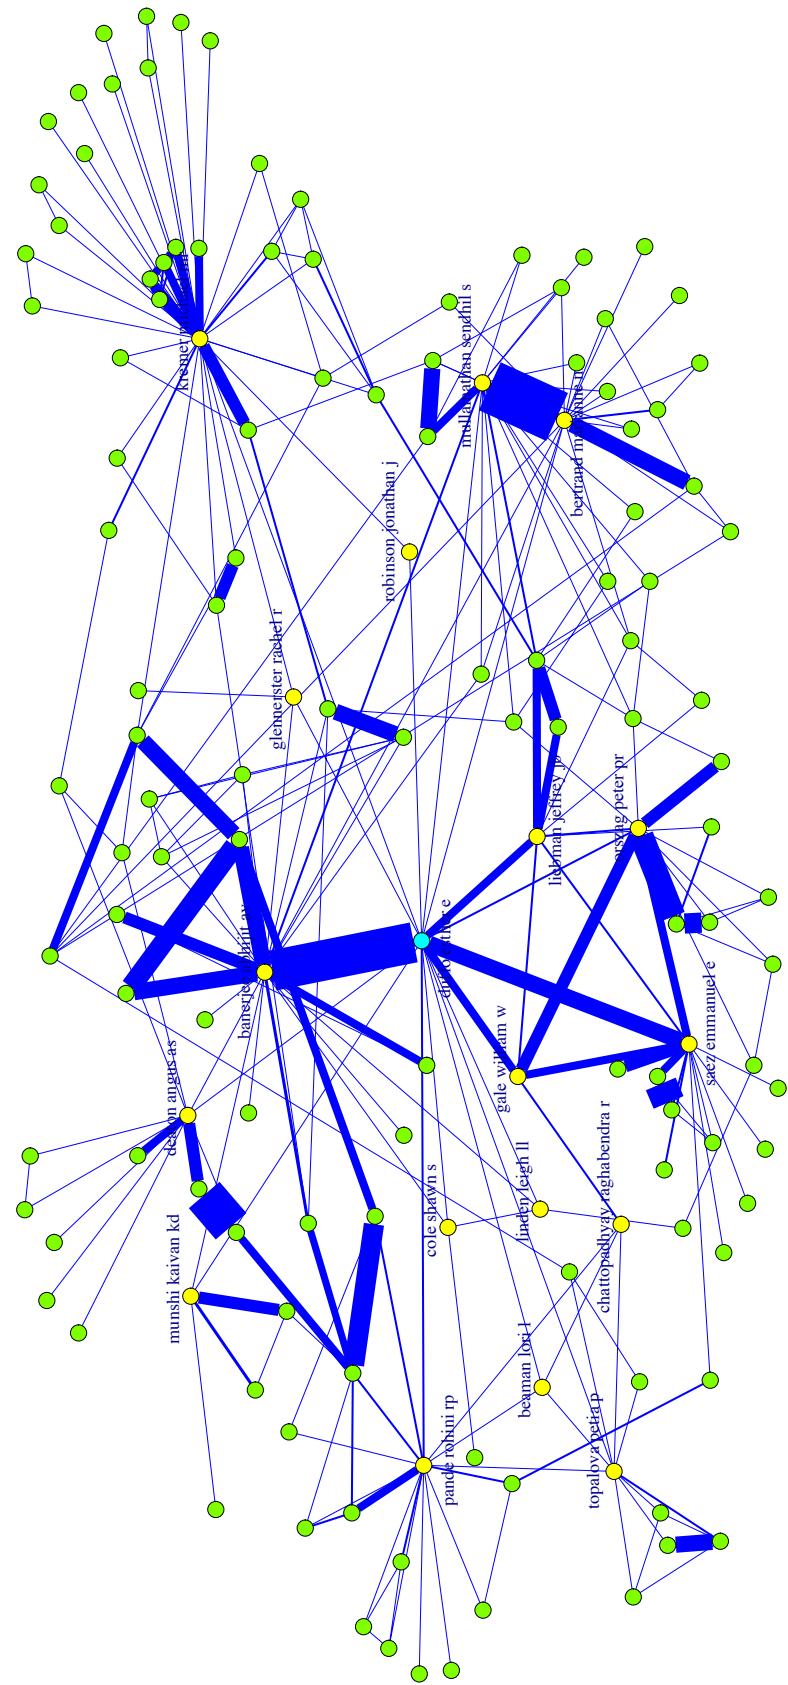

Figure 18.16: Local network of collaboration of Esther Duflo, 2000-2009.

Note: The figure shows all authors within distance 2 of Esther Duflo as well as the links between them. Some economists might appear twice or are missing due to the use of different initials or misspellings in EconLit. The width denotes the strength of a tie. The figure was created by software program *Pajek*.

## 18.7 Appendix

The network of boards of editors of economics journals includes 28 journals: Journal of Health Economics (JHE), Review of Economics and Statistics (REStat), Review of Economic Studies (REStud), Econometric Theory (ET), Journal of Monetary Economics (JME), Quarterly Journal of Economics (QJE), Journal of Economic Literature (JEL), Journal of Business and Economic Statistics (JBES), Econometrica (ECMA), Review of Financial Studies (RFS), RAND Journal of Economics (RAND), Economic Journal (EJ), Journal of Environmental Economics and Management (JEEM), Journal of Finance (JoF), Journal of Econometrics (JoE), Journal of International Economics (JIE), European Economic Review (EER), World Bank Economic Review (WBER), International Economic Review (IER), American Economic Review (AER), Journal of Human Resources (JHR), Journal of Labor Economics (JLE), Journal of Political Economy (JPolE) Journal of Public Economics (JPubE), Games and Economic Behavior (GEB), Journal of Economic Theory (JET), Journal of Economic Perspectives (JEP), Journal of Financial Economics (JFE).

## 18.8 Reading Notes

The study of trust spans many disciplines. It is closely connected to the ideas of social capital in sociology and political science and to ideas of reputations and repeated interaction in game theory. More recently, a large strand of research in economics studies the role of culture in shaping trust.

For an early and classical discussion of the role of trust in reducing transaction costs see Arrow [1972] and Arrow [1974]. The origins of the ideas on social capital may be found in Bourdieu [1977], Bourdieu [1984], Jacobs [2016], and Loury [1976]. Coleman [1988] and Coleman [1994] provided a broad conceptual foundation for social capital and also drew attention to the importance of network closure for norms of monitoring and cooperation. Gambetta [1988] provides an introduction to different perspectives on the subject of trust and Dasgupta and Serageldin [2001] and Portes [1998] provides an excellent overview of the literature on social capital. Mention must also be made of the Russell Sage series on Trust (especially the work of Cook, Levi, and Hardin [2009] and the early work of Wellman and Wortley [1990]).

The impetus provided by the work in the 1980's, and especially Coleman's work, led to two distinct strands of work – a microeconomic approach more focused on local trust and a line of macroeconomic strand concerned with the role of culture in understanding generalized trust. We briefly discuss evidence on trust in section 18.2. The material there

draws on the Global Values Surveys, the early work of Coleman [1988] and Coleman [1994] and the empirical work of Knack and Keefer [1997].

Economists have traditionally studied questions of cooperation and social norms using models of repeated games. For a survey of this literature, see Mailath and Samuelson [2006]. A general message from this work is that cooperation is difficult to sustain in large communities with anonymous interaction. In section 18.3, we focus on small communities and examine the role of network closure in sustaining cooperation. For a survey of the work on networks and repeated games, see Nava [2016]. To bring out the role of network in the simplest way, in section 18.3, we focus on a model of social collateral, that is taken from Karlan, Mobius, Rosenblat, and Szeidl [2009]. The empirical study of Peruvian towns is also taken from the same paper. The case study of favour exchange in rural India is taken from Jackson, Rodriguez-Barraquer, and Tan [2012]. This paper also provides a general theory of favour exchange in networks and we draw on it to elaborate on the role of common neighbours.

We do not discuss this point in the chapter, but it should be clear that shared norms based on altruism and identity are not incompatible with the role of self interest in sustaining cooperation even in small groups. Networks evolve in response to changes in the larger environment; for a study of networks that support cooperation in a changing environment, see Vega-Redondo [2006]. For an early study of repeated games and network structure see Haag and Lagunoff [2006].

There is a large literature on the relations between culture, trust and economic performance in political science and sociology. Max Weber's work on the Protestant Ethic remains a powerful influence in this field. Similarly, Edward Banfield's early study of 'amoral familism' in Southern Italy casts a long shadow on our understanding of the importance of culture (Banfield [1958]). Banfield attributes underdevelopment to the excessive pursuit of narrow self interest by its inhabitants, a condition he labels "amoral familism". More recently, Fukuyama (Fukuyama [1995a]), argues for a key role for culture and the fabric of society in our understanding of economic success and failure. Similarly, (Putnam et al. [1993]), in his study of the differences between North and South Italy argues for the positive effects of "civic" culture on the quality of political institutions.

Trust can be measured by using surveys and laboratory experiments. Empirical research investigating the link between economic performance and trust usually draws on answers from survey questions. The reason for this is the availability of surveys, which cover a large number of countries since the beginning of the 1980s. Nevertheless, these surveys raise difficulties in interpretation. It is not clear how respondents interpret the question: for instance, who do they have in mind when they think of trustworthiness?

Some of these points are taken up in the next and final chapter.

This work in political science and the positive empirical correlations between generalized trust and a number of economic performance indicators demonstrated by Knack and Keefer [1997] and Zak and Knack [2001] drew the attention of economists to the study of trust.

A large body of subsequent work studies the role of culture in shaping trust and economic performance. Influential contributions in this field include Algan and Cahuc [2010], Bisin and Verdier [2000], Guiso, Sapienza, and Zingales [2003], Guiso, Sapienza, and Zingales [2006a], and Glaeser, Laibson, Scheinkman, and Soutter [2000]. For a survey of this work see Algan and Cahuc [2014] and Guiso, Sapienza, and Zingales [2011]. The issue of trust and distrust in large scale settings is examined in Aghion, Algan, Cahuc, and Shleifer [2010], Nunn and Wantchekon [2011] and La Porta et al. [1997]. Section 18.4 presents the game of trust and provides a brief summary of the relation between culture and trust.

The game of trust was introduced in Berg, Dickhaut, and McCabe [1995]; for a related game of trust, also see Dasgupta [1988]. The game of trust has been used to systematically investigate the different elements of trust – in terms of own behaviour, expectations of other's behaviour and so forth (Glaeser, Laibson, Scheinkman, and Soutter [2000], Glaeser, Laibson, and Sacerdote [2002]). There is also a literature that examines the relation between survey based trust measures and actual behaviour in trust games; see e.g., Glaeser et al. [2000].

Section 18.6 takes up the relation between local and generalized trust. Bourdieu [1984], Banfield [1958] and Fukuyama [1995b] draw attention to the tension between local trust and generalized trust. We present a simple model of within group favour exchange to examine this tension. This model of group based favour exchange is taken from Bramoullé and Goyal [2016]. We briefly comment on the role of formal institutions in overcoming the negative consequences of group based favour exchange. We draw on Granovetter [2017a] and Van der Leij and Goyal [2011a] to discuss the aspects of social structure that can facilitate scaling up of social norms and trust from the local setting to larger collectivities. This discussion forms a bridge to the next chapter, where we study the role of formal institutions and social structure in scaling up trust in a society.

I thank Mark Granovetter for comments on this chapter.

## 18.9 Questions

1. Based on the model of social collateral in section 18.3, compute the maximum loan that individual S can take from individual T in the two networks presented in Figures

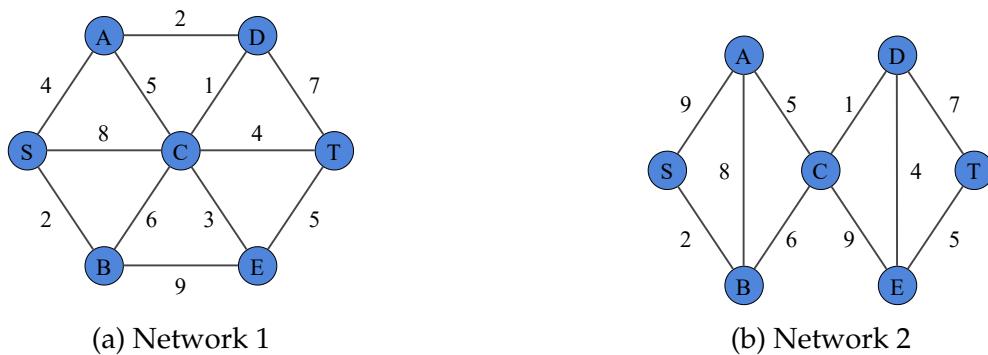

Figure 18.18: Social Collateral in Networks

18.18 below.

2. This question explores variations on the model of group based favoritism presented in section 18.5.1.
  - (a) Due to historical and institutional reasons, it is often the case that one group of individuals – for instance, a tribe, linguistic group or an ethnic group in power – is more likely to hear about economic opportunities than other groups. Similarly, due to historical reasons, some groups may have greater expertise than other groups. Using the model show that heterogeneity in opportunities across groups makes favoritism easier to sustain, while heterogeneity within a group makes favoritism less sustainable.
  - (b) We assumed that individuals have linear preferences. Show that risk aversion will reinforce the pressure toward favoritism in groups.
3. The problem of trust arises only in large anonymous groups. Discuss.
4. Cultural beliefs are a natural foundation for trust among strangers. Discuss the role of social structure in sustaining such cultural beliefs.
5. Figure 18.19 presents a network of ties between board of leading economic journals in 2010. We see that the network is connected and that most of the links are relatively weak. Interestingly the network is held together through a hierarchical structure – the general interest journals share common editors with field journals; there are relatively few ties among the general interest journals and the field journals, respectively. Use this network in combination with the discussion in section 18.6 to discuss the social structure basis of shared norms in economics. The list of journals is provided in the appendix to the chapter.

# **Chapter 19: Kinships, Impersonal Exchange and the State**

Americans of all ages, all conditions, all minds constantly unite. Not only do they have commercial and industrial associations in which all take part, but they also have a thousand other kinds: religious, moral, grave, futile, very general and very particular, immense and very small: Americans use associations to give fetes, to found seminaries, to build inns, to raise churches, to distribute books, to send missionaries to the antipodes; in this manner they create hospitals, prisons, schools. Finally, if it is a question of bringing to light a truth or developing a sentiment with the support of a great example, they associate. Everywhere that, at the head of a new undertaking you see the government in France and a great lord in England, count on it that you will perceive an association in the United States. Tocqueville [2004], page 489.

When historians record the history of our time, 300 years from now, the end of the Cold War will be at most a third story in that history. Events in the Middle East will be the second story. When the history of our times is written, the events in Asia, the changes in the lives of so many people so quickly and its ramifications for the global system will be the most important story. Summers [2007], page 4.

## **19.1 Introduction**

The role of kin-based groups in its relation to economic performance remains highly contested. The dominance of family and kin-based groups is an impediment to the evolution of broader circles of trust; as generalized trust is important for impersonal exchange, and impersonal exchange central to efficient economic activity, strong kin-based ties inhibit economic performance. On the other hand, there are well known examples of societies centred on nuclear families and weak kinship groups that are economic and social failures.

Perhaps even more tellingly, there are prominent instances of societies with strong family and kin-based groups that have enjoyed rapid economic growth. Thus kin-based groups have a rich and varied relationship with economic performance. The goal of this chapter is to develop a theoretical framework that helps us identify principles to understand this relationship.

In the next section, we begin by showing that there is a negative correlation between the strength of kin-based institutions and generalized trust. This is the point of departure for a number of case studies of how different societies organize economic and political activity – those with small kin-based groups as well as those with large and powerful kin-based groups. Of particular interest is the relation between kin-based groups, the nature of impersonal exchange and the role of the state.

Section 19.3 draws on anthropology, sociology, political science and economics to discuss, in very broad terms, a number of concepts that we use to locate the experience of different countries within a common framework. We view culture as a ‘composite’ that includes beliefs and values and social structure. We use this approach to argue that empirically observed configurations of civic culture, impersonal exchange, and the state can therefore be understood with the help of the concepts of complements and substitutes: whether civic capital and the state are complements or substitutes.

Section 19.4 presents a theoretical model. The ingredients of this model are social structure (kin-based groups and horizontal social linkages across groups), economic exchange (within and across groups), and the formal institutions of the state. Kin-based exchange is frictionless but it is constrained by the size of the group but exchange outside the group has the potential to be more valuable but it entails transaction costs. The magnitude of these costs depends on the effectiveness of the state and formal institutions and on generalized trust. Generalized trust in turn is correlated with the quality of civic community and is measured by the strength of ties across kin-based groups in a society. A larger state and greater civic community both lower frictions.

The model proceeds as follows: given a social structure, individuals choose their level of civic engagement. These choices determine the civic capital in a society. Given the civic capital, individuals decide on the tax rate through majority voting. The tax revenue shapes the size of the state. Given civic capital and state capacity, individuals finally choose whether to limit themselves to kinship based exchange or to engage in impersonal exchange.

Our analysis draws attention to the role of the social structure in defining the level of civic engagement and size of the state, how these outcomes determine the relative magnitude of group-based and impersonal exchange, and how that in turn shapes economic

performance.

## 19.2 Empirical Background

We begin with a brief recapitulation of our discussion in the chapter on trust. In the World Values Surveys, the key question on generalized trust is:

Generally speaking, would you say that most people can be trusted, or that you can't be too careful when dealing with others?

The two possible responses are “Most people can be trusted” and “Need to be very careful.” The fraction of population giving the first answer is interpreted as a measure of trust. The surveys show that there are very great variations in the level of trust across countries and these differences are stable over time. For instance, in Sweden the trust level is 56% percent and 60%, while in Brazil the level of trust is 2.8% and 5.5% in 1995 and 2017, respectively. In that chapter, we showed that generalized trust is positively correlated with income. The wide variations in generalized trust and the positive correlation motivate a closer examination of the sources of trust. We discussed the contrast between local and generalized trust and we introduced the role of culture and examined the relation between stable indicators of culture – such as religious affiliation and ethnicity – and generalized trust. We now take that discussion further. We introduce one the notion of universalism and then study how these two variables, generalized trust and universalism, are related to the strength of kin-based groups in a society.

Universalism is defined in terms of responses to a hypothetical scenario, the *Passenger's Dilemma*.

You are riding in a car driven by your friend. He hits a pedestrian. You know that he was going at least 35 miles per hour in an area of the city where the maximum allowed speed is 20 miles per hour. There are no witnesses, except for you. His lawyer says that if you testify under oath that he was driving only 20 miles per hour it may save him from serious legal consequences.

Do you think:

1. that your friend has a definite right to expect your to testify (as his close friend), and that you would testify that he was getting 20 miles per hour, or
2. that your friend has little or no right to expect you to testify and that you would not falsely testify that he was only going 20 miles per hour?

Surveys have been conducted with managers and business people in different countries across the world. The first response is interpreted as *particularistic* or *relational*, while the second response is interpreted as a *universalistic* or *non-relational*. In a number of countries such as South Korea, Venezuela and Nepal, the vast majority of responses were (1). By contrast, in a number of other countries like the United States, Canada, and Switzerland, over 90% of respondents answered (2).

The studies on generalized trust and universalism are striking in a numbers of ways. One, there is wide variation in outcomes with regard to both variables. Two, countries that score high on one measure do not always score high on the other measure. For instance, some Asian countries like Korea and Japan score highly on generalized trust but score poorly on universalism. Finally, there are some outlier countries – such as the United States, Germany, Switzerland, and Sweden – that score very highly on both measures. Following the terminology coined by Joseph Henrich and his collaborators, we will refer to these countries as WEIRD ('WEIRD' standing for 'Western-Educated-Industrialized-Rich-Developed'). Let us examine the relation between the strength of kin-based groups and universalism and generalized trust.

#### KINSHIP AND WEIRDNESS

In our discussions on local trust in Chapter 18 we elaborated on the idea of how favour exchange can arise through personal connections. This was a very concrete and specific instance of how kinship based networks can support trust. More generally, there are many features of kin-based institutions that promote a sense of trust and that depend on interconnectedness with those within the group. At the same time, and also as noted in our discussions in Chapter 18, kin-based norms may well breed a sharper recognition of those within and those outside the group and this appreciation can undermine generalized trust. Building on this observation, we examined how strong kin-based institutions affect generalized trust, but now we take care to pose the question on generalized trust in a manner that distinguishes between (within kinship group) insiders and (non-kin) outsiders. Our discussion draws heavily on Henrich [2020] and Enke [2019].

The questions on trust distinguish between different sets of people. They ask how much individuals trust (i) their own families (ii) their neighbours (iii) people they know (iv) people they don't know (v) people they have met for the first time (vi) foreigners (vii) adherents to religions other than their own. We construct an in-group trust measure by averaging people's responses to the first three categories about family, neighbours and people they know. Similarly, we can construct a measure of out-group trust by averaging responses to responses to the latter four categories. When we take the difference between the two averages, we arrive at the Out-In-Group Trust. Figure 19.1 summarizes the data on this

measure (the data is from 75 countries; it must be noted that the data does not cover large parts of Africa and the Middle East).

The first point to note is that, as with generalized trust, there is also great variation in Out-In-Group Trust across countries. We next note an interesting and more subtle issue: there are countries – such as China – in which individuals responded very positively to the original generalized trust question in the World Values Survey, but in which the Out-In-Group Trust measure is low. One way to interpret this discrepancy between the generalized trust measure and the Out-In-Group Trust measure is as follows: when faced with the generalized trust question, individuals may think this is a question about people they meet on a day-to day basis. If they mostly meet own kin-based members then their response would be to say that such individuals can be trusted. However, when asked specifically about different types of individuals in the seven categories mentioned above, individuals may be more precise about their trust attitudes. Equipped with this more sophisticated notion of generalized trust, let us now turn to the relation between kin-based institutions and Out-In-Group Trust and universalism.

Kin-based institutions posses a wide range of features and they differ in many ways from each other. A natural place to start is rules and practices concerning marriage: some societies allow men to have multiple wives while others allow only one wife (this variable is termed ‘polygamy versus monogamy’). A related feature pertains to which partners are allowed and which are disallowed: in some societies marriages between uncles and nieces or between first or second cousins are allowed, whereas in others even marriages between fifth cousins is disallowed (this variable is termed ‘cousin marriage’).

A second dimension pertains to habitation: in some societies the expectation is for multiple generations such as parents, their sons, and the families of the sons to live together; in other societies the norm is that children live with their parents until adulthood and they then move to set up their own households (this variable is termed ‘joint versus nuclear family’). Finally, there is the issue of descent: in some societies, descent is solely through the male side (father and the son), while in others descent is traced through both the paternal and the maternal side (this variable is termed ‘paternal versus bilateral descent’).

Building on these considerations, we will study the following five attributes of kinship institutions: (i) bilateral descent (ii) second or closer cousin marriage (iii) monogamy (iv) nuclear family and (v) separate/neolocal residence. Anthropologists have collected data on these traits from over 1200 pre-industrial societies (available in the Database of Places, Language, Culture, and Environment at D-PLACE.org). The frequencies of these different traits vary from a high of 28% for bilateral descent to a low of 5% for neolocal residence. Table 19.1 taken from Henrich [2020] summarizes these data.

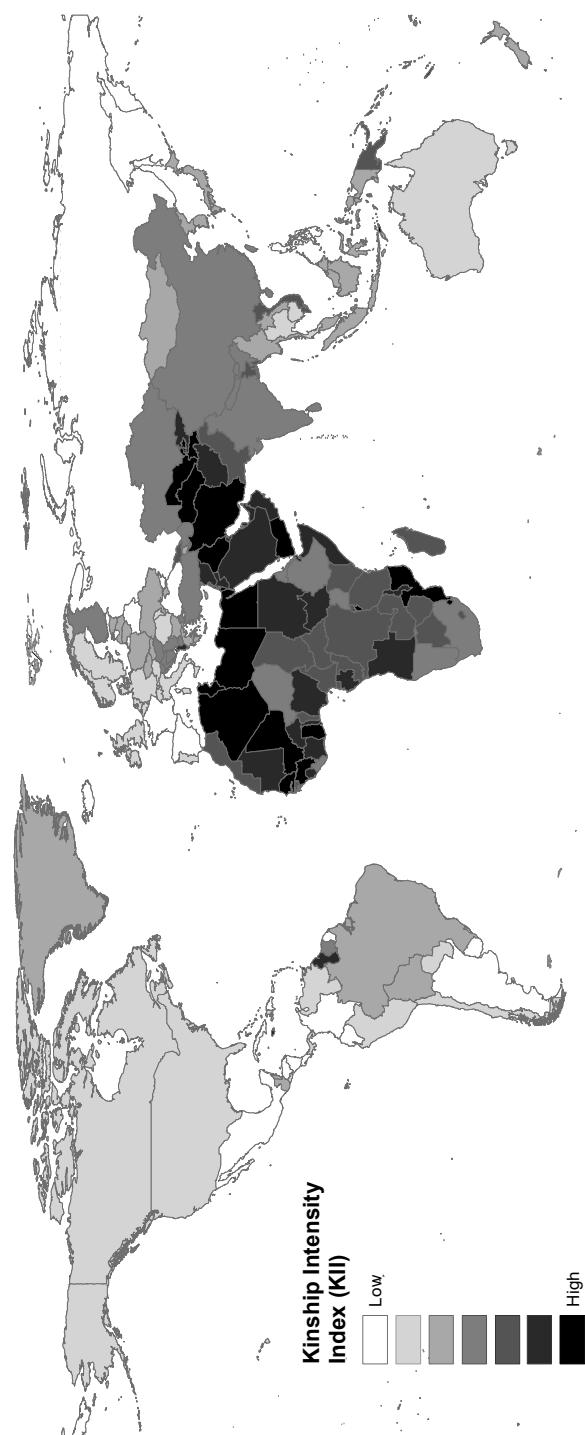

Figure 19.1: World Map of Kinship Patterns, based on Figure 6.1 in Henrich [2020]

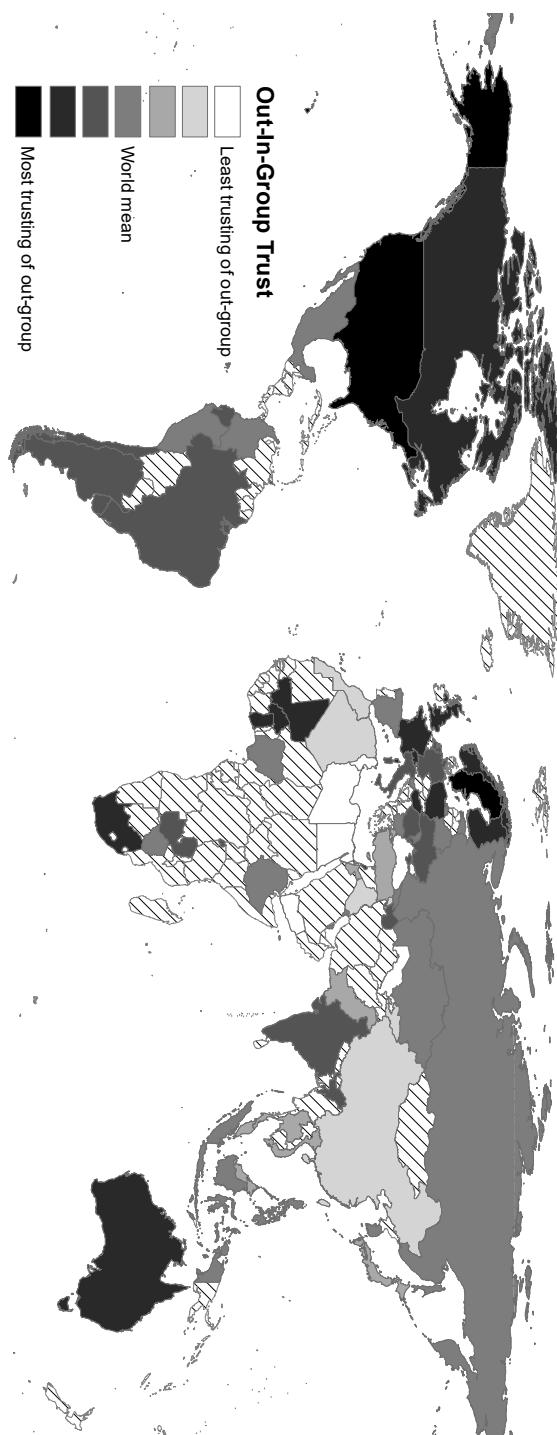

Figure 19.2: World Map of Out-In-Trust, based on Figure 6.5 in Henrich [2020]

Traits	% of Pre-Industrial Societies
Bilateral descent	28
Cousin marriage	25
Monogamy	15
Nuclear family	8
Neolocal residence	5

Table 19.1: Distribution of Kinship Traits: Taken from Table 5.1 in Henrich [2020].

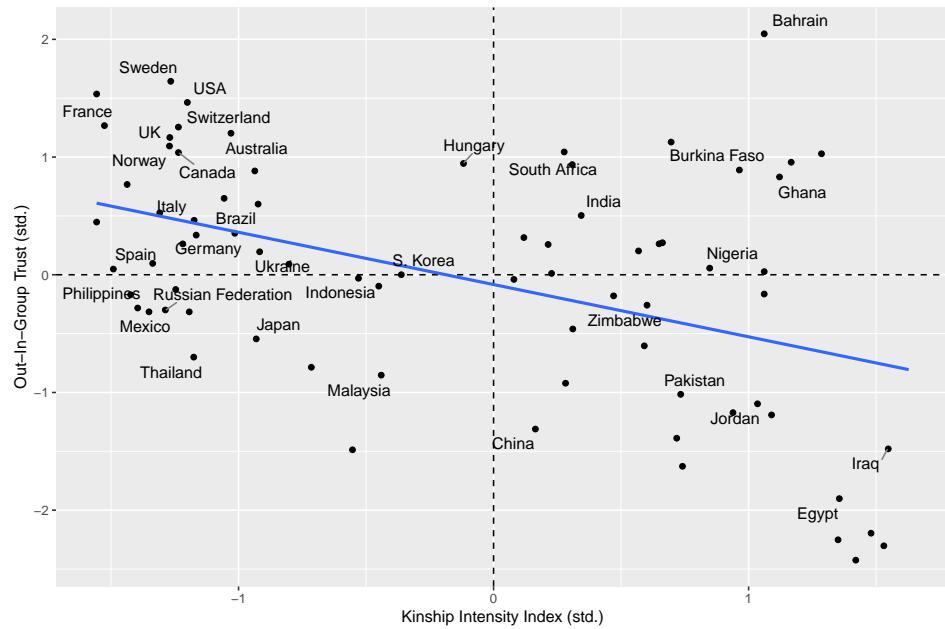

Table 19.1 is based on data from late 19<sup>th</sup> or early 20<sup>th</sup> century. Moving forward in time to the 21<sup>st</sup> century, let us briefly consider the empirical patterns on marriage among individuals related through the extended family. For concreteness, let us consider marriages between relations that are second or closer cousins. At one end of the spectrum, in the Middle East and Africa, more than a quarter of all marriages fall in this category. At the other end of the spectrum, in countries like the United States, Britain and the Netherlands, only about 0.2% of marriages fall in this class. Large countries like China and India fall in the middle, with intermediate levels of cousin marriage (around one in ten marriages is a cousin marriage).

When we place the evidence on kinship groups alongside the evidence on generalized trust and universalism we find that a greater strength of kinship relations is negatively associated with Out-In-Group Trust and also negatively associated with universalism. Figures 19.3 and 19.4 present these correlations.

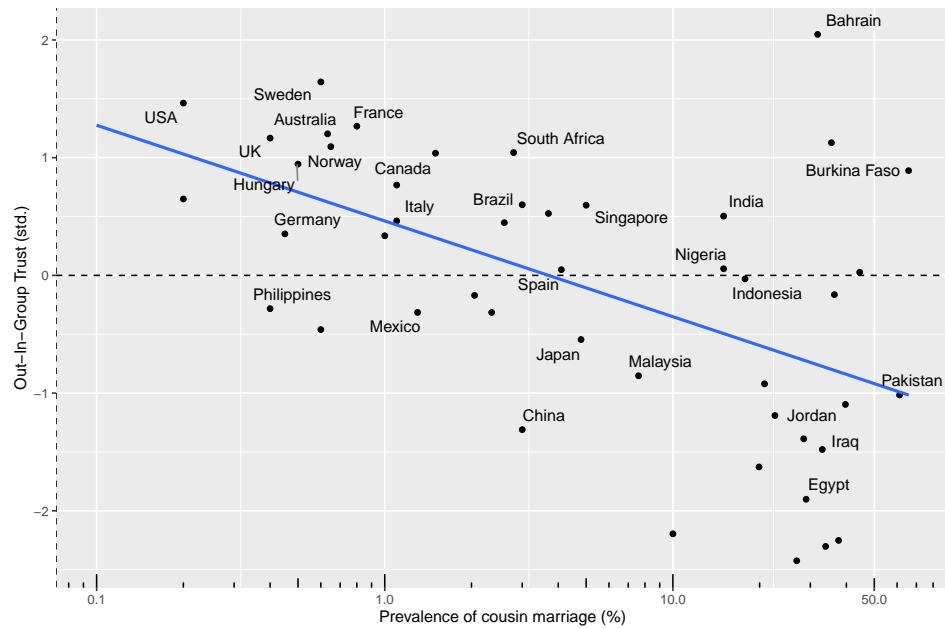

These statistical correlations are striking. As we are interested in understanding the relation between kinship institutions and economic performance, let us now put together what we have learnt on kinship based institutions and generalized trust and universalism together with some data on economic performance for a few specific countries.

The set of 'WEIRD' countries includes USA, UK, Canada, North Western Europe, and Australia and New Zealand. These countries are characterized by low strength of kinship groups, and high scores on generalized trust, Out-In-Group Trust, and universalism. Our discussions in Chapter 18 brought out the positive correlation between measures of generalized trust and economic performance. That correlation taken together with our observations on kin-based groups suggest a negative relation between the strength of kin-based groups and economic performance. Once we move out of the WEIRD group of countries the picture becomes considerably richer. The growth rates are presented in Figures 19.6.

Moving east in Europe, let us consider formerly communist countries. Russia has weak kinship based groups, modest generalized trust, modest Out-In-Group Trust, and low universalism. After the fall of communism, economic performance has been very uneven.

(a) Kin-based groups and Out-In-Group Trust

(b) Cousin Marriage and Out-In-Group Trust

Figure 19.3: Society and Out-In-Trust, based on Figure 6.6 in Henrich [2020]

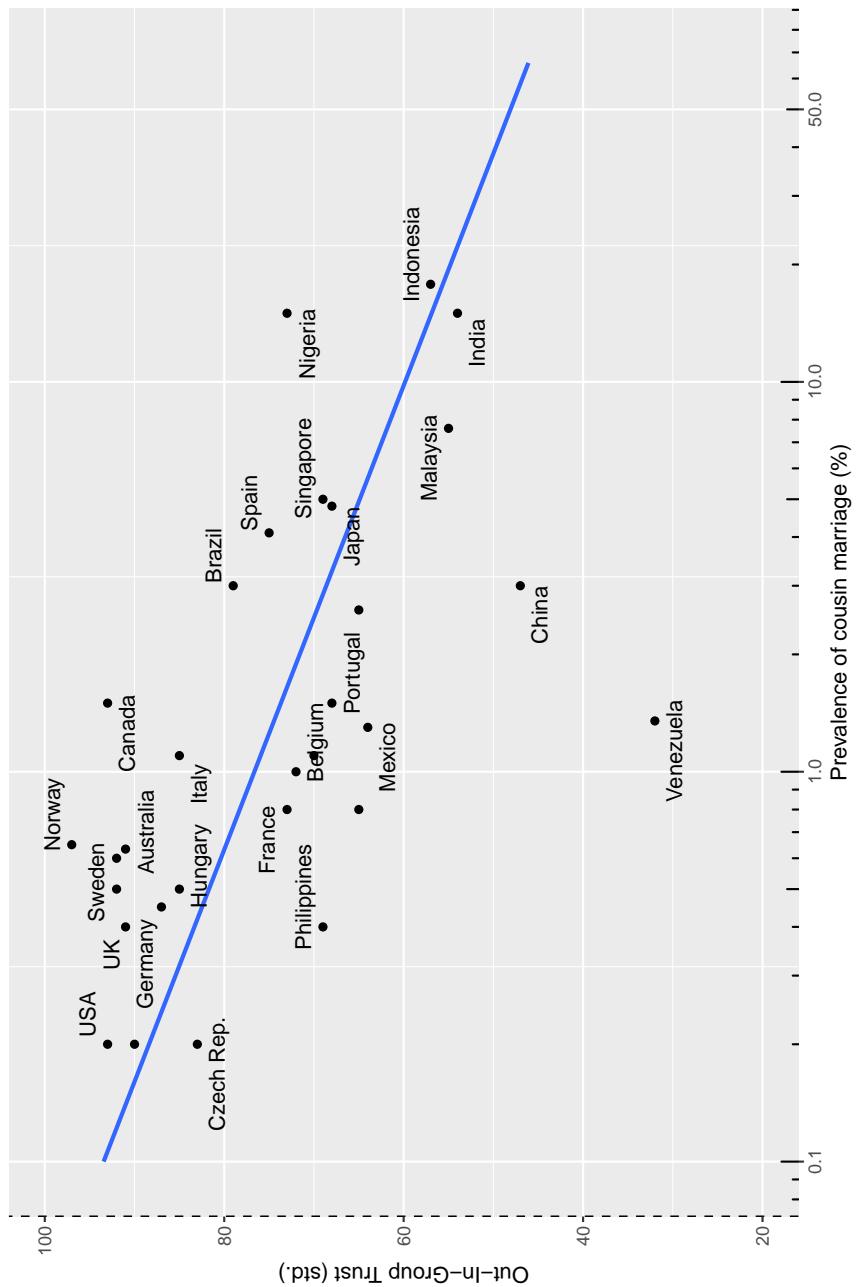

Figure 19.4: Cousin Marriage and Universalism, based on Figure 6.7 in Henrich [2020]

Over the period 1990-2020, growth rates have fluctuated widely from a negative 5% to a positive 5%. The average growth rate has been very modest. The growth rates are presented in Figures 19.5.

Consider next a group of countries in East Asia that includes the People's Republic of China, Taiwan, Korea and Singapore. Within this group there are significant variations that we will comment upon in our second case study below. Here we comment on the experience of the Peoples Republic of China (PRC). In the PRC, kinships groups are strong and generalized trust is strong. But a closer examination of the sources of trust revealed that Out-In-Group Trust is low to modest. In addition, the PRC also has a low score on universalism. These patterns must be set alongside the extraordinary economic success of the PRC. For example, the Chinese economy has grown at a rate averaging around 8% over the period 1990 to 2020 (see Figure 19.5). These very high growth rates raise questions about the compatibility of strong kin-based institutions and economic performance that are taken up in a case study below.

Moving South in Asia, let us next consider India: kinship based groups are strong and so is generalized trust. But a closer examination of the evidence suggests that Out-In-Group Trust is modest. Moreover, India also has a low score on universalism. These institutional and cultural arrangements have been accompanied with impressive economic performance growth rates over the 1990-2020 period, with rates of growth ranging between 4% and 8% (see Figure 19.5). We will examine the kinship based institutions in India in a case study below.

Turning to Latin and South America, consider Brazil: kinship based groups are weak and the generalized trust score is very low. In addition, Out-In-Group Trust and universalism scores are modest. Economic performance over the period 1990-2020 has been very uneven, with rates of growth ranging between 0% and 6%. Figure 19.5 presents the data.

Finally, we take up two prominent countries in Africa: the Democratic Republic of the Congo and Egypt. We will discuss the case of the Democratic Republic of Congo in some detail below. Here we note that the population of Congo consists of a very large number of ethnic groups who have limited experience of cohabiting the same country. We note that the rate of economic growth was very low for a long period of time until 2003, when the Great War of Congo ended. The rate of growth has improved significantly after 2003. In Egypt, the strength of kinship groups is high (as reflected in high rates of cousin marriage), generalized trust is low, and Out-In-Group Trust is very low. Economic performance over the past two decades has been uneven, with rates of growth ranging from 2% to 6% (see Figure 19.5).

We summarize the growth rates in income for these countries in Figures 19.5-19.6. For

ease of comparison we place these countries in two separate plots, one plot contains Brazil, China, Egypt, India, Democratic Republic of Congo, South Korea, Russia, and the second plot contains a set of WEIRD countries (Australia, Canada, France, Germany, Netherlands, United Kingdom, United States).

Our discussion on kinship institutions and ‘weirdness’ suggests a few high level observations. One, the strength of kinship-based groups has a negative relationship with Out-In-Group Trust and with universalism. Two, the relationship between the strength of kinship based groups and economic performance is less clear: on the one hand, some societies with weak kinship based ties (the so called WEIRD societies) have performed well for extended periods of time and continue to perform well, but there also countries (like Brazil) that have performed much less well. On the other hand, there exist societies with strong kinship based ties (such as South Korea, China and India) that have registered very high rates of growth, and there are others (such as Congo) that have performed less well. To develop a better sense of possible explanations, we now turn to a closer study of a few countries that draws attention to the relation between kinship groups, trust, and the nature of the state.

### LINEAGES AND CLANS

The Chinese constitute the world’s largest racial, linguistic and cultural group. They are spread across a vast geographic area and live in wide variety of states, from the communist Peoples Republic of China, to overseas Chinese settlements in South East Asia (Taiwan, Hong Kong, Singapore and Malaysia), to industrial democracies like UK, United States and Canada. We discuss the role of lineages and extended families in Chinese communities. Our discussion draws on a wide range of sources that include Allen, Qian, and Qian [2005], Daiy, Mookherjee, Munshi, and Zhang [2020], Song, Storesletten, and Zilibotti [2011], Fleisher, Hud, McGuiree, and Zhang [2010], Nee and Opper [2012], Peng [2004], and Greif and Tabellini [2017], and especially Fukuyama [1995a].

Let us briefly recapitulate some of the main points on our discussion in the chapter on economic growth and communities. We start by noting that China has witnessed the same degree of industrialization in three decades as Europe did over the course of two centuries (Summers [2007]). This economic transformation began in the early 1980’s with the establishment of township-village enterprises (TVE’s) and accelerated with the entry of private firms in the 1990’s. Starting with almost no private firms in 1990, there were 15 million registered private firms in 2014 (they accounted for over 90% of all registered firms). Alongside this growth in numbers, the share of registered capital held by private firms has grown sharply: by 2014, private firms held 60% of all registered capital in the economy. Depending on how the accounting is done, China is now the world’s largest or

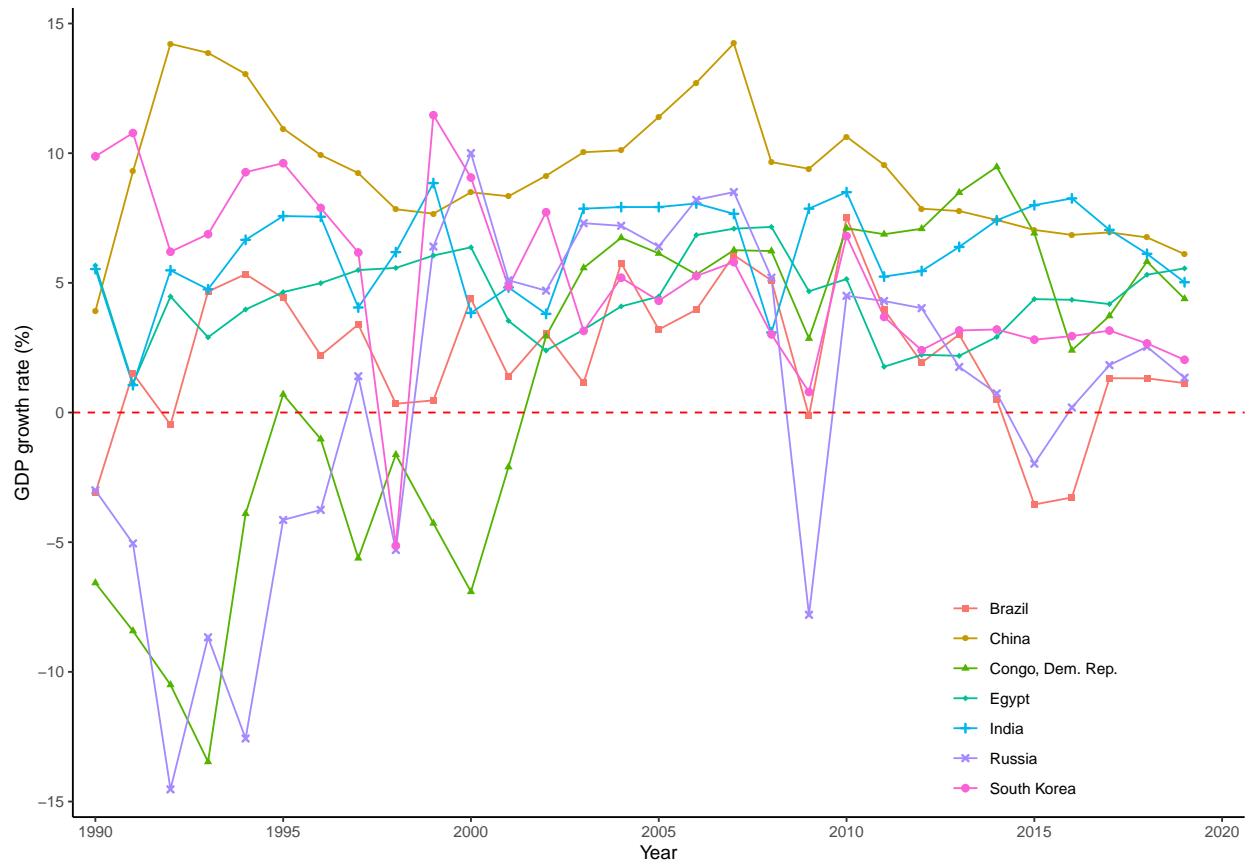

Figure 19.5: Rate of Economic Growth in Selected Countries. Data from <https://data.worldbank.org/>

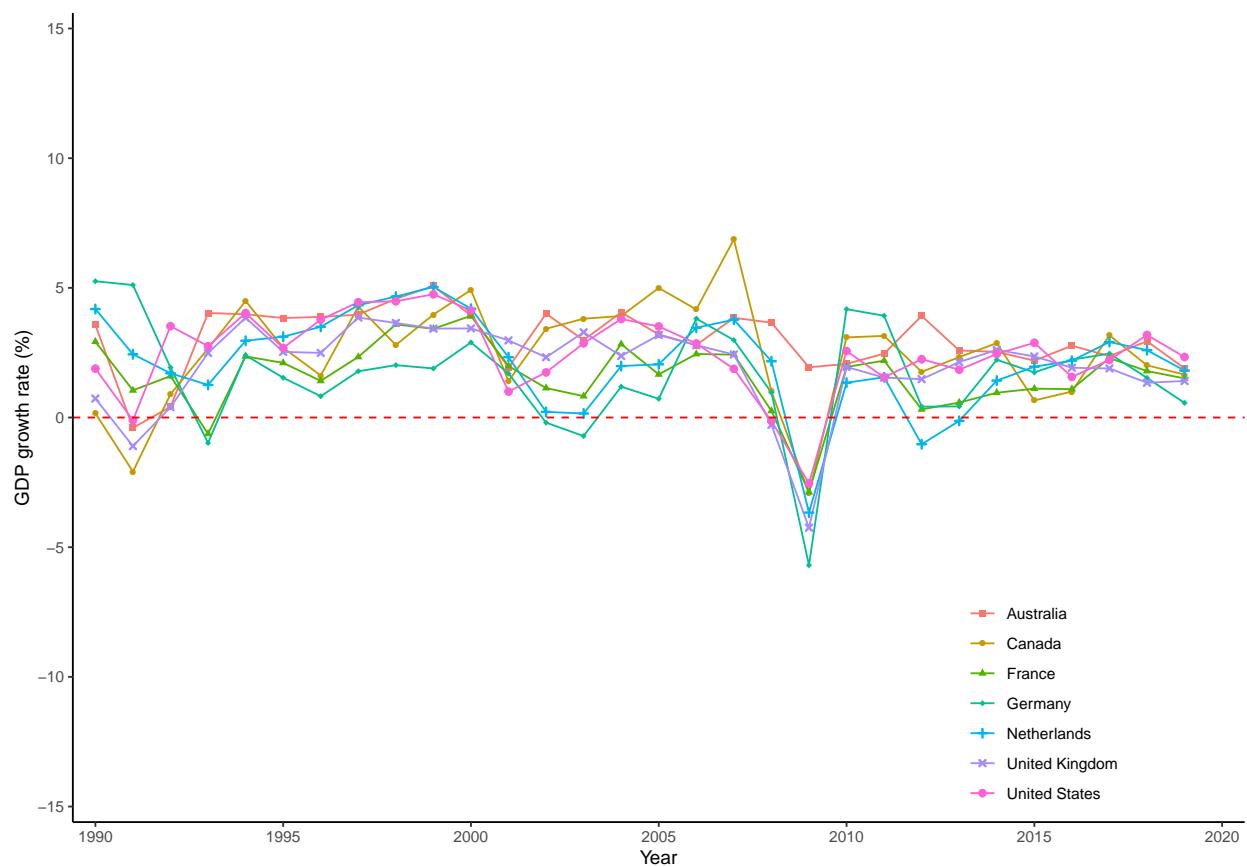

Figure 19.6: Rate of Economic Growth in Selected Weird Countries. Data from <https://data.worldbank.org/>

second-largest economy. Its growth has had profound effects on the flow of goods and services and capital and on balance of political influence across the world.

The dynamism of the Chinese economy is reflected along different dimensions. Take, for instance, in the list of the world's largest firms by revenue brought out by Fortune magazine. In 1990, there were no Chinese firms in the list; by 2020, China and Hong Kong accounted for the most firms in this list. Indeed, there are more Fortune Global 500 companies based in Mainland China and Hong Kong than in the U.S. – 124 versus 121. In 2020, China has more firms on the list than France, Germany and the Great Britain combined! A second feature of the economic growth that is worth noting is that in spite of the very high growth rates of private sector firms, many of the largest firms in China are state-owned. Again, let us look at the largest firms by revenue: in the 2020 Fortune list, 84 (i.e., 68%) of the Chinese firms in the Fortune 500 largest firms worldwide are state owned.

We next turn to the role of kin-based groups and the state in Chinese economic growth.

Governments at the local (county), provincial, and central level played an important role in China's economic transformation. Local governments provide the infrastructure to support production clusters that are a distinctive feature of the Chinese economy (for a discussion of production clusters, see our chapter on coordination problems). Provincial governments and the central government supported firms by giving them subsidized credit and by aggressively promoting exports. In addition, large parts of the economy are still dominated by state firms (as we noted above). But there still remains the question of how this growth in private firms occurred without effective legal systems and well functioning financial institutions, i.e., without the preconditions generally believed to be necessary for market-based development. Specifically, how did millions of individuals who were born in rural areas transition into the role of entrepreneurs, set up and successfully run such a vast array of extraordinarily successful companies?

Patrilineal lineages – also referred to as clans – have long been associated with Chinese society; see for instance Weber [1951]. A clan rests on blood ties, confers cultural identity, and has clearly nominated leaders. Clans are characterized by rules on obligations that have high ethical standing. The Communist Party took a number of steps to suppress lineage organizations, but recent research shows that clans persisted through the communist period and that they have reconstituted themselves and been revived after the market reforms of 1979. In Chapter 17 we provided an account for the role of lineages and clans in shaping economic growth.

*South Korea:* We next turn to South Korea (as another instance of a society based on strong family ties) to illustrate a possible configuration of society, state and market. First, we note the extraordinary economic growth that started in 1960 and has made South Korea one of

the technologically most advanced countries in the world today. Second, we note the state support and the dominance of internationally powerful large private sector firms. A third point is that in 2020, there were 14 Korean firms in Fortune list of 500 world's largest firms by revenue: most of them were controlled by a few large conglomerates (the chaebols) of which only a few are state-owned.

We will discuss the story of Samsung as it serves to bring out the broader contours of the growth process in South Korea. The factual information is taken from Wikipedia (<https://en.wikipedia.org/wiki/Samsung>) and the broader argument concerning Korea draws on Fukuyama [1995a] and Granovetter [2017b].

Samsung is one of the world's largest producers of electronic devices, covering a wide variety of consumer and industry electronics, including appliances, digital media devices, semiconductors, memory chips, and integrated systems. It produces about a fifth of South Korea's total exports. Samsung was founded as a grocery trading store on March 1, 1938, by Lee Byung-Chull. He started his business in Taegu, Korea, trading noodles and other goods produced in and around the city and exporting them to China and its provinces. After the Korean War, Lee expanded his business into textiles. During that period his business benefited from the policies adopted by the Korean government that helped large domestic firms by shielding them from competition and providing them easy financing. During the 1970s the company expanded its textile-manufacturing processes and entered of other new industries through the launching of new subsidiaries such as Samsung Heavy Industries, Samsung Techwin, and Samsung Shipbuilding.

Samsung first entered the electronics industry in 1969. In the 1970's it acquired a 50 percent stake in Korea Semiconductor. The late 1970s and early '80s witnessed the rapid expansion of Samsung's technology businesses. Separate semiconductor and electronics branches were established. Samsung Data Systems (now Samsung SDS) was established in 1985 to serve the growing need for systems development. In the 1990's, Samsung continued its expansion into the global electronics markets, with a number of its technology products—ranging from semiconductors to computer-monitor and LCD screens. The 2000's saw the birth of Samsung's Galaxy smart phone series, one of the top selling smart phones in the world. Since 2006, the company has also been the top-selling global manufacturer of televisions. As of 2020, the conglomerate includes over 60 firms that range across most important sectors of the Korean economy and constitute over 20% of its total exports. Notable affiliates include Samsung Electronics, Samsung Heavy Industries, Samsung Engineering and Samsung C&T.

In this highly diversified conglomerate, the convention is that the top management positions are typically held by male members of the family of the founder, Lee Byung-Chull.

By way of illustration, consider Samsung Electronics: the Chairman, Lee-Kun Hee is the son of the founder, while the vice-chairman (and Chairman designate), Lee Jae-yong is the son of Lee-Kun Hee. The firms in Samsung group are closely interconnected through a network of cross-ownerships. So, for instance, Samsung Electronics is a dominant shareholder in Samsung Heavy Industries.

The Samsung story shows how strong family ties in combination with deep and sustained state support can give rise to world leading firms.

#### THE CASTE BASED SOCIETY

Hindu society is centred on castes. Formally, there are four castes but there is also a large part of the population that lies outside these four castes that is referred to as Dalits. The central rule in Hindu society is of marriage within a caste (endogamy). This rule has been followed over the past two thousand years and even today nine out of ten marriages respect this rule. There are roughly 3000-4000 sub-castes, each of whom has on average approximately 250,000 members. Within a village there is spatial clustering based on caste, but caste members are usually spread across many villages and also in urban centres. Thus caste networks have an interesting structure: local spatial clustering within a village alongside wide spatial spread. The local clustering is accompanied by rules on social interaction both horizontally as well as vertically across caste. Caste has been a major factor shaping social relations and continues to be a powerful presence in contemporary Indian society, economy, and in its democracy. The discussion here draws on Srinivas [1987], Beteille [1965], Mayer [1960], Munshi [(2019] and Munshi and Rosenzweig [2015]. The prominent role of caste in favour exchange was brought out in our discussion of Indian villages in Chapter 1 and in Chapter 17.

Historically, caste networks helped smooth consumption of their members in the face of income fluctuations. More recently, since the middle of the 19th century, they have expanded into the urban labor market and into business when new opportunities became available. As a result, in contemporary India caste networks shape participation in labour markets, in allocation of capital, and in entry into new markets. Indeed, a distinctive feature of the Indian economy is that the large and dynamic private sector is dominated by large conglomerates that are centred on extended family and sub-caste networks. For further discussions on the caste system also see chapter 12 on communities and economic growth.

One reason for the prominence of caste is that it has an important relation to trust. Munshi and Rosenzweig [2015] present cross country results from wave five of the World Values Survey (conducted between 2005–09) on questions relating to trust and tolerance of outsiders. Restricting the sample to countries with a population in excess of twenty mil-

lion that are classified by the World Bank as low, lower-middle, or upper-middle income, India ranks close to the top of the list with regard to trust in neighbors. On the face of it, this appears to be strong evidence for generalized trust. However, on measures of tolerance of neighbours following a different religion or speaking a different language, India ranks at the bottom of the list. This suggests that an alternative interpretation may be more accurate: Indian respondents are essentially reporting that they have a high degree of trust in their fellow caste members living nearby.

Caste is the basis for one of the most extensive and aggressive affirmative action programmes in the world: in many parts of the country over one half of all public sector jobs are reserved for members of historically disadvantaged castes. At different levels of the political system positions may be reserved for particular communities.

At a more general level, since independence from British Rule in 1947, caste has also become a central pillar of representative democracy in India. Parties come to power on the basis of alliances across different caste groups. The ability of a party to win elections therefore depends on how successful it is in forming partnerships with different caste groups. A politician makes decisions that favour a group, which rewards him by voting for him. Caste has become the natural social unit around which "vote banks" are organized. It can be said that the democratic process has reinforced caste identity and strengthened the strength of kinship based groups.

We conclude with a brief comment on aspects of Indian economic growth since independence from Britain in 1947. Since the early years after independence, the Indian government has played a prominent role in shaping the pace and the direction of economic change. However, economic growth was modest until the early 1990's. It has picked up over the past twenty five years partly due to liberalization of the market and the opening up of the economy to foreign firms and capital. Figure 19.5 presents an overview of the economic growth rate over the period 1990-2020. The dynamism in the economy is also reflected in the list of the world's largest firms. In 1990, there were no Indian firms in the Fortune top 100 list, there were 10 Indian firms in this list in 2010 and 7 by 2020. In spite of the dynamism of the private sector, we note that some of the largest firms in India are still state owned: for example, in the list of 7 largest firms, 4 were state owned. Another feature of the Indian economy is that family based conglomerates control the largest private firms.

#### CIVIC COMMUNITY AND DEMOCRACY IN ITALY

In their landmark study, 'Making Democracy Work', Putnam, Leonardi, and Nanetti [1993] argued for a central role for civic community in the effective functioning of representative democratic institutions. They studied the impact of a political reform that shifted

budgetary authority from the national government to the regions (in several key areas such as education and health care). The result was that starting at 10% in the pre-reform period, the control of regions over the national budget increased to over 25% by 1977. How did this shift in resources and authority affect performance of government in the twenty different regions of Italy?

The first finding is that there were large differences in performance of the regional governments across the regions based both on independent measures of policy process, pronouncements, and implementation. These differences were consistent with citizens' assessment of regional governments. Figure 19.7 provides a mapping of different levels of performance.

The second finding is that these differences in performance of regional governments were closely related to the civic culture. Civic culture was seen as a combination of civil associations, voter turnout at referenda, (lack of) clientelism, and local newspaper circulation. Civil associations include sports societies, leisure clubs, music and theatre, and health and social services, among others. Figure 19.8 charts the levels of civic community in Italy's twenty regions according to these factors. A comparison of Figures 19.7 and 19.8 reveals a very strong correlation between civic culture and institutional performance: northern regions were characterized by high levels of civic engagement; the southern regions by hierarchically organized public life and far less engagement.

The third finding is that the origins of differences in civic culture in the late twentieth century participation may be traced to differences in the modes of governance in the early Medieval period. The republicanism of Italian regions at the beginning of the 14<sup>th</sup> century corresponds closely to the strength of the civic tradition in the 20th century. The parallel between this pattern and the distribution of civic norms and networks in the 1970s, as displayed in Figure 19.8, is remarkable. The southern territories once ruled by the Norman kings constitute exactly the seven least civic regions in the 1970s. Almost as precisely, the Papal States (minus the communal republics that lay in the northern section of the Pope's domains) correspond to the next three or four regions up the civic ladder in the 1970s. At the other end of the scale, the heartland of republicanism in 1300 corresponds uncannily to the most civic regions of today, followed closely by the areas still further north in which medieval republican traditions, though real, had proved somewhat weaker. The persistence of the high and low civic community cultures in North and South Italy over several hundred years suggests that once attained these widely differing social configurations are very stable.

The differences in civic culture and quality of governance are reflected in large and persistent income differences. Figure 19.9 presents trends on these income differences over

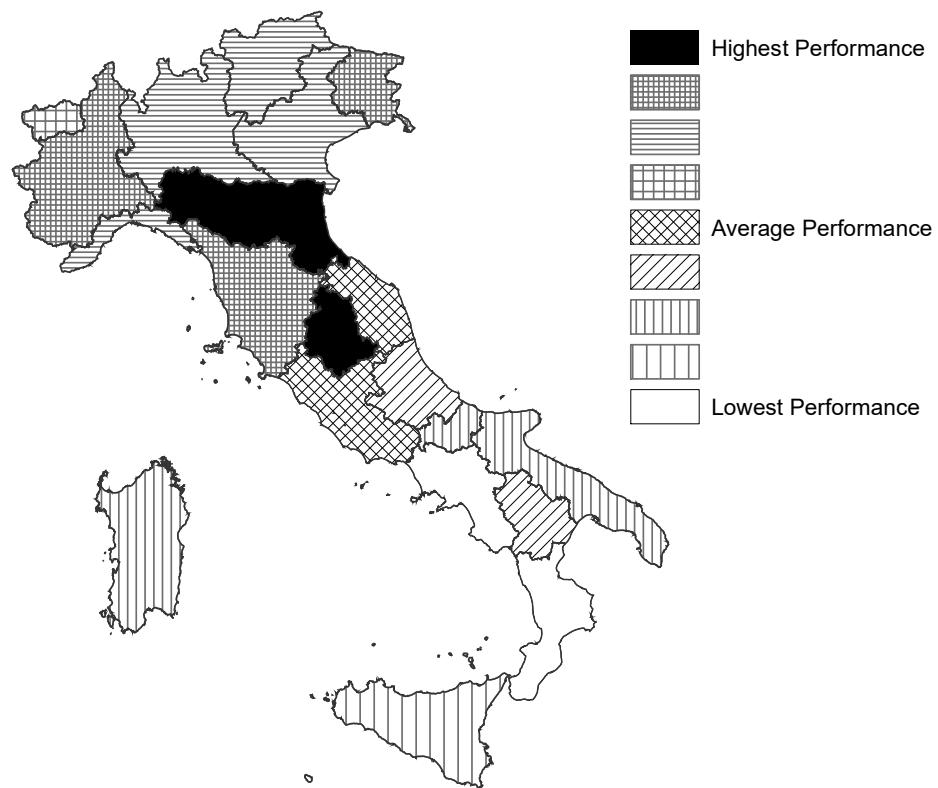

Figure 19.7: Performance of Regional Governments, based on Figure 4.1 in Putnam, Leonardi, and Nanetti [1993]

the past century.

#### ETHNIC FRAGMENTATION

The Democratic Republic of the Congo (in what follows, simply, Congo) has a population of 68 million and is the largest Sub-Saharan African country. Congo gained independence from Belgium in 1960. We discussed the Congo in an earlier chapter on wars. Here we comment briefly on the economic patterns in Congo and then discuss some features of Congolese society and the state.

Figure 19.5 presents the growth rate in gross national product over the period 1990-2020. It shows that growth rates have fluctuated widely and the average has been low over this period. In 2020 the per capita income was around 580 USD, a figure that is less than one percent of Switzerland's per capita income. The low income is reflected in a life expectancy that is 20 years less than Switzerland's. As indicated in Figure 19.6, economic growth was very poor for an extended period lasting until 2003, but it has since then picked

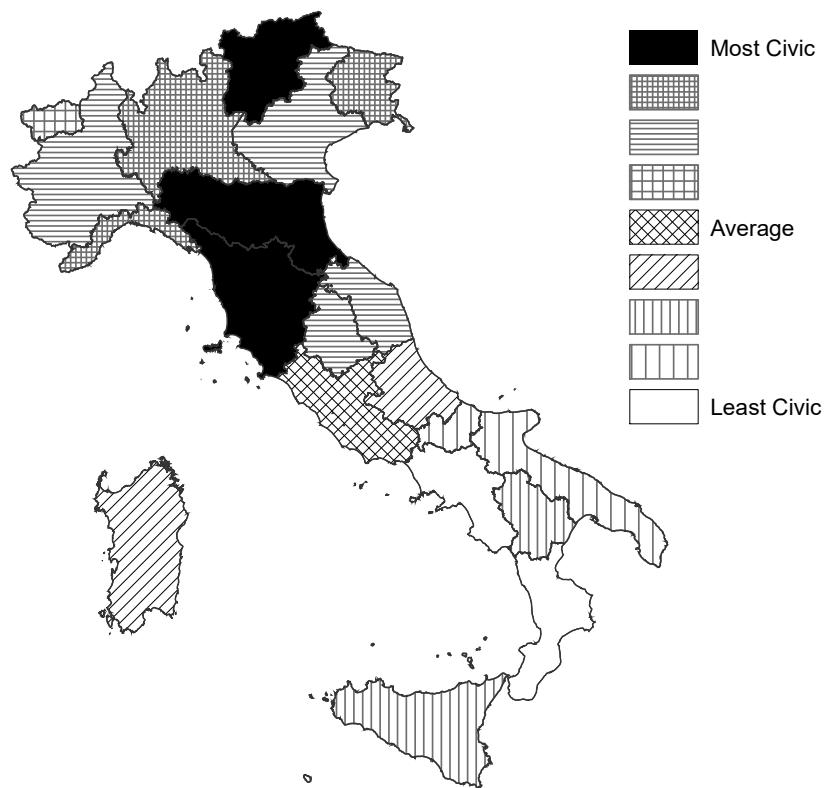

Figure 19.8: Civic Capital in Regions, based on Figure 4.4 in Putnam, Leonardi, and Nanetti [1993]

up. This record of economic performance must be seen against the background of Congo's extraordinary wealth of natural resources: it has some of the world's largest reserves of copper, diamonds, cobalt, and coltan.

An important feature of Congo is that the population belongs to over 200 ethnic groups. There exist close affinities between several of these ethnic groups and groups in adjoining countries: as a result, developments in Congo are closely connected to developments in neighboring countries such as Rwanda and Uganda. These kinship ties are an important aspect of the great war in Congo (1996-1997, 1998-2003). We discussed these issues and their relation with the great war of Congo in the chapter on wars. The state in Congo has failed to provide one of the essential services expected of a government – that of secure borders. It has also been unable to provide personal and economic security within the borders of Congo. The result is that the citizens have not been able to make use of the vast mineral resources in the country, leaving Congo as one of the poorest and more insecure

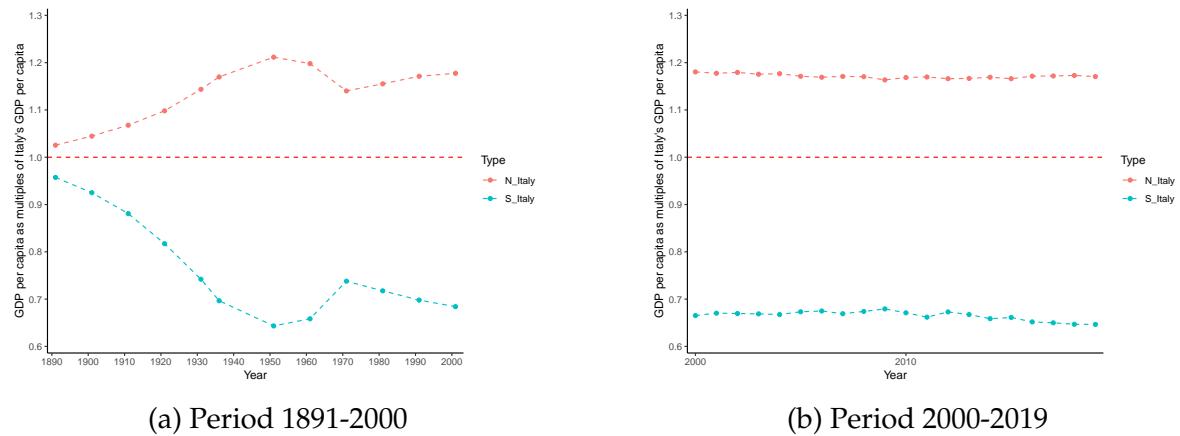

Figure 19.9: Economic differences between North and South Italy: Data from Daniele and Malanima [2014] and <https://ec.europa.eu/eurostat/>

countries in the world.

Let us summarize what we have learnt in this section. First, we found that there are very great variations in the strength of kin-based institutions. Second, the relation between kinship groups and economic performance is complicated. WEIRD societies like the United States, North Western European countries, New Zealand, and Australia suggest a positive correlation between weak kinship ties and economic performance. But the relationship between kinship ties and economic performance is complicated. There are countries like Brazil that have weak kinship groups and low generalized trust and have a record or uneven economic performance. On the other hand, there are countries like South Korea, China, and India with strong kinship groups but with a good to strong record of economic growth. Finally, there are countries with strong kinship groups, such as Congo and Egypt, with poor to uneven economic performance. A recurring theme in the case studies is the important role of the state. We next develop a theoretical framework to better understand these empirical patterns.

### 19.3 Conceptual Considerations

We consider a theoretical framework with a focus on economic activity and social welfare. This section introduces a number of concepts and explains their background.

First, we consider individuals in their relation to kinship based groups. Ties between individuals belonging to the same group are close and reliable. The size of the groups is a key variable and it is one indication of the strength of kinship based relations in a society

(Fukuyama [1995a] and Henrich [2020]). Ties between individuals belonging to different groups is another important element: the ties may be civic and relate to common memberships of a variety of associations as in Putnam, Leonardi, and Nanetti [1993]'s study of democracy in Italy or integrated business organizations and professional associations as in Varshney [2001]'s study of Hindu-Muslim communal violence (where associations involving members of different religious communities is seen as embodying 'bridging capital' in the terminology of Putnam, Leonardi, and Nanetti [1993].

Second, we suppose that individuals earn utility from economic activity and from engagement in civic activities. Economic activity can be carried out within the group or with other individuals outside the group. Economic activity takes place in the presence of asymmetric information, search and matching frictions and commitment problems. Kin-based interaction helps to overcome some of these frictions but at the cost of restrictions on who can work with whom. Economic exchange across kinship groups thus entails transaction costs: the magnitude of these costs will depend on the effectiveness of formal institutions and the level of generalized trust in a society. We borrow these ideas from North and Thomas [1973], North [1990] and Williamson [1985] and the recent literature on kin-based exchange and Fukuyama [1995a] and Henrich [2020].

By contrast, people who do not trust one another will end up cooperating only under a system of formal rules and regulations, which have to be negotiated, agreed to, litigated, and enforced, sometimes by coercive means. This legal apparatus, serving as a substitute for trust, entails what economists call "transaction costs." Widespread distrust in a society, in other words, imposes a kind of tax on all forms of economic activity, a tax that high-trust societies do not have to pay. Fukuyama [1995a]

Third, we consider the state. The state carries out redistribution and provides a range of public goods such as education, health and infrastructure. The state may also run large scale public sector firms that produce key inputs for other sectors, such as iron, steel, coal, and oil and it may run banks that provide credit to private and public firms. The state is supported by tax revenue. The state also contains formal institutions that help enforce contracts and lower transaction costs of impersonal economic exchange. It is therefore important to understand who makes decisions on tax rates and what are their incentives. Our approach to the political economy of taxation draws on a long tradition in political economy and state capacity as summarized for instance in Besley and Persson [2013].

Fourth, we specify the relation between the state and civic community and how this bears on impersonal market exchange. The state and civic community may be complemen-

tary: this is the idea developed in the influential work of Putnam, Leonardi, and Nanetti [1993] and it is a key theme in the recent work of Acemoglu and Robinson [2019] – the effectiveness of the state is only as good as the strength of the social institutions.

..... the failure of democracy to consolidate itself in many parts of the world may be due less to the appeal of the idea itself than to the absence of those material and social conditions that make it possible for accountable government to emerge in the first place. That is, successful liberal democracy requires both a state that is strong, unified, and able to enforce laws on its own territory, and a society that is strong and cohesive and able to impose accountability on the state. It is the balance between a strong state and a strong society that makes democracy work, not just in seventeenth-century England but in contemporary developed democracies as well. Fukuyama [2011]

While complementarity between civic society and state is widely noted, there is also an influential strand of thinking that argues for their substitutability. This idea is implicit in Polanyi [1944], when he says that the growth of national markets for labour were accompanied with a growing role for the government and the weakening of local social ties. This idea is consistent with the line of work that stresses the importance of larger state involvement in later developing countries, Gerschenkron [1962]. It is also consistent with the idea of Fukuyama [1995a] and others who have argued that strong kinship based groups and weak civic institutions may be substituted for by a powerful and active state. The example of an activist state in France is mentioned in this context. More generally, it is possible to see some aspects of civic engagement as complementary to the activities of the state, while others are substitutes.

Fifth, we use a notion of civic capital as a composite that combines beliefs and expectations and social structure. In this, we draw upon Fukuyama [1995a] and Geertz [1973].

Cultural anthropologists and sociologists distinguish between culture and what they term social structure. Culture in this sense is restricted to meanings, symbols, values and ideas and encompasses phenomena like religion and ideology. Geertz' own definition of culture is "an historical transmitted pattern of meanings embodied in symbols, a system of inherited conceptions expressed in symbolic forms by means of which en communicate, perpetuate, and develop their knowledge about and attitudes toward life'. Social structure, by contrast, concerns concrete social organizations such as the family, clan, legal system, or nation. In this sense, Confucian doctrines about the relationship between fathers and sons belong to culture; the actual Chinese family is social structure.

..... I will not make use of this distinction between culture and social structure because it is often difficult to distinguish between the two: values and ideas shape concrete social relationships, and vice versa. The Chinese family has a patrilineal structure in large measure *because* Confucian ideology gives preference to males and teaches children to honor their fathers. Conversely, Confucian ideology seems reasonable to those who have been brought up in Chinese families. Fukuyama [1995a], page 34.

In our model below we will present a model of civic capital as arising out of social structure and expectations about behaviour. In this model, expectations and beliefs and the autonomy of individuals in shaping them will play a major role. We refer the interested reader to Swidler [1986] for a discussion on different ways of accommodating individual agency within notions of culture.

## 19.4 A Model

This section presents a theoretical framework within which we can locate different types of societies and assess their economic performance. The framework is taken from Bramoullé and Goyal [2021]. It builds on the model of network and market activity in chapter 17 (taken from Gagnon and Goyal [2017]), the model of group favoritism in chapter 18 (taken from Bramoullé and Goyal [2016]), and we incorporate in addition the concepts of group fractionalization (taken from Alesina, Devleeschauwer, Easterly, Kurlat, and Wacziarg [2003]), of state capacity (taken from Besley and Persson [2013]).

We consider a society composed of individuals, who belong to kinship groups. Denote by  $N = 1, \dots, n$  the set of individuals and by  $M = 1, \dots, m$  the set of groups with  $m \geq 2$ . The size of group  $j$  is  $s_j$  and  $\sum_{j \in M} s_j = N$ . Nuclear families give rise to small groups; castes, tribes, extended families, lineages, or clans give rise to larger groups. For simplicity, we will suppose that individuals within a group are fully connected to each other. In addition, there may exist links between individuals across groups. We denote this network of cross group links by  $g_o$ .

There are three stages in the model. In stage 1, individuals decide on the level of civic activity (this defines civic capital in the society). In stage 2, the tax rate is determined and tax revenue is used to build state capacity broadly construed. In stage 3, individuals decide on whether they will conduct exchange within their kinship group or in impersonal markets.

Individuals earn utility through economic exchange. Exchange could take place either between individuals within the same group or between individuals in different groups.

The return from an exchange depends on the quality of the match between the individuals and on the costs of transaction between them. The ideal match yields value 1, while a non-ideal match yields  $r \in [0, 1]$ . We assume that every individual is equally likely to be an ideal match. The ideal match is then an individual in one's own group with probability proportional to the size of one's group minus 1,  $s_i - 1$ , and someone from another group with probability proportional to  $n - s_i$ .

Economic exchange within a group has lower transaction costs: this may be due to advantages of repeated interaction and cooperative norms within a group or it may reflect group level altruism. For simplicity let us say that the within groups transaction costs are zero. An ideal match with a groups yields full value, 1, while a non-ideal match yields  $r < 1$ . The return from exchange between members belonging to different groups depends on the formal institutions and on civic culture. This return is denoted by  $F(T, K) \leq 1$ , where  $T$  is the amount of government funds invested in the functioning of impersonal markets and  $K$  the level of civic culture.

A larger revenue can support a more extensive set of executive and legal institutions that would enhance the quality of contract enforcement. Similarly, high civic capital would support higher levels of generalized trust and this in turn would mitigate the transaction costs among members of different groups. This leads us to suppose that the function  $F$  is increasing with respect to both  $T$  and  $K$ . We will explore both the situation in which state and civic capital complement each other as well as the situation in which weaknesses in one can be offset by expansion in the other. We introduce the concepts of strategic complements and substitutes to model these relations.

**Assumption 19.1.**  $F(0, 0) = 0$ ,  $F \leq 1$ , and  $F$  is weakly increasing and concave in both arguments. We shall say that civic capital and government are complements if  $F$  displays increasing differences, for  $T' \geq T$  and  $K' \geq K$ :

$$F(T', K') - F(T, K') \geq F(T', K) - F(T, K)$$

Civic capital and government are substitutes if  $F$  displays decreasing differences:

$$F(T', K') - F(T, K') \leq F(T', K) - F(T, K)$$

By way of illustration, consider a specific functional form:  $F(T, K) = \phi T^\alpha K^\alpha$ . If we assume that  $0 < \alpha < 1$  then the function satisfies Assumption 19.1 and displays complements. By contrast,  $F(T, K) = \phi(T + K)^\alpha$  satisfies Assumption 19.1 and displays substitutes (in either case,  $F \leq 1$  when  $T$  and  $K$  are bounded from above, and  $\phi$  is small enough.)

The government is funded by taxes on individual citizens. Let  $t \in [0, 1]$  be the tax rate. Suppose that an individual  $i \in N$  starts with initial income,  $y_i$ . Set  $Y = \sum_i y_i$ . Government's resources are equal to tax earnings  $tY$ . We study a utilitarian social planner and compare that with the choices of a majority based democratic government.

Finally, in state 3, given a level of tax revenue, individuals choose whether to take part in impersonal exchange. Let  $x_i \in \{0, 1\}$  denote that the choice on exchange; it takes value 1 if an individual engages in outside exchange and takes value 0 otherwise. When  $x_i = 1$ , individual  $i$  matches with an ideal partner while when  $x_i = 0$ ,  $i$  matches with someone in her own group. For simplicity, assume that an individual gets to keep the entire value of the exchange that she initiates. The ideal partner is an outsider with probability  $\frac{n-s_i}{n-1}$ . An individual's payoff from tax rate  $t$ , action  $x_i$  and group size  $s_i$  is thus equal to:

$$u_i = (1-t)y_i + x_i \left[ F(T, K) \frac{n-s_i}{n-1} + \frac{s_i-1}{n-1} \right] + (1-x_i) \left[ r \frac{n-s_i}{n-1} + \frac{s_i-1}{n-1} \right] \quad (19.1)$$

and we see that the individual strictly prefers to engage in outside exchange,  $x_i = 1$ , if and only if  $F(T, K) > r$ . It is worth noting that the decision on whether to participate in within group or outside exchange does not depend on incomes or group size. In other words, either all individuals engage in outside exchange or none do, and individual utility can be rewritten:

$$u_i = (1-t)y_i + \max(F(T, K), r) \frac{n-s_i}{n-1} + \frac{s_i-1}{n-1} \quad (19.2)$$

**A utilitarian social planner:** We consider a utilitarian planner who seeks to maximize the sum of utilities. This provides a benchmark normative analysis and will serve as a basis to assess performance of democratic government later. As is standard, we start at the second stage of the model, and take the level of civic culture,  $K$ , as a given.

We note that, in this setting, the only use of tax revenue is that improves state capacity. This improvement mitigates the transactions costs of impersonal exchange. Transaction costs arise when ideal match lies across groups. Therefore the social return to improving state capacity is intimately related to the proportion of exchanges that will involve individuals of different groups.

Given a group structure the fraction of ideal exchanges that will be across groups is given by

$$f = 1 - \sum_{j \in M} \left( \frac{s_j}{n} \right)^2. \quad (19.3)$$

Following Alesina, Devleeschauwer, Easterly, Kurlat, and Wacziarg [2003], we will refer to  $f$  as a measure of *fractionalisation*.

The fractionalisation index takes value 0 if all individuals belong to a single group, and it is maximized if all individuals belong to different groups. Thus  $0 \leq f \leq 1 - \frac{1}{n}$ . When the number of groups is fixed, fractionalisation decreases following a mean-preserving spread in sizes. Moreover, if all groups have the same size, fractionalisation increases with the number of groups.

Our first result characterizes optimal taxation and brings out the relation between state capacity, the fractionalisation index, and civic capital.

**Proposition 19.1.** *Suppose that  $F$  satisfies Assumption 19.1 and that  $\frac{\partial F}{\partial T}(0, K) > \frac{1}{2}$  and  $\frac{\partial F}{\partial T}(Y, K) < \frac{1}{n}$ . Let  $t_u^*$  be the tax rate chosen by an utilitarian planner. Then, the following equation has a solution  $t_u \in ]0, 1[$ .*

$$\frac{\partial F}{\partial T}(t_u Y, K) = \frac{n-1}{n^2} \frac{1}{f} \quad (19.4)$$

If  $F(t_u Y, K) < r$ , then  $t_u^* = 0$  and  $\forall i, x_i = 0$ . If  $F(t_u Y, K) > r$ ,  $t_u^* = t_u$  and  $\forall i, x_i = 1$ .

**Proof:** Define  $W = \sum_i u_i$ , with

$$W = (1-t)Y + \max(F(T, K), r) \sum_i \frac{n-s_i}{n-1} + \sum_i \frac{s_i-1}{n-1}. \quad (19.5)$$

Using the definition of fractionalization, we may write aggregate out-group exchange as follows

$$\sum_i \frac{n-s_i}{n-1} = \frac{n^2 - \sum_{j \in M} s_j^2}{n-1} = \frac{n^2}{n-1} f$$

Consider a situation where  $\forall i, x_i = 1$ . Then,

$$\frac{\partial W}{\partial t} = -Y + Y \frac{\partial F}{\partial T}(tY, K) \frac{n^2}{n-1} f$$

and since  $F$  is concave in  $T$ ,

$$\frac{\partial^2 W}{\partial t^2} = Y^2 \frac{\partial^2 F}{\partial T^2} \frac{n^2}{n-1} f \leq 0.$$

Moreover, since there are at least two groups,  $f \geq \frac{2(n-1)}{n^2}$ . Therefore,

$$\frac{\partial W}{\partial t}(0, K) = Y(-1 + \frac{\partial F}{\partial T}(0, K) \frac{n^2}{n-1} f) \geq Y(-1 + \frac{\partial F}{\partial T}(0, K) 2).$$

This means that

$$\frac{\partial W}{\partial t}(0, K) > 0 \text{ if } \frac{\partial F}{\partial T}(0, K) > \frac{1}{2}.$$

Since  $f \leq 1 - \frac{1}{n}$ ,

$$\frac{\partial W}{\partial t}(1, K) = Y(-1 + \frac{\partial F}{\partial T}(Y, K) \frac{n^2}{n-1} f) \leq Y(-1 + \frac{\partial F}{\partial T}(Y, K))n$$

This means that

$$\frac{\partial W}{\partial t}(1, K) < 0 \text{ if } \frac{\partial F}{\partial T}(Y, K) < \frac{1}{n}$$

Therefore, the first order condition  $\frac{\partial W}{\partial t} = 0$  has an interior solution,  $0 < t_u < 1$ , under the stated conditions.

Finally, observe that this is the solution of the planner's program only if  $F(t_u Y, K) > r$ . If  $F(t_u Y, K) < r$ , agents choose not to engage in impersonal markets even when the planner sets its best possible tax rate. Therefore, investing in impersonal markets is socially not worthwhile and  $t_u^* = 0$ .

■

Proposition 19.1 shows that the optimal tax rate is a (weakly) increasing function of fractionalization. Impersonal exchange may bring higher benefits than exchange within groups only when the ideal match is an outsider. Our measure of fractionalization provides us a measure of out-group exchange. As we noted above, fractionalization is high in the presence of many groups and when group sizes are of the same size. Thus societies with high fractionalization are precisely the societies where impersonal markets generate high social benefits and they are therefore also the societies in which a large state would be especially valuable.

We now examine the relation between optimal tax and civic capital.

**Corollary 19.1.** *Suppose the conditions for Proposition 19.1 hold and civic capital and governments are complements. Then there exists a threshold value of civic capital  $\bar{K}_u$  such that  $t_u^* = 0$  if  $K < \bar{K}_u$  and  $t_u^* = t_u > 0$  and it is increasing in  $K$  if  $K > \bar{K}_u$ .*

**Proof:** First note that the tax rate is positive  $t_u^* > 0$  only if the  $F(t_u^* Y, K) > r$ . Next implicitly differentiate the optimal tax rate with respect to  $K$  and we get:

$$Y \frac{\partial t_u}{\partial K} \frac{\partial^2 F}{\partial T^2} + \frac{\partial^2 F}{\partial T \partial K} = 0$$

Since  $\frac{\partial^2 F}{\partial T^2} < 0$ ,  $t_u$  is (weakly) increasing with respect to  $K$  under complements, i.e., when  $\frac{\partial^2 F}{\partial T \partial K} \geq 0$ . We may therefore define the threshold  $\bar{K}_u$  as the solution to  $F(t_u Y, \bar{K}_u) = r$ .

Under assumption 19.1,  $F(0, K) = 0$ : it then follows that the optimal tax is a discontinuous function of civic capital  $K$ : optimal tax  $t_u^*$  is equal to 0 for  $K \leq \bar{K}_u$  and then strictly positive and increasing in  $K$  for  $K > \bar{K}_u$ . ■

As the optimal tax rate is a discontinuous and (weakly) increasing function of civic capital  $K$ , civic capital must reach a specific threshold for public investment in impersonal exchange to be socially worthwhile.

To bring out the different aspects of the utilitarian optimization problem, we present an example with an explicit functional form.

### Example 19.1. Optimal Tax Rates

Suppose that  $F(T, K) = \phi T^\alpha K^\alpha$  with  $0 < \alpha < 1$ . In this case,

$$\frac{\partial F}{\partial T}(0, K) = \infty$$

while

$$\frac{\partial F}{\partial T}(Y, K) = \phi \alpha \frac{K^\alpha}{Y^{1-\alpha}} \quad (19.6)$$

Therefore

$$\frac{\partial F}{\partial T}(Y, K) < \frac{1}{n}$$

if  $Y$  is large enough. This means that the conditions of Proposition 19.1 are satisfied and that  $t_u$  solves

$$\phi \alpha t_u^{\alpha-1} Y^{\alpha-1} K^\alpha = \frac{n-1}{n^2} \frac{1}{f} \quad (19.7)$$

leading to

$$t_u = \left( \frac{n^2}{n-1} \alpha f \right)^{\frac{1}{1-\alpha}} Y^{-1} K^{\frac{\alpha}{1-\alpha}} \quad (19.8)$$

We see that  $t_u$  is increasing in civic capital  $K$ , and that this function is concave if  $\alpha \leq \frac{1}{2}$  and convex if  $\alpha \geq \frac{1}{2}$ . Then,

$$F(t_u Y, K) = \left( \frac{n^2}{n-1} \alpha f \right)^{\frac{\alpha}{1-\alpha}} \phi^{\frac{\alpha}{1-\alpha}} K^{\frac{\alpha}{1-\alpha}}. \quad (19.9)$$

This means that  $t_u^* = 0$  if  $K < \bar{K}_u$  and  $t_u^* = t_u$  if  $K > \bar{K}_u$  where the threshold  $\bar{K}_u$  is given by

$$\bar{K}_u = \frac{n-1}{n^2} \frac{1}{\alpha f} \phi^{-\frac{1}{\alpha}} r^{\frac{\alpha}{1-\alpha}}. \quad (19.10)$$

We note that Corollary 19.1 relies on the complements property. Under substitutes,  $t_u$  is weakly decreasing in  $K$  since  $\frac{\partial^2 F}{\partial T \partial K} \leq 0$ . But the optimal tax rate  $t_u^* = t_u$  if and only if  $F(t_u Y, K) > r$ . There is a positive direct effect of increasing  $K$  but there is also an indirect negative effect via  $t_u^*$ . The two effects go in opposite directions and so the effects of  $K$  on optimal tax rate  $t_u^*$  may be non-monotonic ( $t_u^*$  may initially decline in  $K$ , then be equal to zero for a range of  $K$  values, and then become positive and decline again in  $K$ ).

**A democratic government:** We next study optimal taxes in a democratic society. Building on the theory of the median voter, we say that a profile of tax  $t$  and exchange choice  $(x_1, \dots, x_n)$  is majority stable if: (1) Given  $t$ ,  $x_i$  is optimal for every  $i$ , and (2) Given  $(x_1, \dots, x_n)$ ,  $t$  is equal to the median of the distribution of individual-specific tax rates.

When  $\forall i, x_i = 0$ , a positive tax rate brings no benefit and all agents prefer zero tax. Conversely if  $t = 0$ ,  $x_i = 0$  is optimal when  $F(0, K) < r$ . By contrast, when  $x_i = 1$  for all  $i \in N$ , the preferred tax rate of agent  $i$ ,  $t_i$ , solves

$$\max_{0 \leq t \leq 1} (1 - t)y_i + F(tY, K) \frac{n - s_i}{n - 1} + \frac{s_i - 1}{n - 1} \quad (19.11)$$

Since  $1 \leq s_i \leq n - 1$ , an interior solution is guaranteed if

$$\frac{\partial F}{\partial T}(0, K) > \frac{n - 1}{n - s_i} \frac{y_i}{Y} \quad (19.12)$$

and

$$\frac{\partial F}{\partial T}(Y, K) < \frac{n - 1}{n - s_i} \frac{y_i}{Y}. \quad (19.13)$$

The interior tax rate is given as a solution to

$$\frac{\partial F}{\partial T}(t_i Y, K) = \frac{n - 1}{n - s_i} \frac{y_i}{Y} \quad (19.14)$$

Since  $F$  is concave in  $T$ , preferred tax rates in the population increase with  $\frac{n - s_i}{y_i}$ . Therefore the median of the distribution of preferred individual tax rates is the tax rate of the individual with median value of  $\frac{n - s_i}{y_i}$ . This observation yields us the following result on optimal taxes in a democratic society.

**Proposition 19.2.** Let  $d$  be the individual with median value of  $\frac{n - s_d}{y_d}$ . Suppose that  $F$  satisfies Assumption 19.1 and that  $\frac{\partial F}{\partial T}(0, K) > \frac{n - 1}{n - s_d} \frac{y_d}{Y}$  and  $\frac{\partial F}{\partial T}(Y, K) < \frac{n - 1}{n - s_d} \frac{y_d}{Y}$ . The following equation has a solution  $t_d \in ]0, 1[$ :

$$\frac{\partial F}{\partial T}(t_d Y, K) = \frac{n - 1}{n - s_d} \frac{y_d}{Y} \quad (19.15)$$

A majority stable outcome  $(t_d^*, x^*)$  is either: (1)  $t_d^* = 0$  and  $\forall i, x_i = 0$  if  $F(0, K) \leq r$ , or (2)  $t_d^* = t_d$  and  $\forall i, x_i = 1$  if  $F(t_d Y, K) \geq r$ . When civic capital and governments are complements, there exist a threshold value of civic capital  $\bar{K}_d$  such that  $t_d^* = 0$  if  $K < \bar{K}_d$  and  $t_d^* = t_d$  if  $K > \bar{K}_d$ , and  $t_d^* = t_d > 0$  is increasing in  $K$  if  $K > \bar{K}_d$ .

If  $F(t_d Y, K) > r$ , then there is a majority stable profile  $(t, x)$ , in which optimal tax rate  $t_d^* > 0$ , and everyone engages in impersonal exchange,  $x_i = 1$  for all  $i \in N$ . However, the profile of zero tax and no impersonal exchange is always stable so long as markets cannot function without formal institutions (i.e., if  $F(0, K) = 0$ ).

Let us next compare utilitarian optimum taxes with democratic tax rates. A preliminary observation is that with democratic governance there is a potential coordination problem: an active state and impersonal market bring higher welfare but society can be stuck in the equilibrium with no tax and no market. Moving beyond the coordination problem, we note that even the active government outcome will generally be different from the utilitarian optimum.

To see why, let us examine the optimal tax rates and the democratic tax rates in greater detail. Define  $\bar{y} = Y/n$  as average income and  $\bar{s} = \sum_i s_i/n$  as average size of group across individuals. Note that these are population averages and  $\bar{s}$  usually differs from the average size when we average across groups,  $\sum_j s_j/m$ .

**Corollary 19.2.** *The tax rate chosen by a democratic government is (weakly) lower than the socially optimal tax rate if  $\frac{n-s_d}{y_d} \leq \frac{n-\bar{s}}{\bar{y}}$ . It is (weakly) higher than the socially optimal tax rate if  $\frac{n-s_d}{y_d} \geq \frac{n-\bar{s}}{\bar{y}}$ .*

**Proof:** Since  $\frac{\partial F}{\partial T}(T, K)$  is (weakly) decreasing in  $T$ , comparing equations (19.4) and (19.15) shows that  $t_d < t_u$  if and only if

$$\frac{n-1}{n^2} \frac{1}{f} < \frac{n-1}{n-s_d} \frac{y_d}{Y}$$

We can simplify this condition and rewrite it as  $\frac{n-s_d}{y_d} < \frac{nf}{\bar{y}}$ . If  $F(t_u Y, K) > r$ , then  $t_u^* = t_u > t_d^*$  since  $t_d^* = t_d$  or 0. If  $F(t_u Y, K) < r$ , then  $F(t_d Y, K) < r$  and  $t_u^* = t_d^* = 0$ . Similar arguments can be made for the case where the democratic society has a higher tax rate. ■

There is therefore a tension between the utilitarian optimum and the median voter's preferred tax rate. This is because the marginal benefits from impersonal markets depend on  $n - s_i$ , the size of the group of outsiders, while marginal costs depend on income  $y_i$ , through taxation. In a democracy, the tax rate is controlled by the median ratio  $\frac{n-s_d}{y_d}$ . By contrast, a utilitarian planner considers aggregate benefits and aggregate costs, and state

size is then controlled by the ratio of averages  $\frac{n-\bar{s}}{\bar{y}}$ . Corollary 19.2 draws attention to these two ratios.

To further understand the impact of the kinship groups, let us assume that everyone has the same income. In that case, from equations (19.4) and (19.15) it follows that the tax rate is lower in a democracy when median group size is greater than average group size, i.e.,  $s_d \geq \bar{s}$ . Applying the formula of fractionalization, this happens, equivalently, when

$$f \geq 1 - \frac{s_d}{n}$$

Therefore, holding median group size fixed, *tax rate is likely to be lower and hence the state smaller in a democracy when fractionalisation is higher*.

Let us elaborate further on its implications for the relation between the democratic outcomes and the utilitarian optimum. We note that this inequality holds, for instance, in the presence of one large group containing a majority of people. In that case, the median voter belongs to this large group and her expected benefits from impersonal markets are relatively small, leading to a small state in a democracy and potentially large welfare losses (as compared to the utilitarian outcome).

Next consider the converse problem: where the state is too large relative to the social optimum. Start from a situation with  $m$  groups of equal size  $s$ . Here,  $\bar{s} = s_d = s$  and democratic outcomes are efficient. Consider a small change in the group structure with small gains in size for some groups and correspondingly small losses in size in other groups. The median group size remains unchanged, but the fractionalization is lower: this means that a positive tax rate in a democratic society is now too high compared to the first best.

The fact that individual preferred policies depend on group sizes can give rise to interesting regime shifts. To illustrate consider a society composed of one large group of size  $s$  and many small groups of size 2. The median voter is in a small group if  $s < \frac{n}{2}$  and in the large group if  $s > \frac{n}{2}$ . The average group size  $\bar{s}$  lies strictly between 2 and  $s$ . Therefore, a small change in  $s$  from slightly above  $n/2$  to slightly below  $n/2$  leads to a drastic expansion in the size of the state, from inefficiently small to inefficiently high.

We close this section by drawing out an implication of the discontinuous shifts in optimal tax rates at the thresholds  $\bar{K}_u$  and  $\bar{K}_d$ .

**Corollary 19.3.** *Suppose that the conditions for Proposition 19.1 and 19.2 hold and that civic capital and governments are complements. The threshold value for civic capital under democratic regime is higher than under the social optimum,  $\bar{K}_d \geq \bar{K}_u$  when  $\frac{n-s_d}{y_d} \leq \frac{n-\bar{s}}{\bar{y}}$ ; the opposite is true otherwise:  $\bar{K}_d \leq \bar{K}_u$  when  $\frac{n-s_d}{y_d} \geq \frac{n-\bar{s}}{\bar{y}}$ .*

**Proof:** From the arguments in Corollary 19.2 above, we know that utilitarian optimum tax

rate is (weakly) lower than the democratic tax rate if

$$\frac{n - s_d}{y_d} \leq \frac{n - \bar{s}}{\bar{y}}$$

Recall that  $\bar{K}_u$  and  $\bar{K}_d$  are defined by the following equations:

$$F(t_u Y, \bar{K}_u) = r$$

$$F(t_d Y, \bar{K}_d) = r$$

As  $t_d \leq t_u$ , it then follows that  $\bar{K}_d > \bar{K}_u$ .

A similar argument may be used to prove the second part of the corollary. ■

To appreciate how fractionalization and civic capital shape tax rates and the size of the state, we work through an example with specific functional forms.

### Example 19.2. State and Civic Culture as Complements

Suppose that  $F(T, K) = fT^\alpha K^\alpha$ . It may be verified that this function satisfies Assumption 1 and that state and civic culture are complements. Moreover,  $\frac{\partial F}{\partial T}$  is strictly monotonic in  $T$ .

As  $F(0, K) = 0$ , it is immediate that there exists a majority stable outcome with zero tax and zero impersonal exchange. Turning to stable outcomes with positive tax rates, Proposition 19.2 tells us that the median voter tax rate

$$t_m = \left[ \frac{\alpha f Y^\alpha K^\alpha}{n-1} \frac{n - s_m}{y_m} \right]^{\frac{1}{1-\alpha}} \quad (19.16)$$

Observe that  $t_m$  is increasing in  $K$  and decreasing in  $s_m$  and  $y_m$ . Optimal taxes are increasing in the quality of civic culture because the marginal returns to bigger government are higher with better civic culture. The optimal taxation is also falling in the size of this individual's group: this is because the larger the group size the smaller the size of the potential gains from trading with outsiders (as reflected in the term  $(n - s_m)$ ).

An active state and impersonal exchange appear if and only if

$$\alpha^{\frac{1}{1-\alpha}} f^{\frac{2-\alpha}{1-\alpha}} (YK)^{\frac{\alpha(2-\alpha)}{1-\alpha}} \left( \frac{n - s_m}{(n-1)y_m} \right)^{\frac{\alpha}{1-\alpha}} > r \quad (19.17)$$

Thus there exists a threshold level of civic culture  $K^*$ , such that tax rate is positive and state is active if and only if  $K > K^*$ .

Let us compute the aggregate welfare that obtains under the different parametric conditions. When  $K < K^*$  and  $t^* = 0$ ,  $x_i = 0$ , individual utility is

$$u_i = y_i + r \frac{n - s_i}{n - 1} + \frac{s_i - 1}{n - 1}$$

Aggregate utility is

$$\begin{aligned} \sum_i u_i &= Y + \frac{r}{n - 1} \sum_i s_i(n - s_i) + \frac{1}{n - 1} \sum_i s_i(s_i - 1) \\ &= Y + \frac{1}{n - 1} \left( r \sum_i s_i(n - s_i) + \sum_i s_i^2 - n \right) \end{aligned}$$

Since  $F(0, K) = 0$ , everyone opts for kin-based group exchange, and therefore its share in total exchange is equal to 1.

When  $K > K^*$  in a stable outcome with positive tax rates  $x_i = 1$ , for all  $i \in N$ ,  $t = t^* > 0$ . This in turn means individual utility is

$$u_i = (1 - t^*)y_i + F \frac{n - s_i}{n - 1} + \frac{s_i - 1}{n - 1}$$

Aggregate utility is

$$\begin{aligned} \sum_i u_i &= (1 - t^*)Y + \frac{F}{n - 1} \sum_i s_i(n - s_i) + \frac{1}{n - 1} \sum_i s_i(s_i - 1) \\ &= (1 - t^*)Y + \frac{1}{n - 1} \left( F \sum_i s_i(n - s_i) + \sum_i s_i^2 - n \right). \end{aligned}$$

The share of kin-based exchange is

$$\frac{\sum_i s_i(s_i - 1)}{\sum_i s_i(n - s_i) + \sum_i s_i(s_i - 1)}$$

where

$$\sum_i s_i(n - s_i) + \sum_i s_i(s_i - 1) = \sum_i s_i(n - 1) = n(n - 1) \quad (19.18)$$

This yields us

$$\frac{\sum_i s_i(s_i - 1)}{n(n - 1)} = \frac{\sum_i s_i^2 - n}{n^2 - n},$$

that is increasing in  $\sum_i s_i^2$  (hence it is falling in the fractionalization index). ■

The example above assumed that state capacity and civic capital are complements. A

question at the end of the chapter explores the case of substitutes.

Our discussion reveals the relative share of kin-based and impersonal exchange, the size of the state, and economic performance are shaped by group composition and civic culture. We now take a closer look at the determinants of civic capital.

## 19.5 Sources of civic capital

In this section we will discuss the sources of civic capital. We will first take up the view that civic capital arises out of wide ranging horizontal associational ties between individuals, as reflected in the quote from Tocqueville at the start of the chapter. In this study we will mostly focus on a complementary relation between civic capital and state capacity and we will have in mind some form of majority based government in mind. But this is only one setting among many and toward the end we will comment on settings where civic capital may have a substitutes relation with state capacity.

### 19.5.1 Horizontal Associations

We return to our model and recall that, in stage 1, individuals will choose an action  $z_i \in \{0, 1\}$ , where  $z_i = 0$  refers to low activity while  $z_i = 1$  refers to high activity. Social engagement takes time and effort and this cost is given by  $c > 0$ . Let  $z = (z_1, \dots, z_n)$  denote the profile of social engagement. The civic capital in stage 2 is reflects the choices in stage 1. In particular, we will suppose that  $K = \sum_{i \in N} z_i$ .

An individual's returns to social engagement will depend on the level of engagement of others in her neighbourhood: if everyone else is narrowly focused on short term interests of their nuclear family then an individual will expect very little from increasing her own engagement. By contrast, if an individual is surrounded by others who are highly engaged then increasing her social commitment is more likely to be rewarding. The returns to horizontal social engagement across groups rests on the bridging ties between groups, i.e., ties between individuals that belong to different groups. Recall that  $g_o$  be the network of ties outside one's own group. We will suppose that  $N_i(g_o)$  is the neighbourhood of individual  $i$  in network  $g_o$ .

With this notation in hand, we say that the returns to social engagement are increasing in the level of local social engagement. Given a profile of actions  $z$ , let

$$\zeta_i = \sum_{j \in N_i(g_o)} z_j \tag{19.19}$$

be the level of engagement in the neighbourhood of individual  $i$ .

Our analysis in the previous section indicates that  $K$  is central to understanding the size of the government and the share of impersonal exchange. However, as a first step, to keep matters simple, we will assume that in their social engagement problem individuals do not take into account the effects of  $z_i$  choices on  $K$ . Recall that we are primarily concerned with the case where  $n$  is large, so an individual's choices on civic engagement are unlikely to have a large impact on the economy wide scale of  $K$ , so our assumption is a reasonable approximation. With this assumption in place, given a network  $g_o$  and a profile of actions  $z$  the utility of individual  $i$  is

$$H(z_i, \zeta_i) - cz_i. \quad (19.20)$$

We will say that individual efforts and neighbours' efforts are complements if they exhibit increasing differences, i.e., for  $\zeta'_i > \zeta_i$  and  $z'_i > z_i$ :

$$H(\zeta'_i, z'_i) - H(\zeta'_i, z_i) \geq H(\zeta_i, z'_i) - H(\zeta_i, z_i) \quad (19.21)$$

They are strict complements if this inequality is strict. We make the following assumptions on the function  $H(.,.)$ .

**Assumption 19.2.**  $H(0,0) = 0$ ,  $H(.,.)$  is (weakly) increasing in both arguments and it exhibits complementarity.

A simple example of such a function is  $H(z_i, \zeta_i) = \zeta_i z_i$ ; it exhibits strict complementarity between own and neighbours' engagement.

Let us next take up the costs of civic engagement. Our starting point is an observation on the relationship between political and civic freedoms:

Among all the peoples where political associations are prohibited, civil association is rare. It is hardly probable that this is an accident; and one ought rather to conclude that a natural and perhaps necessary relation exists between these two types of association.

A political association draws a multitude of individuals outside themselves at the same time; however separated they are by age, mind, fortune, it brings them together and puts them in contact. They meet each other once and learn to find each other always.

I do not say that there cannot be civil associations in a country where political association is prohibited; for men can never live in a society without engaging in some common undertaking. But I maintain that in a country like this, civil

associations will always be very few in number, weakly conceived, unskillfully conducted, and that they will never embrace vast designs or will fail when they want to execute them. *Tocqueville [2004], page 496-8*

We will bear these considerations in mind when we consider the scope of civic engagement under different types of political regimes in the next section.

Observe that if everyone else chooses action  $z_i = 0$ , then under our assumptions on  $H(\cdot, \cdot)$ , it is a best response to choose 0, as well. Thus, irrespective of the social structure, inactivity  $z = (0, \dots, 0)$  is a Nash equilibrium of the game of social engagement. Let us consider an equilibrium with positive engagement. To fix ideas let us suppose that  $H(\zeta_i, z_i) = \zeta_i z_i$ . In this case, the best that an individual can hope to earn from choosing  $z_i = 1$  is that all her neighbours also choose 1. In other words, her payoff is bounded by the size of her neighbourhood. Fixing a cost of social engagement  $c > 0$ , it then follows that an individual will choose  $z_i = 1$  only if the number of neighbours is greater than or equal to  $c$ . The same reasoning applies to the neighbours of the individual: a neighbour will only choose action  $z_i = 1$  if she has at least  $c$  neighbours, and so forth.

This line of reasoning corresponds to the games we considered in the chapter on network structure and human behaviour. We now apply the methods we developed in that chapter to the problem at hand. Suppose to fix ideas that  $c = 3.1$ . An individual will only choose action 1 if the returns to choosing 1 cover the cost 3.1. This means that at least 4 neighbours must also choose action 1. However, these neighbours will choose action 1 only if each of them have at least 3 other neighbours choosing 1 (in addition to herself). Thus for an individual to choose 1, she must be part of a set of nodes in a network each of whom have at least 4 links with others who have 4 links, and so on. Recall that this line of reasoning led to the 3-core of a network. For easy reference we reproduce the definition of a q-core of a network here:

**Definition 19.1.** *The  $q$ -core of a network  $g_o$ , denoted by  $g_o^q$ , is the largest subgraph of  $g_o$  such that all individuals in  $g_o^q$  have strictly more than  $q$  links to other individuals in  $g_o^q$ .*

Recall from our discussion in the earlier chapters the procedure for obtaining the  $q$ -core of a network is as follows: start with a network  $g$ . In step 1, delete all the nodes (and their links) in  $g$  for which degree  $k \leq q$ . Label the residual graph  $g_1$ . In step 2, delete all the nodes (and their links) in  $g_1$  for which  $k \leq q$ . Iterate until no node with  $k \leq q$  remains (i.e. when  $g_t = g_{t+1}$ ). The residual graph in this last step is the  $q$ -core.

The equilibrium corresponding to the  $q$ -core define the minimal and the maximal level of social engagement in a network. The social structure thus sets an upper bound on the

level of civic activity in a society. The actual outcome will depend on the beliefs that members of the community have. This suggests that in societies with large  $q$ -cores, beliefs about behaviour can make a very great difference for outcomes.

A final remark concerns the utility of individuals: payoffs to an individual who chooses 0 are zero, while the payoffs of an active agent are increasing in the number of neighbours choosing action 1. So given a positive cost  $c$ , it follows that payoffs are larger for nodes in the  $q$ -core as compared to those outside it. Thus for any network, total payoffs are maximized in the equilibrium corresponding to the  $q$ -core.

**Proposition 19.3.** *Given any network,  $g_o$ , a function  $H(.,.)$  satisfying Assumption 19.2, and a cost,  $c > 0$ , there exists a zero activity and a maximal activity equilibrium that corresponds to the  $q$ -core of the network. A society with a larger  $q$ -core therefore has the potential to support a higher level of social engagement. Aggregate payoffs are increasing in the number of active players. Therefore, networks with larger  $q$ -cores have the potential for greater aggregate utility.*

In our model, there are two aspects of social structure: the groups and the ties across groups. We work through a simple example to appreciate the role of the social structure in shaping economic performance.

Consider a society with  $n = 12$  individuals, let  $H(\zeta_i, z_i) = \zeta_i z_i$ , and set (ex-ante) individual income  $y = 1$ . We consider a society with large kin-based groups and a society with small nuclear families. The former is represented as consisting of three groups each of size 4, while the latter consists of twelve groups each of size 1. To study the role of ties across groups, we consider two configurations: in one case, the ties are concentrated within a few individuals, while in the other case the ties are spread out across individuals. The four configurations of group size and ties across groups are presented in Figure 19.10.

The Top Panel (figures (a) and (b)) presents societies with large kin groups, while the bottom panel (figures ((c) and (d))) presents societies with small kin groups. Figures (a) and (c) represent societies in which the ties across kin groups are concentrated among a few individuals (they have a large 3-core) while figures (b) and (d) represent societies in which they are spread across individuals (as a consequence they have an empty 3-core).

Suppose that the cost of social engagement is  $c = 3.1$ . From equation (19.3) we know that the maximal equilibrium corresponds to the 3-core of the social network. This tells us that in societies (a) and (c), individuals can support an active civic community while in societies (b) and (d), there will be no civic engagement. To be precise, the number of active members in the maximal equilibrium is 6 in the former and it is 0 in the latter.

We build on these observations to draw out the implications of civic capital for the size of the state and the magnitude of impersonal exchange.

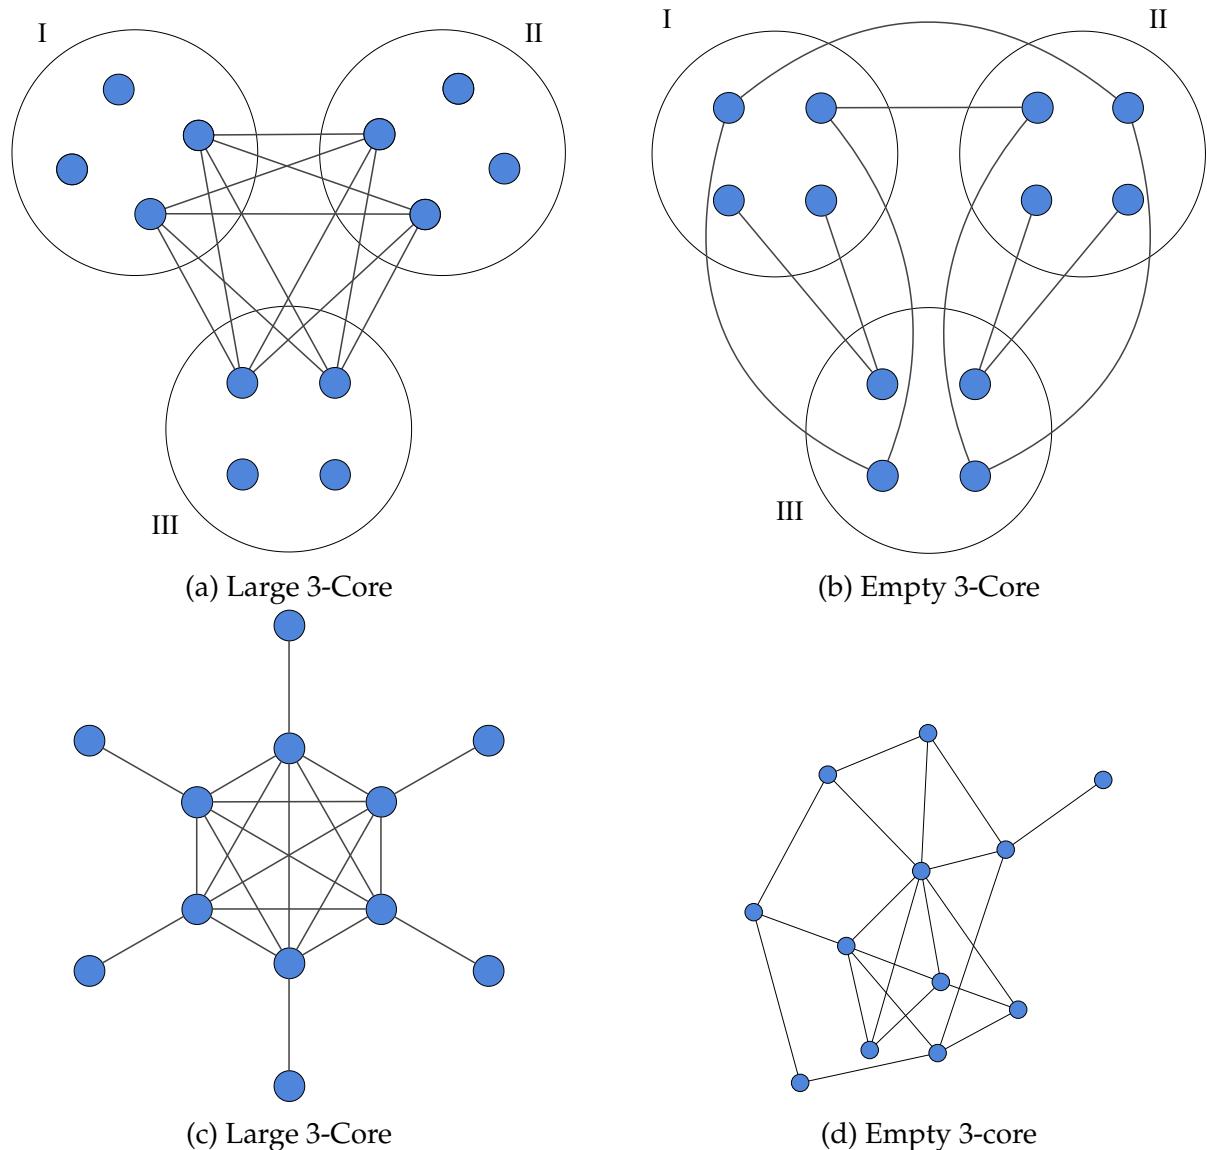

Figure 19.10: Examples of Societies: Top Panel (large groups), Bottom Panel (small groups)

Suppose that  $F(T, K) = (TK)^\alpha$ ,  $\alpha < 1$ . We note that in this case civic capital and the size of the state are complements. As all individuals are in equal size groups and have equal incomes they have the same incentives. The preferred tax rate for an individual therefore corresponds to the utilitarian optimum. From Proposition 19.1 it follows that in (b) and (d) optimal tax rate will be zero. In societies (a) and (c), a positive tax is optimal if  $F(t_U Y, K) > r$ . Let us assume that  $r$  is sufficiently small so that this condition is satisfied in both societies. Under this assumption, differences in tax rates are mirrored in differences in impersonal exchange: in societies (a) and (c), everyone is therefore engaged in impersonal exchange, while in societies (b) and (d), everyone is engaged in kin group exchange. This in turn has implications for utility and welfare. In society (a), the utility for the socially active and inactive individuals are respectively

$$(1 - t^*) + F(12t^*, 6) \frac{8}{11} + \frac{3}{11} + 0.9; \quad (1 - t^*) + F(12t^*, 6) \frac{8}{11} + \frac{3}{11}. \quad (19.22)$$

Thus aggregate utility in society (a)

$$W_a^* = 12(1 - t^*) + \frac{96}{11}F(12t^*, 6) + 12\frac{3}{11} + 5.4. \quad (19.23)$$

In society (b), as there is no taxation (and therefore the state is inactive) all exchange takes place within kin-based groups. Individual utility is

$$1 + \frac{3}{11} + \frac{8}{11}r \quad (19.24)$$

and aggregate utility is given by

$$W_b^* = 12[1 + \frac{3}{11} + \frac{8}{11}r] \quad (19.25)$$

It follows that the zero tax rate outcome is feasible in society (a) and will yield the same utility but the positive tax rate is preferred. So it must yield a higher utility.

In society (c), individual utilities are given by

$$(1 - t^*) + F(12t^*, 6) + 1.9; \quad (1 - t^*) + F(12t^*, 6) \quad (19.26)$$

for the active and the inactive members of the society, respectively. Thus aggregate utility in society (c)

$$W_c^* = 12(1 - t^*) + 12F(12t^*, 6) + 6(1.9). \quad (19.27)$$

Finally, in society (d), as there is zero taxation (and an inactive state), there is also no im-

personal exchange. As group sizes are equal to 1, individual utility is also equal to  $1 + r$ . Aggregate utility in society (d) is

$$W_d^* = 12 + 12r. \quad (19.28)$$

The zero tax outcome is feasible in society (c) and yields the same utility as in society (d), but by definition the positive tax outcome is utility maximizing. Hence society (c) does significantly better than society (d).

Define  $E^*$  as the share of impersonal/market exchange in equilibrium. Our computations are summarized in Table 19.2.

$Q - core$ <i>Fraction</i>	Large	Small
<i>Small</i>	$K^* = 6, t^* > 0, E^* = 0.7, \text{High } W_a^*$	$K^* = 0, t^* = 0, E^* = 0, \text{Modest } W_b^*$
<i>Large</i>	$K^* = 6, t^* > 0, E^* = 1, \text{High } W_c^*$	$K^* = 0, t^* = 0, E^* = 0, \text{Low } W_d^*$

Table 19.2: Social Structure and Outcomes

Propositions 19.1-19.3 develop relations between aspects of social structure on the one hand and the nature of formal versus informal exchange and the size of the state on the other hand. While the theory highlights the role of the  $q$ -core, we must be careful not to take this measure too literally. The  $q$ -core arises due to a specific formulation of the coordination game in civic participation; if we specify the game differently a different but related network measure may be identified. The important point is that for civic capital to arise we need ties that create bridges across groups in a society.

The presumption in the model we have discussed is that ties are horizontal and range across social, political, economic, and cultural spheres (as in Putnam, Leonardi, and Nanetti [1993]'s study of North and South Italy or in Varshney [2001]'s study of Indian riots). The formulation of complementarity between these ties and state reflects a dominant strand of thought that can be traced back to the Tocqueville [2004].

We next turn to circumstances with limited horizontal associations and weak bridging civic capital. There are two broad circumstances to consider that correspond to weak and strong kinship groups, respectively. When a society has both weak kinship groups and limited civic capital, there is a greater need for formal institutions but due to a complementarity between civic capital and state capacity a democratic regime may be unable to provide adequate state capacity. These circumstances can lead to a failed state but under some historical circumstances, such as a communist or a military take over, it can also lead to a strong authoritarian state. We may arrive at a situation where civic capital and state

capacity are substitutes.

A second situation corresponds to strong kinship groups with weak bridging civic capital. Here the need for the state is less pressing as much economic exchange occurs within group; however, due to historical circumstances such as foreign occupation or war, there may be need for public goods more broadly construed. This may give rise to mass social and political movements that can have profound implications for the nature of the state. For example, members of large and distinct kinship groups who take part in a large scale independence movement may be led to support a large state once the foreign occupying power is expelled. These possibilities will surface when we map the theory onto the specific circumstances of different countries.

### 19.5.2 Mapping theory onto the country case studies

In our application of the theory it will be helpful to keep in mind the  $2 \times 2$  matrix presented above, Table 19.2, that covers the cases of high/low fractionalization and small/large bridging capital. Let us now walk through this Table and use it as lens to help organize the historical experience of different countries.

Let us start with the *top-left* cell in Table 19.3: this is a society where fractionalization is low and bridging capital is high. Let us discuss the experience of India, China and Korea in this context.

In the case of India, the mass independent movement against British rule led by the Congress Party (and the associated social reform movements) helped build ties across the different caste and different region based groups that dominate Indian society. These ties allowed the Indian Constituent Assembly to draft a progressive constitution for independent India that created a federal country with a strong central government. Seen through the lens of our model, at this moment in time, India was a society with large groups (high fractionalization) but at that points there was high bridging civic capital due to the mass based freedom movement. In the early 1950's, this bridging civic capital allowed the country to create a large developmental state. In the early 21<sup>st</sup> century, the state continues to be heavily involved in the economy (as we noted some of the largest firms are state controlled). The rapid economic growth over the past twenty five years has also give rise to a large, diverse, and dynamic private sector but private sector firms typically form part of family-based conglomerates reflecting the larger presence of kin-based groups in Indian society. Democratic politics have matured but voting often takes place along lines of caste. In the early 21<sup>st</sup> century, India is a country with strong kinship groups and a state that is deeply involved in its economy. The centrality of caste and region based groups has led

some observers to argue that bridging civic capital ties have eroded. In terms of our model this would lead to a falling civic capital making it difficult for the state to deliver on the large demands made on it. For a notable recent articulation of this view see Acemoglu and Robinson [2019].

The configuration in top-left cell is also helpful to understand the experience of China. The long history of a centralized state and foreign occupation of parts of China by European powers in the 19<sup>th</sup> century and by Japan in the 20th century are an important part of the historical background. The Communist take over of China in 1949 was accompanied by a mass political movement that mobilized millions of people who were scattered across the country and who were traditionally affiliated with lineages and clans. We may interpret this mass mobilization as a form of extensive bridging ties, something that made possible the creation of the Chinese state. Indeed, throughout the 1950's and 1960's, to assert itself, the state attempted to weaken traditional lineages and clans (e.g., cousin marriage was made illegal). However, the market reforms after 1979 have led to a revival of traditional lineages/clans and regional networks. These networks have been an important part of the extraordinarily successful production clusters that have fueled Chinese economic growth. Moreover, close ties between different layers of the state and lineages are an important feature of contemporary China. In the early 21<sup>st</sup> century, China is a country with strong kinship groups and a strong state (that is run by a communist party with close to a 100 million members). For evidence on these social networks and their interactions with the state see Allen and Babus [2009], Daiy, Mookherjee, Munshi, and Zhang [2020], Bai, Hsieh, and Song [2020a] and Bai, Hsieh, Song, and Wang [2020b].

In South Korea, kinship ties based on extended family relations are an important feature aspect of the society but the Japanese occupation in the early part of the 20<sup>th</sup> century and the Korean War led to a strong nationalist ethos. This ethos brought together groups and made possible a strong developmental state led by a sequence of generals (Park Chung-hee, Chun Doo-hwan, and Roh Tae-woo) that undertook large-scale land reforms and supported the rise of kinship based conglomerates. Over time, as the economy has prospered and today Korea is one of the most technologically sophisticated countries in the world. The experience of Korea does not fit in a straightforward manner with our model (as it emphasizes the role of large scale civic capital based on bridging ties across kinship groups) and it therefore raises larger questions on the pathways that developing countries can follow for rapid economic growth.

We next take up the *bottom-left* cell in Table 19.2: high fractionalization and high bridging capital. The theory predicts that these are the ideal circumstances for high tax rates that supports a large and effective state. These conditions describe WEIRD societies such

as United States, Australia, New Zealand and most of North Western Europe. Much has been written about these countries: of the limited scope of kinship groups, of the individualist psychology of their people, and of the strength of out-group ties. These societies exhibit sustained economic performance as is summarized in Figure 19.6.

Next, we take up the *bottom-right* cell in Table 19.2: fractionalization is high and weak bridging capital. The theory predicts that a democratic state may fail to deliver on the demands made on it. However, kinship groups are small so valuable exchange would often be with outsiders and it is subject to high transaction costs. This failure of a democratic state to deliver creates circumstances that are ripe for alternative forms of governance. We use this cell to understand the experience of Russia and Brazil.

In Russia (and in other former communist countries in Eastern Europe) kin-based groups are weak and bridging capital is weak. This is partly due to its pre-communist history but over its long period of rule, from 1917 to 1990, the communist party actively sought to eliminate political opposition and restrict associational life (Putnam, Leonardi, and Nanetti [1993] and Fukuyama [1995a]). This combination of factors creates a situation in which it is difficult to support a democratically accountable government that carries out the functions of a modern state. This difficulty was visible in the years immediately after the collapse of communism; multi-party democratic politics have not survived. Instead, the outcome has been *de facto* one party rule. The following lines have turned out to be prescient.

Many of the formerly Communist societies had weak civic traditions before the advent of Communism, and totalitarian rule abused even that limited stock of social capital. Without norms of reciprocity and networks of civic engagement, the Hobbesian outcome of the Mezzogiorno—amoral familism, clientelism, lawlessness, ineffective government, and economic stagnation seems likelier than successful democratization and economic development. Palermo may represent the future of Moscow. Putnam, Leonardi, and Nanetti [1993], page 183.

Turning to Brazil, at the start of the 20<sup>th</sup> century this is a very diverse society constituted of immigrants from different parts of Europe and Africa (and with a long history of slavery). Our discussion in section 19.2 suggests that Brazil has weak kinship groups. At the same time, generalized trust is very low. This creates the circumstances that make it difficult for society to sustain an accountable democratic state. Indeed, at the start of the 20th century there was a long period of very limited franchise, one party rule, and military dictatorship. Since 1988 Brazil has had regular elections but the economic record is uneven and the political situation remains uncertain.

Finally, we turn to the *top-right* cell in Table 19.2: fractionalization is high and bridging capital is weak. The theory suggests that democratic politics will struggle to support an effective state. Depending on the specific circumstances of a country (such as conflicts with neighbouring countries), this can lead to either a continuing poor governance or the rise of a dictatorship. Let us use the theory to understand the experience of the Congo and Egypt.

<i>Bridging Capital Fraction</i>	Large	Small
Small	India, China	Egypt, Congo
Large	Weird Societies	Brazil, Russia

Table 19.3: Countries Experience: Summary

Turning next to Congo, we discuss the experience in the years after 1960 (the year that it won independence from Belgium). Independence led to a period of instability between 1960 and 1965, when Joseph-Desire Mobuto took power. Our discussion in section 19.2 drew attention to the high fractionalization and the long period of large scale war in Congo. The Great War of Congo and the accompanying disruption of ordinary life suggests that the country has found it difficult to create an effective and accountable state. The circumstances of Congo are special in some respects – the very rich mineral wealth and the complicated overlaps in ethnic groups with neighbouring countries – but the difficulties of creating an effective state are in line with our theory.

We next discuss the case of Egypt in the years after 1922 (the year that it won independence from Britain). Our discussion in section 19.2 reveals a society with high rates of cousin marriage and the use of extended kin-based groups. Generalized trust is low. After a brief period of multi-party politics, from 1956 onward, Egypt has had a combination of military dictatorship and one-party rule. This has been accompanied by restrictions on political activity and limits to associations (the long standing ban on the Muslim Brotherhood is one example). The failure of the 2011 Arab Spring protests and the difficulties faced by a democratically accountable government are consistent with our theory. While these difficulties are well known, it is worth noting from Figure 19.5 that Egypt has a record of uneven economic growth over the period 1990-2020.

## 19.6 Reading Notes

The study of the role of culture in shaping economic change has distinguished antecedents; a prominent early study is Weber [2010]. Kinship groups are an important component of culture. Indeed, Max Weber himself emphasized the importance of the role of families in his study of Chinese society (Weber [1951]). In the previous chapter on trust, we concluded by noting the tension between local (group specific) trust and generalized trust. In that chapter the focus was on culture and social relations. The present chapter takes the discussion one step further by interpreting culture as consisting of a composite of beliefs and social structure and by locating it within a broader conceptual framework that includes the market and the state. Here the focus is on understanding how culture interacts with markets and the state in shaping economic performance.

We begin by providing an empirical background to the relationship between different types of kin-based institutions and different measures of trust and values (such as universalism). This is a subject that been studied in many disciplines – such as anthropology, sociology, political science, and economics, and theory of cultural evolution. The research draws on a wide range of intellectual traditions and uses a wide range of theoretical and empirical methodologies. It is clearly impossible to do justice to this vast body of scholarship within a the space of a single chapter. The goal here is top provide leads into the different bodies of the work. For economics see Enke [2019], Guiso, Sapienza, and Zingales [2006b], Greif and Tabellini [2017], and Guiso, Sapienza, and Zingales [2016]. For sociology, see Peng [2004]. For political science, see Fukuyama [1995a], Putnam, Leonardi, and Nanetti [1993] and Banfield [1958]. Cultural evolution researchers and business scholars have explored this subject extensively, see Schulz, Bahrami-Rad, Beauchamp, and Henrich [2019] and Trompenaars and Hampden-Turner [1998]. Henrich [2020] offers perhaps a comprehensive overview of the research on this subject.

In a sequence of interesting papers, Alberto Alesina and his collaborators explored the relation between the family and political and economic activity. Alesina and Giuliano [2010] construct a measure of the strength of family ties for over 70 countries. They construct this measure with the help of individual responses from the World Value Survey on the role of the family and the love and respect that children need to have for their parents. They find that when family ties are strong there is more reliance on home production and less participation in market activities, especially in the case of youngsters and women. Strong family ties imply a stricter division of labor with the male working in the market and the female working at home. In line with this practice, women's education is lower with strong family ties and fertility levels are higher. Stronger family ties support higher

levels of informal insurance and this substitutes insurance provided by the state. Family ties can better provide the support they do if extended families live close to each other: this in turn leads to lower geographical mobility. Finally, and in line with the discussions in the chapter, individuals in families with strong ties, trust their own family members more but trust non-family members less. In a follow up paper, Alesina and Giuliano [2011] shows that a larger role for the family lowers civic engagement and political participation.

We presented Robert Putnam's study of civic community and democracy in Italy. A large body of subsequent work has documented the robustness of the positive relation between the quality of civic community and local government and the persistence of civic traditions, using rich sets of data from different parts of Europe, see e.g. Henrich [2020] and Guiso et al. [2016].

We then moved beyond kinship and trust and take up the relation between kinship and economic performance. The empirical work is vast and spans many disciplines. The discussion in the chapter is again, due to constraints of space, very short and somewhat narrowly focussed. in our presentation, we draw upon Allen, Qian, and Qian [2005], Daiy, Mookherjee, Munshi, and Zhang [2020], Song, Storesletten, and Zilibotti [2011], Fleisher, Hud, McGuiree, and Zhang [2010], Nee and Opper [2012], Peng [2004], Greif and Tabellini [2017] and Fukuyama [1995a] for work on China and other East Asian societies, on Munshi [(2019] and Beteille [1965] and Beteille [1969] and Srinivas [1987] for work on caste in India, and on Munshi [2014] for an overview of the role of communities in the development process.

Moving toward the theory, our aim was to develop a framework in which economic performance occupies centre stage and we can understand how culture, the state and markets contribute to it. The model is taken from Bramoullé and Goyal [2021].

The modeling of the economics elements builds on the concepts of formal institutions, transaction costs and asymmetric information. These themes are at the heart of modern studies of economic history and of modern economic theory, see e.g., North and Thomas [1973], North [1990] and Williamson [1985]. The roots of the idea that the state and market and kin-based groups may substitute or complement each other in relation to economic activity may be traced to Polanyi [1944] and finds a more modern expression in Acemoglu and Robinson [2019] and Fukuyama [1995a]. That they may be substitutes is suggested by the empirical evidence from the recent development experience of a number of large countries such as China and India. Our formulation of these ideas draws on the economic theory of strategic substitutes and complements (Bulow et al. [1985]) and on the more recent applications to formal and informal institutions, see e.g, Gagnon and Goyal [2017] and Kranton [1996a]. Finally, we draw upon Besley and Persson [2013] in our modeling of

the politics of taxation and the role of the state and on Alesina, Devleeschauwer, Easterly, Kurlat, and Wacziarg [2003] in our formulation of fractionalization.

I thank Mark Granovetter for helpful comments on an earlier draft of the chapter and for leads to the relevant sociology literature. I thank Sam Jindani for extended discussions on an earlier draft of the chapter.

## 19.7 Questions

1. Suppose  $F(T, K) = a(T + K)^\alpha$ , where  $a > 0$ .
  - (a) Show that this function satisfies Assumption 1.
  - (b) Show that  $\frac{\partial F}{\partial T} = a\alpha(T + K)^{\alpha-1}$  is monotonic in  $T$ .
  - (c) Show that if there is a stable outcome with positive tax rates then the median tax rate satisfies

$$a\alpha(t_m Y + K)^{\alpha-1} = \frac{n-1}{Y} \frac{y_m}{n - s_m}. \quad (19.29)$$

This in turn means that

$$t_m = \left( \frac{\alpha a(n - s_m)}{y_m(n - 1)} \right)^{\frac{1}{1-\alpha}} Y^{\frac{\alpha}{1-\alpha}} - \frac{K}{Y} \quad (19.30)$$

if this value is positive.

- (d) Argue that there exists a threshold  $K^{**}$ , such that if  $K > K^{**}$ , the median tax rate is equal to 0.
- (e) Show that the median voter's preferred tax rate,  $t_m$ , is decreasing in  $K$  and decreasing in the size of his group  $s_m$  and his income  $y_m$ .
- (f) Show that optimal taxes are decreasing in  $K$  and in the size of the median individual's group size,  $s_m$ .
- (g) Impersonal exchange appears if  $F(t_m Y, K) > r$ . In other words,

$$a \left( \frac{\alpha a Y(n - s_m)}{y_m(n - 1)} \right)^{\frac{\alpha}{1-\alpha}} > r. \quad (19.31)$$

Show that when  $K > K^{**}$  and  $t^* = 0$ , individual utility

$$u_i = y_i + r \frac{n - s_i}{n - 1} + \frac{s_i - 1}{n - 1}$$

In this case everyone opts for kin-based group exchange and therefore its share in total exchange is equal to 1.

- (h) If  $K < K^{**}$ , and equation (19.31) is satisfied, then in a stable outcome with positive tax rates  $x_i = 1$  for all  $i \in N$ ,  $t = t^* > 0$ . Show that in this case individual utility is

$$u_i = (1 - t^*)y_i + F \frac{n - s_i}{n - 1} + \frac{s_i - 1}{n - 1}$$

Show that in this final case the share of kin-based exchange is

$$\frac{\sum_i s_i^2 - n}{n^2 - n}$$

2. This question explores the effects of group composition on majority outcomes. Suppose there is one large group,  $S$ , and several small groups of size,  $s$ . Then the average group size lies strictly between  $s$  and  $S$ . Discuss the conditions – on group sizes – under which majority tax rate and size of state would be larger and smaller than the utilitarian optimum, respectively.
3. Suppose that incomes are equal across individuals in the model of tax rate choice.
  - (a) Show that utilitarian tax rate is higher than the democratic tax rate if  $s_d \geq \bar{s}$ , where  $s_d$  is the size of the median voter's group, and  $\bar{s}$  is the average size of a group.
  - (b) Construct an example for which democratic tax rate is higher than the utilitarian optimum tax rate.
4. Corollary 19.2 develops conditions under which threshold for positive tax rate is higher under the democratic society as compared to the utilitarian optimum. Discuss the ways in which an autocratic government can function and how it may be able to address the problems of under-provision of state services.
5. Difficulties in sustaining democratic governments and the persistence of authoritarian governments in many countries is due to a lack of appropriate civic capital as embodied in horizontal associations between citizens. Discuss.

6. "Democratic politics fail to deliver on economic performance in societies with strong kinship groups". Discuss with reference to the experience of Korea, India and China.
